CASE III.—James R. B., admitted to the Chicago State Hospital October 20, 1921. American, white, 47 years old. History as given by his wife states that the patient worked regularly until three weeks before he was committed, when he began to drink moonshine. He had been a periodical drinker for years, but it never lasted long. This time he drank so much that he became paralyzed. He saw imaginary things, and became helpless and his wife was not able to care for him, so had him committed. The records from the Psychopathic Hospital are as follows: Physical: Pupils rather sluggish; spinal fluid negative. Mental: Patient mumbles to himself, mutters incoherently, repeats 1189 to all questions; appears deteriorated; speech is slurring. When admitted to the Chicago State Hospital he was a stretcher case. He was helpless, and had to be assisted on the ward; was confused and could give no details about himself, his speech was thick and slurring, suggestive of paresis; he was restless and talkative. He gradually improved, and by the time the mental examination was made, he was well oriented, although his speech was still thick and slurring. He told the examiner that he began to drink 20 years ago, and became a periodical drinker 8 years ago, but had never before seen or heard things. Two or three weeks before he was committed he drank moonshine with friends. He did not drink much, but it must have been very poisonous, as he lost his senses. He does not remember much that took place for several weeks afterward until a few days ago. States during that time he saw many animals that scared him for the time being. He also heard some voices, but they were not of importance. He is not able to explain what the voices were, nor where they came from. For several weeks his mind was a blank. His general knowledge was good, and his physical and laboratory examinations were entirely negative. This patient improved constantly, and was paroled to his wife on November 14 in good physical and mental condition.

CASE IV.—Joseph P., admitted to the Chicago State Hospital October 20, 1921. Patient is a Lithuanian, 44 years old; in the United States 24 years. The history as given by a friend is as follows: Patient worked regularly until a week before he was committed, when he began to drink moonshine. The friend knew nothing that took place after that until he was notified that the patient was in the Psychopathic Hospital. When he visited the patient at the Psychopathic, the patient told him that the doctors there were trying to electrocute him, and that he felt electricity all over his body. The records from the Psychopathic state: Physical: Pupils sluggish. Mental: Orientation and memory fair; calculation, general information, retention and judgment poor; quiet, cooperative, but indifferent; is in poor contact; feels electricity all over his body; hears voices. This has been going on for months. When admitted to the Chicago State Hospital he was clear and oriented. He told the examiner that he worked steadily until the Monday before he was committed. He had been hearing voices since before Christmas, but they did not bother him enough to keep him from working. Every time he turned his head, they said in his own language that he was not going to live long; that he must die; that they wanted his money. He further stated that the voice he heard was the voice of the doctor who had been doctoring him. The doctor wanted his money, and bothered him so much that he once gave him two hundred dollars. The doctor put electricity over his body and it caused him great pain in his head and feet. He stated that he had been drinking moonshine since Christmas. When he first heard the voice, it frightened him, but now he had become accustomed to it. His general knowledge was in keeping with his station, and his physical and laboratory examinations were negative. This patient is improving gradually.

CASE V.—David S., admitted to the Chicago State Hospital October 27, 1921. American, white, 56 years of age. There was very little history in this case, as the man had lived away from his family for years owing to his drinking habits, as he had been a heavy drinker. The records from the Psychopathic are as follows: Physical: Arteriosclerosis; senile changes. Mental: Patient is disoriented, is out of contact, indifferent, and answers questions slowly. Patient is deteriorated. When admitted to the Chicago State Hospital he was a stretcher case and in a very weak physical condition. The heart sounds were feeble and he could not even stand. Had a large pressure sore on the back. He was in a stuporous condition, and no information could be gotten from him. After a few days he improved sufficiently to give an account of himself.

At that time it was found that he was only partially oriented. He gave his name correctly, called the place the County Hospital, knew the year was 1921 and the month November, but could not give the date nor the day of the week. He could not state exactly how long he had been here, nor how he came. Said he came here to get cured of the weak spells. He was walking to Chicago, fell on the sidewalk and an ambulance brought him out here. States that he has been drinking since he was 22 years of age. Thirteen years ago he was drunk and at that time he saw and heard different things, but during this present attack he does not remember having seen and heard things. States he stopped drinking for about a year after prohibition, but started to drink again, and drank moonshine. His personal identification was well given, but he was very deficient in general knowledge. He could not name the President or Governor, or the Mayor of Chicago. He named five of the largest cities in the United States and three of the Great Lakes. He named the Spanish-American, the Mexican, and the last war as the wars this country has had. He knew that there were other countries in the last war, but could not name them. He knew that George Washington had been president but he did not know that he was the first president. Abraham Lincoln, he stated was the man who cleared up the West. He knew the days in the week and months in the year. His calculations were also deficient. This patient improved physically. His pressure sore healed and he became stronger. He is able to be up, and at present is even helping care for other patients. Mentally, he shows apathy, and when not occupied he will sit down in a chair by himself; will not mingle with other patients; does not talk spontaneously, but answers when spoken to; is pleasant and agreeable and has developed a fabrication of memory. He tells what he did the day before, how he visited his brother, and how he was walking in many other places while he was not out of the ward. However, he is steadily improving, both physically and mentally.

PROGNOSIS IN INFANCY AND CHILDHOOD.

By JOSEPH H MARCUS, M.D.,

ATLANTIC CITY, N. J.

PEDIATRIST TO THE BAMBERGER HOME; PEDIATRIST TO THE JEWISH SEASIDE HOME AND ATLANTIC CITY HOSPITAL.

THE conspicuous feature in the prognosis of disease of early life is the age of the patient, and so we may stipulate without much reservation, that "the younger the patient, the worse is the prognosis in all the diseases of childhood." It is for this undisputed fact that the mortality in the first year of life is so high, and that it shows a relative decrease throughout the remaining years of childhood. In the second year of life, when the child commences to crawl about and creep, and walk, and when its diet embraces other foods, in addition to milk, the pathogenesis will be seen to depend, not so much on the internal, as on the external influences and environment. The scope of this monograph is not intended to embrace that much discussed question of infant mortality, nor to consider the different causes of death at the different ages, in a detailed narrative. Briefly, the causes of the high mortality of infancy may be stated as follows: (*a*) The feeble resistance of the infantile organism to the external causes of disease, demonstrated not only against those external causes which have a marked tendency to produce disturbance of function, but also against infections. (*b*) The frail resistance of the undeveloped organism may be increased both by inherited conditions and by congenital faults of development. (*c*) A wide and prevailing ignorance as to the hygienic requisites of the young and tender organism and the necessary considerations that are essential to its proper growth and future health.

In the first year of life, gastrointestinal disorders hold first place as the cause of death; acute respiratory infections come second; congenital malnutrition third; other acute infections is the fourth factor in importance. In the second year of life, the gastrointestinal conditions still hold a position of primary importance in the causation of death. It is rather difficult to draw a sharp line of demarcation between acute infections of the respiratory tract and the acute contagious diseases, because death so often occurs when the pulmonary infection has become a complication of the acute contagious disease. Measles, diphtheria and pertussis appear to hold second place. Acute tuberculosis and tuberculous meningitis certainly ought to receive an important statistical consideration, but the present available figures appear to be rather too low. After the second year, the acute infections rank ahead of all other conditions.

During the fifth and sixth years of life, the peculiarities of children more closely resemble those of the adult. Nervous disorders appear as a result of mental strain; scoliosis, due to faulty position; myopia and other eye disorders, as a result of reading and writing to an excess or in a faulty light. The increased social intercourse at this time presents a favorable opportunity for the transmission of the infectious diseases, and certain nervous hysterical diseases. To be sure, the proper predisposition must be present.

In considering the phase of prognosis, it must not be forgotten that, in general, infants and young children succumb easily to acute infections and, in addition, they demonstrate more markedly the effects of chronic functional disturbance. On the other hand, there are numerous conditions, accompanied by organic lesions in early life, that show a remarkable possibility of recovery as compared to adult life, and which is due to the rapid metabolism of childhood. So it is quite possible for many conditions of an organic nature to disappear with the passing of time, or as the expression is to-day, "to be outgrown," provided that the patient can be placed under the proper hygienic surroundings, so that the general nutrition can be carried to the highest point. Owing to the certain distinctiveness of the anatomy of early life, there are a number of infectious diseases which run a less severe course in the infant than in the adult. The course of each disease depends on many factors, the important phases being the lack of development and peculiarities of functional resistance, which form the unknown factor in the giving of a prognosis. In the adult this can be compared to the effects of all abuses, such as of alcohol, and the various other forms of wear and tear of the adult human organism. The prognosis of any diseased condition can be estimated only from an understanding of the characteristics of the particular disease in early life, and from an estimate of the constitutional distinctiveness of the individual patient. In chronic functional disturbances, the prognosis largely depends upon the length of time which the disease has existed and the degree of malnutrition and the lowered resistance which are present. In those with apparently robust constitutions and normal

development, the prognosis in those acute diseases which do not tend inevitably to a fatal termination is fairly good. In children with poor constitutional resistance and development the prognosis is comparatively bad. Tuberculosis, while having a bad outlook during childhood, presents an especially poor prognosis in the nursing infant. Inherited syphilis also has a bad outlook, and at this time of life measles, pertussis and scarlet fever are prognostically bad. While the course of so many diseases is more severe in the early years of life, the later years of childhood are seen to offer a more favorable outcome. Pneumonia, which is so often seen at this time, has a much better prognosis than when it occurs in adults. The strength of the heart is of the greatest importance, and since valvular disease, and the causes of fatty degeneration—the abuse of alcohol and tobacco, and obesity, are all absent in children, it is perfectly understandable why the course of pneumonia in a child and that in adult life may be so different. While the uncomplicated course of every disease is more or less typical, as a rule it is markedly affected by complications. Factors that increase the source of infection afford a poor prognosis; previously existing disease has the same influence in the prognosis. Tuberculosis previously existing can well be imagined to have a very bad effect on any acute infection. Unhygienic surroundings, such as poverty, deficient care, foul and dusty air, lack of light and fresh air, and improper and inadequate nourishment are factors yielding an unfavorable influence upon the course of the disease. The influence on the morbidity and mortality of infancy and childhood of unhygienic surroundings and unfavorable environment due to poverty and ignorance is enormous. The physical development and well-being of the child is the result of three factors, namely: inheritance, environment and feeding. Certainly, heredity is beyond the power of the physician to alter; the second factor is somewhat within his control; and the third, that of food, is almost entirely within his influence, in most classes of people.

In giving a prognosis in early life, the physician must bear in mind two things; one is the liability in infancy to sudden and unexpected death from various unsuspected causes, the other factor to keep in mind is the susceptibility of infants and children to develop complications. The occurrence of sudden death is not an uncommon incident, and in those who are apparently healthy. At times they are found dead in bed, and this usually happens with those who are delicate or suffering from malnutrition. The most frequent causes for sudden death in infants are as follows: Malformations, internal hemorrhage, asphyxia, thymic enlargement, atelectasis, marasmus, convulsions, and unknown causes ushered in with a very high temperature.

Successful Inoculation of a Cock's Wattles With Variola.—The cornea of the cock having been shown to be negative to inoculation with variolous pus the experiment was repeated in the wattles in a scarified area. After the usual incubation period characteristic variolous pustules appeared. Bertarelli, the experimenter, believes this test will rank with the rabbit cornea inoculation in the differential diagnosis of smallpox.—*Gazette hebdomadaire des sciences médicales de Bordeaux.*

Medicolegal Notes.

Death Certificate Admissible in Utah as to Cause of Death Notwithstanding Privileged Communications Statute.—The Utah Supreme Court holds that where a certificate of death is in the form prescribed by Comp. Laws 1917, § 5045, and recorded as required by statute, a certified copy of the record, declared by section 5058 to be prima facie evidence in all courts and places of the facts therein stated, is admissible in an action for death as to the cause thereof. It is also held that section 5058 does not contravene section 7123, subd. 4, prohibiting a physician, without consent of his patient, testifying in a civil action as to information acquired in attending the patient which was necessary to enable him to prescribe. If it did, being part of a later act, it would prevail.—Bozicevich v. Kenilworth Mercantile Co. (Utah) 199 Pac. 406.

Physician Not Liable for Patient's Ignorance of Consequences of Refusing to Follow Advice.—In an action against a physician for failure to treat with proper care and skill a "fracture of the bone of the upper tibia at the knee joint," the jury found for the plaintiff, who excepted to an instruction of the trial court, and its refusal to give requested instructions. The evidence conflicted on the question of negligance of the defendant in failing to have an *x*-ray photograph of the plaintiff's leg taken, which, it was claimed, would have disclosed a fracture at the knee joint. There was evidence that the defendant advised the plaintiff to have the photograph taken, but that he declined because of the expense connected therewith. The plaintiff offered evidence that no such suggestion or advice was given. The defendant requested the trial court to rule: "If the jury find that the *x*-ray photograph was required to determine whether any bone of the plaintiff's leg was broken, and he was so informed by the defendant and declined to have such photograph taken, then the defendant is not responsible for not discovering the broken bone." This request was refused. The Supreme Judicial Court of Massachusetts holds that this request should have been given. If the *x*-ray photograph was not taken because of the plaintiff's refusal, the defendant could not be charged with negligence in this respect.

He was responsible to the plaintiff for the failure to use the care and skill of an ordinary practitioner in the community where he practiced. If such a photograph was essential in order to discover the fracture, and the physician, in the exercise of that degree of care required of him, advised that it be taken, and the patient refused this advice, the physician could not be charged with negligence. The plaintiff could not hold the defendant responsible for the consequences of his own want of care, nor attribute to him damages resulting from his own neglect; and he could not complain if the injury resulted from his refusal to follow the advice of the attending physician. The defendant excepted to the instruction: "You would have to find that the patient refused to have the *x*-ray taken with the full knowledge on the part of the patient of the danger that was involved." It was held that this instruction was not a correct statement of the law. A patient, when he places himself in the care of a physician, cannot decline to follow his advice or adopt his suggestions because the patient does not possess full knowledge of the dangers involved in his neglect, or in his failure to do what the physician recommended. The patient cannot charge the physician with negligence if the patient himself refuses to carry out the directions because ignorant of the consequences which might result from such failure. The patient may fail to understand fully the necessity of doing what the physician recommends, but he cannot attribute to the physician the damages which resulted from his own failure to have something done, when this was caused by his own conduct, even if he was ignorant of the consequences which would result from his refusal. If the rule were as given in this instruction to the jury it would place an unreasonable burden upon the physician, and would require of him a much higher standard of care than the law requires. The defendant's exceptions were sustained.——Carey v. Mercer (Mass.) 132 N. E. 353.

MEDICAL RECORD.

New York, February 18, 1922.

THE TOXEMIA (ACIDOSIS?) OF PREGNANCY.

THE tendency during the past quarter century to group almost the entire special pathology of pregnancy under one head which comprises especially acute yellow atrophy, pernicious vomiting, cholemia, eclampsia, etc., has always been opposed by conservative obstetricians, with the result that the old nomenclature and nosological distinctions still obtain in a majority of reports. It is admitted that in these severe and fatal complications of gestation the liver shows more or less degeneration. In eclampsia these lesions may be minimal, while in acute yellow atrophy they are total, and in pernicious vomiting, although present at times, they are often wanting. This common participation of the hepatic cells does not appear to prove the identity of the affections in question and some obstetricians reserve the term toxemia of pregnancy for such conditions as "eclampsia without convulsions" or without renal lesions, these conditions being sometimes spoken of as cholemia. In a case recently reported by Couvelaire and republished with a second case by the same author with Aubertin in the *Journal de médecine et de chirurgie pratiques* for Dec. 25, 1921, cviii, 24, the summary is as follows: the woman, aged 45, was presumably sound although a history of scarlatina and typhoid fever suggested the possibility of damaged kidneys, and her record as a childbearer was also suggestive of syphilis. Her fifth gestation went ahead uneventfully with no elevation of blood pressure and but a trace of urinary albumin. Labor was also normal from the merely obstetrical angle, although she developed cyanosis and dyspnea and two hours after delivery died with these symptoms, but with no suggestion of uremia, convulsions, coma, or jaundice. Autopsy showed but one lesion to account for death—an acute fatty degeneration of the liver suggesting the liver of phosphorus poisoning. The kidneys showed some evidence of former nephritis but apparently had functioned well. The authors make no mention of the term acute yellow atrophy and clinically of course such a condition did not exist. The postmortem appearances, the occurrence in pregnancy, the suspicion of syphilis, the fatal ending, all suggest acute yellow atrophy, but in that affection there is seldom or never a suppression of the entire clinical syndrome. The authors use the term acute hepatic degeneration and are inclined to suspect the existence of an acidosis, the suspicion having been formed after study of a second case which was of the same order but with a notable acidosis. The patient, aged 24, was seven months pregnant when she developed, within two days, headache, vomiting, dyspnea, cyanosis, albuminuria, and a small, rapid and compressible pulse. Acetonuria then appeared and although there was some initial improvement the symptoms all returned in full force and a dead child was brought away by *accouchement forcé*. Delivery gave no relief and the woman died in a few hours with dyspnea and cyanosis and imperceptible pulse. Autopsy revealed apparently intact organs to the naked eye but the hepatic tissue was found by the microscope to show central lobular necrosis. The fetus presented similar lesions in the liver. Acidosis, according to the author, is a symptom of acute hepatic insufficiency, and its presence was shown not only by the urinary examination but by the syndrome of incoercible vomiting, epigastric pain, and dyspnea *sine materia*.

INVOLUNTARY MOVEMENTS IN SYRINGOMYELIA.

MARINESCO of Bucharest was the first to describe disturbances of the voluntary movements in syringomyelia. These have a double interest inasmuch as they concern both the clinical aspect and the physiological pathology of the disease. These patients present involuntary movements of the upper limbs, involving the fingers and especially the thumb. They consist of rapid vibratory jerks, usually occurring in paroxysms, which appear and disappear without any apparent cause. The patients present the classical type of syringomyelia, and cerebral disturbances or epileptic attacks are not noted. The clonic movements observed vary in intensity; the thumb in one case presented vibratory clonic movements during the entire day, but decreased when the patient took hold of some object using energy in so doing. When a registering apparatus is used it will be found that these clonic movements occur in paroxysms followed by isolated jerks, separated by variable intervals of rest. The onset of these paroxysms is sudden and the type of jerk is not always the same. The oscillations are rapid—averaging about five per second. A very notable difference in the amplitude of the jerks is not observed. It is interesting to note that the jerks do not coalesce but are completely separate. The direction of the clonic movements is indicated by the action of the antagonist muscles; thus in some cases the clonic movements have the same direction as extension of the thumb, which still persists, although weakly, while flexion is practically nil.

The pathological physiology of clonic movements and myoclonics in general has given rise to many opinions on the subject. The seat of clonic move-

ments has been much discussed; some, like Friedreich, Loewenfeld, Marie, and Venturi, believe in a spinal origin of myoclonus. Others, like Minkowski and Grawitz, regard it as cortical in origin, and Raymond is likewise of this opinion. Seppilli developed the cortical theory, showing that clonic movements are associated with epilepsy, while Ziehen has also maintained that clonic convulsions proceed from the cerebral cortex, while tonic convulsions have their origin in the subcortical centers. Bouly believes that clonic movements met with in syringomyelia—an affection of spinal origin—warrant us in affirming that the cord is capable of giving rise to clonic movements, and he points out that his cases were all syringomyelia without cerebral complications. One of these patients died and autopsy showed that the cord presented characteristic lesions of syringomyelia while the brain was normal in appearance.

Now, what portion of the cord is the site of origin of these movements? Hoffmann and Marinesco have shown that the process of gliosis in syringomyelia has its starting point in the periependymal epithelium and neuroglia. The hyperplasia of the neuroglia produces, either through the intermediary of circulatory disturbances or by mechanical compression, an irritation of certain cell groups; this is slight, but its equivalent is the production of these clonic movements. It therefore results that the faculty of provoking the occurrence of clonic movements does not belong to any special nerve center, but is the manner of reaction of the nervous motor centers under the influence of stimuli, sufficiently strong to determine movements, yet sufficiently weak so that there is fusion of the jerks. The researches of Schlesinger, Marinesco, Ingelraus, Bouly, and others sustain this point of view.

VISUAL DISTURBANCES AFTER HEMORRHAGES.

It is common knowledge that losses of blood of all types, single or repeated, irrespective of the importance, causation, and seat, are followed at times by divers disturbances of vision which in about half the cases are succeeded by atrophy of the optic nerves and terminal loss of sight. It must not be understood that this condition is at all common. There are about 250 recorded cases, an almost infinitesimal fraction when compared with the great frequency of hemorrhage. The latent period is very short in most of these cases—from 3 to 8 days only between the hemorrhage and visual disturbance. The latter comprises nyctalopia, which is of brief duration and benign; homonymous hemianopsia of cortical origin, without fundal alteration, and bilateral amblyopia (rarely unilateral) which passes rapidly to complete or partial blindness. Thus far there is no case on record in which the latent period has exceeded three weeks. Subjects of these disorders have been of all ages, hemorrhages of all clinical forms. If the condition were common it would be apt to manifest itself especially after menorrhagia and childbirth and, in the days of universal bloodletting, in those who were bled to excess.

Professor Terson of Paris, who read a paper on this subject before the Ophthalmological Society of that city last November (*Gazette des Hôpitaux*, December 1-3, 1921, xciv, 95) states that the fundal finds in these cases consist usually of ischemia of the optic nerve with contraction of the retinal arteries and, at times, edema of the retina and optic disk. After this picture is in evidence recovery is still possible. The nerve atrophy which sets in may be partial or total.

The ophthalmologist is interested in determining the pathogenesis of this affection and in the discovery of an intensive plan of treatment to arrest its progress. As it stands to-day the affection is an enigma. What does comparative pathology teach us, what general pathology in man, what experiment?

For purposes of comparison we have certain ischemic intoxications, for example quinine amaurosis, which might throw light on the possible genesis of a substance toxic to the optic nerve in connection with regeneration of the blood following hemorrhage. The hypothetic substance, does it produce its effects by contraction of the blood-vessels? There is no evidence in pathology which warrants the assumption that a mere ischemia can entail atrophic changes in the nerve. The most profuse hemorrhage may not affect the eyes at all. The occasional occurrence of unilateral cases, however, is the chief stumbling-block for all theorizing. Does the hemorrhage mobilize some toxic principle in the organism? It is possible that blood studies at the right moment might disclose a hemoclastic (colloidoclastic) crisis, such as might cause a precipitation in the peripheral vessels; which, however, might be harmless in regions other than the fundus oculi. The few recorded autopsies agree in the absence of all intravascular pathology—neither inflammation, hemorrhage, embolism, nor thrombosis.

The Physiological Complex.

The general public has picked up so much of the psychoanalytic jargon that it has become now quite the thing to discuss one's complexes and repressions and fixations in social intercourse. Probably the most popular term which has been borrowed by the laity is the "complex." This is used not only approximately correctly, but in all sorts of erroneous ways. It is a facile way out of a difficulty to say that one has a "complex" about it, even though the statement may mean nothing in particular. The general understanding moreover seems to be that these complexes are pernicious things and that the task of the psychoanalyst is to remove them. Thus we see facetious reference in the public prints to "going to a psychoanalyst and getting one's complexes cut out." Even in the profession this is the view somewhat generally held. Indeed psychotherapeutists themselves are not entirely free from the idea of the essentially pathological nature of the complex. The complex is not so obviously an evil

as some other things, but in psychotherapy it is blamed for a great deal. It would be well then to call attention to the fact that it is not necessarily pathological, and may even prove to be a beneficial factor in the patient's life. In the familiar example of the Œdipus complex we may find that the mother fixation in certain cases makes for a more satisfactory adjustment to the world than would be possible without it. And when such is the case, it would of course be positively harmful to try and rid the patient's mind of it. A complex acting in this way might very well be termed a physiological complex to imply that its force is exerted in a direction collinear with the patient's best interests.

The Structure of Bacteria.

Despite our knowledge of the structure of the cell, that of the microscopic nature of the bacterium is fragmentary. Differences in staining effects signify differences in structure, but these show a notable lack of type. In some bacteria the ends stain more strongly than the middle, while in others the so-called zebra stripes appear. It is evident that these differences throw little light on the common microscopic structure of microorganisms and that what is wanted is not difference but similarity. Something is known of the intimate nature of fungi. Yeast cells and fungi exhibit protoplasm which stains and vacuoles which do not stain. But these vacuoles may contain various granules and liquids which take a notable stain. Some kinds of granule exhibit certain movements and have been named dancing corpuscles. It appears very likely that, like the yeasts and fungi, the bacteria show ordinary protoplasm, vacuoles and different forms of granule within the latter, including the dancing corpuscles. Differences in distribution might then explain differences in details, which do not antagonize the existence of a basic identity in structure. Bergstrand of Stockholm discusses the structure of bacteria in the *Acta Medica Scandinavica* for December 5, 1921, lv, 6, and shows that structure of the individual bacterium varies much with age; that vacuoles may differ in nature and that they may fill with various fluids and granular bodies; that protoplasm tends to break up and form clumps in old bacteria; that a bacterium has no nucleus in the sense that yeast cells and fungi have nuclei. In one species of bacterium at least he has seen the so-called budding disk found in yeast cells, which may perhaps play a role in bacterial reproduction or be homologous with a nucleus.

News of the Week.

Sleeping Sickness Appears in Russia.—According to a cablegram under date of Feb. 7, epidemic encephalitis is making its appearance in Russia on a scale to cause alarm. Moscow is said to have more than 100 cases at the present time. The disease appeared in the Ukraine in considerable proportions two years ago this winter and later spread northward. About 70 per cent. of the patients die. Dr. D. Gorokhoff, professor of surgery and gynecology at Moscow University, died a victim of the disease.

Conference on Nervous and Mental Ills of Ex-Soldiers.—Director Forbes of the Veterans' Bureau conferred with leading neuropsychiatric specialists of the country in Washington, D. C., on Feb. 10, on means of improving the bureau's method of dealing with mental and nervous cases among disabled former service men. Questions of physiotherapy were discussed. The hospitalization of mentally afflicted and nervous men, the necessity for additional hospitalization, and the training of the personnel of the bureau dealing with those patients were also laid before the conference. The bureau's records show that approximately 9,000 former service men are being treated in hospitals for mental diseases. Mr. Forbes said, however, that there were thousands of these cases, beneficiaries of the bureau, who are not receiving hospital care.

Medical Training Not Yet Wholly Under Rockefeller Direction.—The General Education Board of the Rockefeller Foundation has just made public its annual report, in which it endeavors to show that medical education in the United States is not now as far advanced as was that of Germany in 1914. The report states that there is still lacking in this country a medical school that is on the clinical side well rounded and well equipped. A comparison is drawn between the state of the fine Johns Hopkins Medical School and that of the two smallest of the twenty-two German universities, at Marburg and Giessen. The total teaching equipment of Johns Hopkins is not much more than 400 beds, and some important branches have none at all. Marburg has more than 700 teaching beds and Giessen more than 600. The report adds: "It is no exaggeration to say that there is this day no medical school in the United States which possesses under complete university control clinical facilities as extensive as these two smallest and weakest of German universities which are about to be discontinued." The report goes on to say that the entire fund of the Board for medical education might be spent in perfecting a few institutions, but it is believed greater good can be accomplished by stimulating and improving medical education in all sections of the country by smaller contributions. In other words it is better to buy a controlling interest in all the schools than to own a few outright.

To Build Up Western Reserve Medical School.—The trustees of the Western Reserve University have accepted a donation of $2,500,000 from Samuel Mather of Cleveland for the purpose of building a new medical school building. The gift will make possible one of the finest medical school buildings in the United States. Mr. Mather's gifts to the university total more than $4,000,000.

To Place Arkansas Medical School on Accredited List.—A conference was recently held with the American Medical Association Committee on Medical Education with the purpose of making arrangements whereby the Arkansas Medical School may be placed on an accredited basis by the addition to the present curriculum of junior and senior years. Two years ago the course was reduced from four to two years because opportunities for clinical work were not available. Since then students have been forced to go outside of the State to complete the required work for a medical degree. Two new hospitals have been completed which will afford facili-

ties for clinical work, and it is probable that the medical school will resume its full course in the near future.

Kentucky Physicians Oppose Shorter Medical Course.—Delegates of the Kentucky State Medical Society, in joint session with the health and sanitary committees of the House and Senate, on Jan. 21, 1922, opposed a legislative measure designed to relieve a shortage of physicians in rural districts by reducing the standard of medical training. The meeting was called at the request of the Governor for the purpose of drafting a bill which would encourage the training of more physicians so as to aid the rural districts of the State.

Medical Clinics for Physicians.—The Society for the Advancement of Clinical Study in New York announces that the principal hospitals of New York are joining in a plan to provide daily medical clinics which shall be open to all members of the medical profession. The Committee on Medical Clinics will so arrange the clinic dates for each hospital that at least one clinic will be given daily. The attempt will also be made to have subjects of paramount importance covered at regular intervals. The value of such a plan for the advancement of medicine is entirely obvious. At an early date regular weekly bulletins will be issued, giving in detail the program of the clinics for the following week. For the present these bulletins will be sent without charge to those physicians who signify their interest and expectation to attend these clinics at least occasionally. The clinics will be held with a few exceptions at three in the afternoon. Further information may at any time be secured at the office of the Society for the Advancement of Clinical Study, New York Academy of Medicine, 17 West Forty-third Street. The Committee on Medical Clinics is composed of Dr. Dudley Roberts, chairman, and Drs. William R. Williams, Rowland G. Freeman, Walter L. Niles, Lewis F. Frissell, and Dever S. Byard.

Physicians Organize to Fight Chiropractor Bill.—Committees representing the Medical Society of the State of New York and the Medical Society of the County of New York met recently to organize opposition to a bill introduced into the Legislature to license chiropractors. According to a statement made by George W. Whiteside, counsel for the medical societies, the bill contains a "waiver" clause, which would license all chiropractors now practising without any sort of examination. It would make every outlaw practitioner today a "Doctor of Chiropractic" and would subject future candidates for that title to examinations prepared by an organization created under the bill. This organization would be named by the State Board of Regents from a list of names approved by the chiropractic organization here.

Brewers Lose Medicinal Beer Suit.—Piel Brothers, brewers, the first brewing concern in New York State to seek a permit to manufacture medicinal beer after the ruling of the Attorney General several months ago, have lost in their action to enjoin and restrain the Federal authorities from interfering with them in the manufacture of beer for medicinal purposes. The decision was rendered in Brooklyn by Federal Judge Edwin L. Garvin who, in his decision, went into the provisions of the Eighteenth Amendment, the Volstead Act, and the Willis-Campbell Act. He held both of the latter acts constitutional. He took the position that beer is to be considered more as a beverage than as a medicine. He cited other decisions to support his position and held that it appeared that Congress deemed this legislation imperative to accomplish effective enforcement of the amendment, and at the same time was satisfied that there is little or no value in beer either as a therapeutic agent or as a galactagogue.

Ohio State Hospitals To Be Improved.—According to a statement made by State Welfare Director H. S. MacAyeal, arrangements have been completed for increasing the personnel of the Ohio State hospitals. The individual problems of each institution have been investigated and each has been authorized to enroll new staff members, district nurses, and specialists.

Medical Society Condemns Contract Practice for Reduced Fees.—At a regular meeting of the Sedgwick County Medical Society, held in Wichita, Kan., Jan. 29, 1922, resolutions were adopted recommending that the Society condemn any contract practice that pays a fee less than the regulation fee adopted by this Society. The recommendations also condemned other methods of organizations interested in promoting contract practice.

Influenza in New York During January.—The New York Health Department in its *Weekly Bulletin* analyzes from the standpoint of age and sex the 1691 cases of influenza reported in the Borough of Manhattan from Jan. 3 to 31, inclusive. In 385 cases no information as to the age and sex of the person affected was given. Of the balance 626 were male and 680 female. One hundred and twenty-five children under five years of age were affected; among these there were more females attacked than males. In the age group from 5 to 9 years, 101 cases were reported from 10 to 14 years, 77 cases were reported; in persons over 60 years of age only 48 cases were reported. The greatest number of cases occurred in the group between the ages of 20 and 40 years. The disease, therefore, presents very much the same features that were noted in previous outbreaks, so far as age distribution is concerned.

Amendment to Sanitary Code Regulates Barber Shops and Beauty Parlors.—At a meeting of the New York City Board of Health, held on Jan. 26, 1922, Section 335 of the Sanitary Code was amended to regulate in minute detail the conduct of barbers, hair-dressers, manicures and beauty cultivators. The amendment provides that henceforth no public barber shop, hair-dressing establishment, manicuring or beauty parlor shall be conducted or maintained in the City of New York without a permit therefor issued by the Board of Health, or otherwise than in accordance with the terms of said permit and with the regulations of said board. These regulations are twenty in number and call for sterilization of all instruments after each separate use. Stick astringents, powder puffs, sponges and neck dusters are prohibited. One piece of soap must not be used for more than one person and individual finger bowls and shaving cups must be provided. Recent investigation has shown that some of the largest barber shops in the city have not been complying with the present regulations.

Hospital Notes.—The Hospital for Joint Diseases, New York, has acquired a three story dwelling house at 50 East 124th Street. With this purchase the hospital has now assembled a site 200 x 154 feet, upon which it plans to construct a new eight story building.

The new Government sanatorium at Dawson Springs, Ky., will be opened on Washington's Birthday, Feb. 22. The buildings have just been completed at a cost of $2,300,000 and are equipped to accommodate 700 former service men. Dr. H. E. Hitledge, former medical officer in charge at Fort Bayard, N. M., has been appointed commanding officer at the sanatorium.

At the annual meeting of the trustees of the Faxton Hospital, Utica, N. Y., held Jan. 26, it was announced that $206,280 had been raised toward the construction of a new building, which will be begun early this spring. Dr. T. H. Farrell was elected president of the hospital staff.

The new Haaf Hospital at Northampton, Pa., erected at a cost of $100,000, was dedicated on Feb. 2. The new hospital is named in honor of Dr. Charles A. Haaf, who was instrumental in founding the institution.

A two story building for the treatment of diphtheria is to be added to the Philadelphia Hospital for Contagious Diseases, at Second and Luzerne streets. The estimated cost of the addition is $39,000.

Mr. William Jennings Bryan has donated his former home in the suburbs of Lincoln, Neb., to be used as a national Presbyterian Hospital for missionaries and teachers and their families who have been incapacited for work while in China and Japan.

Work will soon be begun on a large general hospital in Louisville, Ky., which according to estimates will cost about $500,000. This amount has been raised by the Baptist Church in Kentucky.

A modern hospital building is in the process of construction to replace the Seller's Hospital at Anniston, Ala., which was destroyed by fire some time ago. The cost of the new structure will be approximately $100,000.

The Tuscaloosa Hospital Association announces an issuance of city bonds to the amount of $50,000 and cash contributions of $32,000, which will enable them to begin work on a new city hospital immediately.

More than one-half of the $150,000 required for the construction of the proposed Methodist Hospital at Scottsbluff, Neb., has been pledged.

The Presbyterian Hospital, Philadelphia, has resumed its building plans outlined before the war. The trustees of the hospital recently executed a contract for the construction of the first three units of the new buildings, to be located on the hospital property. Work on the building operations will commence next month and will be completed, it is anticipated, within a year. With the completion of the extension plans, it is proposed to establish industrial clinics at the hospital equipped with special apparatus for the treatment of such cases. At present an average of 125 industrial cases are treated there monthly.

The board of managers of the Chester (Pa.) Hospital have awarded the contract for a new hospital building to cost $205,500. The hospital will have a capacity of 125 beds. Construction work will be begun immediately.

According to its annual report, the Roanoke (Va.) Hospital has just completed its most successful year. A new $150,000 building is expected to be erected during the present year.

Dr. John Dill Robertson has resigned the position of Health Commissioner of Chicago, which he has held for the past seven years. Dr. Herman N. Bundesen has been appointed to succeed him.

Dr. Wilfred T. Grenfell, known as the "Labrador doctor," is in this country delivering a series of lectures on the development of medical and social work in Labrador.

Dr. Richard Derby of Oyster Bay, L. I., has been appointed to the position of manager of the Kings Park State Hospital. He succeeds Dr. Henry Brown, whose term expired.

Dr. Stuart McGuire of Richmond, Va., has been awarded the Distinguished Service Medal by the United States Government, in recognition of his work in organizing a hospital unit and serving as its head throughout its training and its service in the battle areas of France.

Dr. William S. Thayer of Baltimore and Dr. Herbert C. Moffitt of San Francisco have been selected as candidates for the Harvard Board of Overseers by the Nominating Committee of the Harvard Alumni Association.

Dr. Samuel J. Crowe and **Dr. John I. Baylor** of Johns Hopkins Hospital have sailed for Europe to study surgical methods in foreign hospitals.

Dr. L. R. Williams, director of the Rockefeller Foundation, is touring Central Europe in connection with the work of the Foundation.

Dr. Edward T. Delehanty of Albany has been named county physician to succeed Dr. G. L. Ullman.

Gifts and Bequests.—The A. Barton Hepburn Hospital at Ogdensburg, N. Y., is the recipient of a bequest of $250,000 by the will of its founder, whose name it bears.

The Good Samaritan and St. Joseph's Hospitals at Lexington, Ky., receive $10,000 each, by the will of Edmund J. Curley, who died recently in Monte Carlo, France.

Indian, Thought To Be World's Oldest Human, Dies.—Ga-be-nah-gewn-wonce, also known as John Smith, a Chippewa Indian, reputed to be 137 years of age, died at Cass Lake, Minn., on Feb. 7, after a week's illness with pneumonia. According to the Bureau of Indian Affairs he was fire raker of the once powerful Blackfeet tribe, and was able to corroborate many historical events as far back as 1800.

The Association of Cardiac Clinics held a meeting at the New York Academy of Medicine on the evening of Feb. 8, at which Dr. Frank N. Wilson of Ann Arbor, Mich., delivered an address on "X-Ray in Clinical Diagnosis."

The Brooklyn Diagnostic Society held its nineteenth scientific session on the evening of Feb. 3, 1922, at which Dr. Frederick M. Allen, Director of the Psychiatric Institute at Morristown, N. J., delivered an address on "How Shall We Feed Our Diabetic Patients."

Medical Society Elections.—THE NORTHAMPTON COUNTY MEDICAL SOCIETY, at its annual meeting held in Easton, Pa., Jan. 20, 1922, elected the fol-

lowing officers for the ensuing year: *President*, Dr. D. K. Santee, Bethlehem; *First Vice-President*, Dr. Paul Correll, Easton; *Second Vice-President*, Dr. Harry Pohl, Nazareth; *Secretary-Treasurer*, Dr. V. S. Messinger, Easton.

The Pocatello (Idaho) Medical Society, at a recent meeting, elected the following officers for the ensuing year: *President*, Dr. J. R. Young; *Vice-President*, Dr. W. W. Brothers; *Secretary*, Dr. J. E. Dameron.

The Canandaigua (N. Y.) Society of Physicians, at a recent meeting, elected the following officers for the ensuing year: *President*, Dr. George Gregg; *Vice-President*, Dr. C. Willard Selover; *Secretary and Treasurer*, Dr. Frederick C. McClellan.

The Central District and Merrimac County Medical Society, at its one hundredth anniversary meeting held in Concord, N. H., Jan. 17, 1922, elected the following officers for the ensuing year: *President*, Dr. J. B. Woodman, Franklin; *Vice-President*, Dr. James W. Jameson, Concord; *Secretary-Treasurer*, Dr. A. L. McMillan, Jr., Concord.

The Surgical Section of the Hartford Medical Society, at a meeting held Jan. 23, 1922, elected the following officers for the ensuing year: *Chairman*, A. M. Outerson; *Secretary*, Clinton Demming; *Treasurer*, Donald Wells.

Obituary Notes. — Dr. James W. Fleming of Brooklyn, N. Y., died suddenly on the street while returning from a professional call on Feb. 8, at the age of sixty-eight years. He was graduated from the Long Island College Hospital in 1880. He was a member of the American Medical Society, the Medical Society of the State of New York, the Kings County Medical Society, and the Brooklyn Pathological Society. He was consulting physician to the Long Island College Hospital and the Baptist Home and a member of the Board of Regents of the Long Island Medical College.

Dr. Wade D. Stevens of Pawpaw, Ill., a graduate of the College of Physicians and Surgeons, Chicago, in 1894, died recently as the result of an overdose of a narcotic, apparently self-administered. He was fifty-four years of age.

Dr. Walter Lindley of Los Angeles, Cal., died of cerebral hemorrhage at his home on Jan. 24, at the age of seventy years. He was born in Monrovia, Ind., Jan. 13, 1852, and was graduated from Long Island College Hospital in 1875. He founded the California Hospital, of which he was manager and secretary for many years. He was at one time Dean of the medical department of the University of Southern California. He also served as president of the State Board of Medical Examiners and acting secretary of the State Board of Health. He was a Fellow of the American Medical Association and a member of the State and County Medical Societies. He made many contributions to medical, sociological, and literary journals and was the author of "California of the South," "The Delinquent Child in Great Britain and France," "The Traducers of Shakespeare," and "Irish Dramatists and the Irish Drama."

Dr. James A. Hill of Mooresville, Ala., a graduate of Vanderbilt University Medical Department, Nashville, in 1884, died at his home on Jan. 27.

Dr. John M. Maloney of Dundee, N. Y., a graduate of Georgetown University Medical College in 1870, died on Jan. 21 after a lingering illness, at the age of seventy-six years.

Dr. Robert Reed Stewart died at Philadelphia on Feb. 2, at the age of seventy-four years. He was graduated from Jefferson Medical College in the class of 1882.

Obituary.

PEARCE BAILEY, M.D.

NEW YORK.

Dr. Pearce Bailey, neurologist and psychiatrist, died at his home in New York City of pneumonia following an attack of influenza on February 11. He was born in this city July 12, 1865, and was graduated from Princeton University in 1886, and in medicine from Columbia University in 1889. He was for several years adjunct professor of neurology at Columbia University and was consulting neurologist to St. Luke's, Roosevelt, New York, Orthopedic, Manhattan State, and St. John's Hospitals. He was a member of the Medical Society of the County and State of New York, the American Medical Association, the American Neurological Association, the New York Neurological Society, the New York Pathological Society and the New York Academy of Medicine. He was a founder of the New York Neurological Institute.

During the war Dr. Bailey served in the army with the rank of Colonel. He was put in charge of the organization of the neuropsychiatric service of the army, and for this and other work received the Distinguished Service Medal. He had built a new department, one of great importance for the efficiency and morale of the army, through the elimination of the mentally unstable and unfit. At the close of the war Dr. Bailey devoted himself to developing the care of nervous and mental defectives in New York State, serving as member of the State Commission for Feeble Minded. He was instrumental in establishing the Classification Clinic, where tests were carried out to determine the expediency of young people taking college training.

Dr. Bailey was widely known for his scholarly essays on neurological and psychiatrical subjects and also for his original magazine stories and literary skits. His death will be felt as a serious and almost irreplaceable loss by both the medical profession and the State.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

COMMON SENSE IN THE PREVENTION OF INFLUENZA.

To the Editor of the Medical Record:

Sir:—The commonest disease of mankind, an acute infection of the upper respiratory passages most frequently called influenza or grippe, has had innumerable names proposed for it. Influenza, grippe, and cold were undoubtedly coined by the laity, for they have not the slightest scientific significance. The word influenza is of Italian origin and was suggested during the seventeenth century, for it was believed that this disease was the result of some influence exerted by the stars, hence influenza. Grippe was proposed by the French about the same period. The term cold is of later origin and is the most reasonable of all terms employed, for it gives a clue to some of the exciting causes of the disease—climatic changes, exposure, etc. The terms all refer to the same type of an infection which prevails chiefly during the cold weather.

There is abundant evidence that for the past three hundred years at least, the medical profession has discussed the etiology of this disease, and unfortunately exact knowledge is still wanting. The presumption established by Pfeiffer in 1893 that he had discovered the specific organism of influenza has not been confirmed. It is the common practice in the profession and laity to refer to a mild infection of this type as a cold, and to a more abrupt and serious one as influenza or grippe. This is neither logical nor reasonable, for a generally satisfactory differential diagnosis cannot be made. Furthermore, an attempt to do this is not without danger, for both the family physician and patient are apt to overlook the fact that what is apparently a so-called simple cold may abruptly change its character and assume a serious form. To discard these meaningless terms and substitute one which has some scientific value would be distinctly advantageous to the medical profession as well as the public. Under the present practice the inconsistency of a municipal health ordinance which calls for the reporting of influenza is obvious. The physician does not know what class of case clearly comes within this meaning and neither do health officials.

So-called influenza, grippe, or cold is due to the presence of certain infectious organisms found upon the mucous membrane of the air passages, particularly the nose and throat, therefore every reasonable means should be employed to prevent the transmission of the infectious agents from one person to another. We should also maintain good health by carefully observing the laws of personal hygiene and avoid the well known exciting causes, such as undue exposure to cold, abrupt climatic changes, improper dress, wet or damp feet or clothing, and drafts; the latter is so generally accepted as a common excitant of colds that it would seem unwise to open the windows of public vehicles, particularly subway cars, which allow the entrance at one point of a current of air under great pressure, the effect of which upon those in the immediate vicinity may well be understood.

It is quite true that those in robust health contract colds or so-called influenza, it is also true that those who are unmindful of their health and are not careful to avoid the exciting causes suffer more severely from the disease and are more liable to its complications than others. I believe that the severity of the influenza epidemic of 1918 was due largely to the greatly impaired physical condition of the public following the war, with its depressing influence, long continued nervous tension, and poor and insufficient food; these factors rendered the people of this and other countries far more susceptible to the disease and less resistant to the action of the specific organisms.

Unfortunately the public has not been fully advised as to the importance of good health as a very valuable means of protection. Health officials have endeavored rather to prevent the extension of this disease by the enforcement of measures which relate almost solely to the transmission of infectious agents from one person to another. It is disturbing to the public to note that the methods employed in the various sections of the country are not of a uniform character and are often diametrically opposed to each other. Public schools, churches, theaters, and the like are closed in some places, in others they are allowed to remain open. Health officials in certain cities have seriously considered the disinfection of public conveyances and in some instances the number of passengers has actually been limited; in other places these measures have received no official attention. The public naturally argues from this that the various protective measures employed during outbreaks of infectious disease are dependent largely upon the theory of public health officials and are not well recognized and approved methods of prevention. People will congregate in groups notwithstanding municipal ordinances to the contrary, and it is far better that churches, theaters, and the like should remain open where people can meet in well appointed and ventilated places where they may be informed from the pulpit or the stage concerning the means by which protection may be obtained. This is far better than for persons to seek their own assembling places, where there is no care or observation. Furthermore, the closing of places of amusement during an epidemic tends to depress the public spirit which would militate against overcoming this condition.

If public schools are closed children congregate in the halls of tenement houses and other places where there is no observation or care and where infectious disease may extend with great rapidity. It also deprives children of educational opportunities for a number of weeks or months. If they are not disturbed in their studies and are carefully examined by a nurse or physician upon reaching the school house in the morning and are kept under observation during the day, the early symptoms of the disease may be detected and there is but little danger to their associates; furthermore, if children are at school they are kept away from various sources of infection.

The disinfection of public conveyances like the disinfection of money is so at variance with modern sanitation that it is unworthy of consideration.

The value of vaccine as a preventive measure in connection with this disease has been freely discussed during the past two or three years. Even the most optimistic advocates of this form of treat-

ment do not claim its value has been assured, therefore it would seem unfair to recommend its widespread use, for it leaves the public to decide a question which the medical profession has not yet determined.

If the public could be better informed concerning the importance of maintaining good health and avoiding the exciting causes of this disease, the result would be more effective in the way of prevention than the employment of unreasonable and drastic measures which tend to depress the public and which do not secure its cooperation—a most important consideration.

ALVAH H. DOTY, M.D.

NEW YORK.

DENIAL BY PROXY OF A VERY GRAVE CHARGE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—A schoolboy in the South is said to have been responsible for the best definition of a friend as follows: "A friend is someone who knows all about you and likes you just the same." In this attitude of mind toward the MEDICAL RECORD and its editor, my neighbor and fellow alumnus of St. Luke's Hospital, I desire the privilege of indulging in a little criticism of your editorial published Feb. 4, 1922, under the title, "A Very Grave Charge," referring to statements made in Congress by Representative Volk, himself a physician, about four or five medical men and a lawyer. Dr. Volk is a lawyer also, as well as a Congressman, and named five of the men to whom his remarks were applicable, and the MEDICAL RECORD repeats these names.

In the closing paragraph of your editorial, although you say "The MEDICAL RECORD is very loth to believe, and cannot believe unless further proof is brought forward, that these men, who are regarded by their friends as honorable members of an honorable profession, could be guilty of the despicable practices with which they are charged in the quoted remarks and elsewhere in Representative Volk's speech," you do not stop there as you might fairly have done, but continue as follows: "But since the charges have been made publicly by a physician and a representative from this State in Congress, the men named can do no less than disprove them."

Now, I desire to make the observation that this is a very grave conclusion. I maintain that Dr. Volk's privileged speech on the floor of the House of Representatives places no man under obligation to disprove anything. I charge that your conclusion is unfair, unwarranted, and un-American. The persons named have not been indicted by any jury, or accused of crime in any court, nor have charges been preferred against them in any duly organized medical society. And one can imagine from the bitterness of the controversy that such proceedings would have been instituted had there been sufficient grounds.

My own attitude toward members of our profession accused of, or under indictment for, alleged crime or misconduct is indicated in a letter published in the *New York State Journal of Medicine*, October, 1920. The letter was addressed to James Taylor Lewis, Esq., then counsel of the Medical Society of the State of New York, and included an expression of my views (largely in accord with those of Mr. Lewis) as previously stated by me on the floor of the House of Delegates of our State Society, of which I have been a member continuously for several years. After a preamble relating to the defense of members of the Society who were awaiting trial under indictment by a Federal Grand Jury for alleged misconduct under the Harrison law, in advocating that our counsel should aid in their defense if preliminary investigation seemed to warrant such procedure, I put myself on record as follows: "In other words, I believe your action and the Society's position should be determined in every case on its merits, but giving the benefit of the doubt (if there be elements of doubt) to our accused fellow-member, be he great or small, be he accused of a great or small offense, and without undue deference to the rating of the interests arrayed against him."

I feel sure that the editor of the MEDICAL RECORD will realize that he acted hastily in assuming that the burden of *proof* is upon the accused. Even denial of charges so made would be elective rather than mandatory. And you seem to have overlooked the published *denial* of Dr. Volk's charge, which appeared in the *Brooklyn Daily Eagle*, Jan. 18, 1922, under a heading in large type, "Doctors Denounce Volk Attack—Deny Conspiracy Charge," the four signing the letter being "Drs. S. Dana Hubbard, E. Eliot Harris, and Alfred C. Prentice, and Arthur D. Greenfield, a lawyer." That published letter contained so much information along the lines apparenly demanded in your editorial, that it would be well worth while to give it in full to your readers, but I do not deem it my privilege to ask for space to include it in this communication. I do wish, however, to quote briefly from the *Congressional Record* of Jan. 24, 1922—over ten days prior to the date of the MEDICAL RERORD containing your editorial which called upon the persons named to disprove the charge made against them.

Representative Mills of New York, on the floor of the House, secured "unanimous consent to proceed out of order for five minutes," and, after stating Dr. Volk's charge, made the following statement: "On behalf of these gentlemen, I desire to deny categorically that any one of these men has any interest in any sanitarium, has benefited or could possibly benefit personally in any way through measures taken by the New York City Department of Health and by the Bureau of Internal Revenue. I desire, furthermore, to call the House's attention to an article which appeared in the *Brooklyn Daily Eagle* of Jan. 18, 1922, in which the gentleman from New York [Dr. Volk] admitted that he could not prove any connection between the gentlemen mentioned and sanitarium owners. I challenge the gentleman to produce proof to sustain the charges which he has publicly made, or, if he has not such proof, to withdraw the charges. The fact that the Constitution provides that no member may be questioned in any other place for a speech made on the floor of the House places on him a great responsibility. Surely it was never intended that that privilege should authorize a member of Congress to blacken the character and impugn the integrity and honor of his fellow citizens without

proof of any kind to sustain the charges, while denying to his victims adequate opportunity of refuting them."

I am well acquainted with at least two of the men named by Dr. Volk, and I am satisfied that they are absolutely innocent of selfish or sinister motives in connection with narcotic drug control in any and all of its relations. I shall patiently await their vindication—and I mean the vindication of all those named by Dr. Volk—but not necessarily by themselves and at their own expense. I should have expected the grand old MEDICAL RECORD to be on what I believe to be the right side, and hope yet to see it at least neutral and impartial. It should take heed lest it be deceived by the clever devices of what I have previously characterized in your columns as "the gentle art of propaganda, conveying an entirely erroneous impression to persons unfamiliar with the facts." "Judge not, that ye be not judged."

J. MILTON MABBOTT, M.D.

19 FIFTH AVENUE.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 25, 1922.

The Study of Psychology in Great Britain.—The study of psychology has been greatly neglected in this country, but the importance of the subject is becoming impressed upon the minds of the more far-seeing members of the British medical profession. Sir Frederick Mott, the well-known authority on diseases of the nervous system, is one of those who advocates, in and out of season, the teaching of psychology at the medical schools. He said not long ago that if his time were to come over again to deliver lectures on physiology to students that he would make psychology a part of the courses. Owing to his insistence and that of others who see alike with him, a diploma of psychological medicine is now granted in London. Under the auspices of the London County Council a series of lectures and practical courses of instruction are being given at the Maudsley Hospital in South East London. The fourth course by Sir Frederick Mott began on Jan. 3, last. This course consists of eight lectures on the anatomy of the nervous system and takes place on Tuesdays at 2.30 p. m. Beginning on Jan. 6 eight lectures on the physiology of the nervous system will be given by Dr. F. Golla. These lectures take place on Fridays at 2.30 p. m. Beginning on Jan. 5 eight lectures on psychology will be given by Dr. Henry Devine. These lectures take place on Thursdays at 2.30 p. m. During April, 1922, lectures and demonstrations will be given on the following subjects: (1) The diagnosis, prognosis, and treatment of mental diseases, (2) Mental defect and crime. (3) The practical aspect of mental deficiency. (4) Pathology of mental diseases, including brain syphilis, its symptomatology and treatment. (5) The symptomatology of mental diseases. (6) The psychoneuroses. (7) Demonstrations in neurology.

The Greenfield Medical Prize.—Prof. W. S. Greenfield, one of the greatest, if not the greatest, British pathologist, is to have his memory kept green by a memorial of a peculiarly fitting character. It has been announced recently that Mrs. Greenfield, on behalf of the family of her late husband, has decided to offer an annual prize to the junior members of the Pathological and Bacteriological Laboratory Assistants' Association as a memorial of Prof. Greenfield's long and distinguished association with pathological research and teaching. In so doing Mrs. Greenfield wishes to show her sympathy with, and appreciation of, the work of the Laboratory Assistants and the part they play in the development of the science of pathology. It is obvious that the work of this young association will be greatly helped forward by such a gift, and it appears that many former residents and assistants of Prof. Greenfield may welcome the opportunity to commemorate his memory and help to widen the scope of this scheme by offering also a prize to be competed for by senior members of the association, and by giving Greenfield Memorial Medals to the successful competitors. It is suggested that the prizes be awarded as follows: (1) The Junior Medal and Prize, by oral and practical examination of members of the Pathological and Bacteriological Laboratory Assistants' Association under 21 years of age. Any recent certificate in chemistry, physics, mathematics, or other subjects approved by the Examining Council, submitted along with the candidate's application, to be taken into consideration by the Examining Council. (2) The Senior Medal and Prize, for an account of, or essay on, some original investigation on a subject announced at least one year before the award is due. It is suggested that in both cases the prizes and medals should be awarded in one year for pathology, in the next year for bacteriology, and at longer intervals for museum technique. No Senior medallist shall be eligible to compete for a second medal, but winners of a Junior medal are eligible to compete for the Senior. The object of the prizes would be to enable the prizemen to travel in order that they might study the methods in use in other laboratories than their own, and to enable the winner of the Senior prize to travel abroad. While on the subject of the late Prof. Greenfield it may not be amiss and will be of some interest to American medical readers to give an account of the career of William Smith Greenfield, who at the time of his death, Aug. 23, 1919, was Emeritus Professor of Pathology and Clinical Medicine in the University of Edinburgh. Greenfield was one of the greatest of British pathologists and also possessed that rare gift of being able to impart his knowledge to students. His appointment to the Chair of Pathology in Edinburgh University came somewhat as a surprise. When Prof. W. R. Sanders died near the commencement of the winter session, 1880-81, it was generally thought that the late Dr. D. T. Hamilton, who during the months following the decease of Prof. Sanders took over the professional duties, would be given the position in his stead, but the curators chose the young and brilliant professor in the Brown Institution, London. Thus it came about that Scotland secured for the teaching of pathology both Greenfield and Hamilton, the latter being soon afterward elected to the professorship of that subject in Aberdeen University Medical

School. Greenfield held the post for 31 years, during which period it would be no hyperbole to say that the whole aspect of pathology was changed. Bacteriology progressed by leaps and bounds, so much so, indeed, that in 1912 a separate professorship had to be established to cope with the teaching of it. About this time the teaching of clinical medicine was separated from pathology, and the work that Greenfield carried on with so great zeal and energy for 31 years is at this time done by three professors. William Smith Greenfield was born in Salisbury in 1846, studied at University College and Hospital, London, obtained the diploma of M.R.C.S. Eng. in 1872 and graduated M.D., London, in 1874. He then became demonstrator of morbid anatomy and pathology in the medical school of St. Thomas's Hospital. He proved himself a great assimilator of knowledge and a peculiarly capable teacher and was one of the first to systematize practical instruction in pathological histology. After holding several other important posts, in 1878 he was appointed professor of pathology in the Brown Institution in succession to Burdon-Sanderson and, by his researches on anthrax and pyemia and septicemia, he was instrumental in assisting to lay firmly and well the foundations of bacteriology. The chief characteristics of Greenfield were his thoroughness and accuracy, and these qualities were conspicuous all the time that he labored in Edinburgh. He was a splendid teacher of clinical medicine and was a past master of the art of teaching clinical diagnosis by a mixture of banter, raillery, and seriousness. His remarks were often tinged with more than a little sarcasm. I have referred in a former letter to the teaching of the Edinburgh School of Pathologists and this teaching is well expressed in the work on pathology written by two of his most brilliant pupils, Drs. Beattie and Carnegie Dickson.

Fellowship of Medicine and Postgraduate Medical Association in London.—The arrangements for the special course in surgery, as already advertised to begin on Feb. 20, next, are nearing completion, and the full syllabus will be published shortly. The course will cover a period of six weeks, concluding on April 1, and the following general and special hospitals will take part: North East London Postgraduate Hospital, Cancer Hospital, Hampstead General Hospital, National Hospital for the Paralyzed and Epileptic, Queen's Hospital for Children, Royal Free Hospital, Royal National Orthopedic Hospital, St. Mark's Hospital, St. Peter's Hospital. The course will consist of a morning and afternoon session and will be so arranged as to involve a minimum amount of traveling each day.

1. The Baroness von Olnhausen. Alfred Worcester.
2. Recurrent Inguinal Hernia. Ralph W. French.
3. Fracture and Dislocation of the Cervical Vertebræ Without Paralysis. Report of a Case. Willis E. Hartshorn.

2. Recurrent Inguinal Hernia.—Ralph W. French records that in 300 inguinal hernia cases operated upon at the Truesdale Clinic in Fall River more than six months ago, he found there was a recurrence of five, or 1.7 per cent. The causes of recurrence of inguinal hernia may be summarized as follows: (1) Tension of the sutures; (2) impaired inervation; (3) infection; (4) failure to approximate the internal oblique and Poupart's ligament sufficiently low (5) leaving the internal ring too large; (6) failure to recognize a direct hernia during an operation for the indirect type. The essentials for an operation for recurrent hernia are the same as for the original hernia, that is removal of the sac which obliterates the tract and the restoration of the layers to approach the normal. All scars should be removed, the fascia laid bare of fat and mobilized, dissecting it sufficiently to allow adequate apposition for Poupart's ligament without tension. This same technique should be carried out in dealing with the lower border of the internal oblique. The sac should be isolated and removed completely. The nerves in the region of the inguinal canal, if found intact, should be preserved with care. Free use must be made of adjacent muscles and fascia to repair the deficient portions of the abdominal wall. Whenever it is possible French prefers the modification of the Bassini operation suggested by Andrews, which differs from it in that the upper segment of the flap of the external oblique aponeurosis is drawn down behind the spermatic cord while the lower flap is drawn up in front of it, the two flaps then lapping or imbricating; the cord is included between them. Occasionally it may be found advantageous to flex the thighs as suggested by Lyle, and to keep the thighs flexed during the first week of convalescence.

3. Fracture and Dislocation of the Cervical Vertebræ without Paralysis.—Willis E. Hartshorn reports this case which occurred in a soldier 20 years of age, who was hit by a locomotive while walking on a railroad track. The *x*-ray showed forward displacement of the atlas and forward displacement and fracture of the second and third cervival vertebræ. The fracture was semi-longitudinal, apparently through the arches of the vertebræ and also through the laminæ. The cervical region was swollen, painful and showed marked deformity. There was no paralysis. Advisability of forcible extension was considered, inasmuch as a number of cases have been reported in which reduction has been readily accomplished without accident, but was discarded as dangerous. Moderate traction was applied in order to secure proper splinting of the head and neck. Extension was carried over the bed. Moderate rigidity of the head and neck were secured by sand bags. On leaving bed a mechanical support was applied. Six months after discharge the patient reported for examination. He had no paralysis and no secondary neuralgias, but there was marked stiffness of the neck.

3. Calories for Children.—Francis G. Benedict describes the methods by which the nutritional requirements of infants and children have been estimated at the Nutrition Laboratory of the Carnegie Institute of Washington in Boston. The data collected has made it possible to compare age, weight, pulse rate, gaseous metabolism and heat production. It has been found

that heat production furnishes perhaps the best data for comparing metabolism under the different conditions, when asleep, awake, in repose and in activity. It has been shown that metabolism increases with activity, and there is increased heat production and, to a lesser degree, increased pulse rate. These increases are much more marked in infants and children than in adults. Data have been collected showing the metabolic requirements of children from birth to the age of twelve or thirteen years of age, and a great deal of data has been collected showing the caloric requirements of adults. There was a gap, however, for children from the age of puberty to about eighteen years of age, which Benedict has endeavored to fill by making observations of a series of girl scouts, so that the general trend of heat production may now be traced in girls from birth to the age of seventeen years. The striking points are that in very young girls there is an increase in the metabolism until a weight of about eight or ten kilograms or about the age of one year; thereafter there is a decrease in the heat production per unit of weight, rather rapid at first but slowly falling off after about thirty kilograms with a pretty regular decline. In the group of girls examined the same principle was found to hold as in the younger groups, that was the younger the girls and the lighter the weight the greater the heat production. The findings for boys of these ages has been essentially the same. Comparing the heat production per kilogram of body weight and per unit of surface area for children and adults brings out the striking fact of the greater intensity of heat production during youth. This explains the well-known enormous demands for food by active, growing children. Other things being equal, children must have large food intakes. It may be safely asserted that if digestive disturbances are avoided, it is impossible to overfeed the growing child with good, simple, nourishing food. Benedict points out the great danger in a situation which exists in Vienna to-day, where children are fed on the very narrowest margin, and insists that such rationing conditions are by no means ideal for the life and welfare of children.

5. The Connection Between the Short, Thick Neck and the Tendency to Apoplexy; with a Note on the Relation of the Brachial and Cerebral Blood Pressures.—Edgar F. Cyriax calls attention to the fact that, although it is quite generally admitted that a short, thick neck is frequently encountered in patients with a tendency to apoplexy, no one, so far as he knows, had attempted to classify these two into cause and effect. He considers it quite wrong to regard either in the light of a cause of the other, even though when the tendency to apoplexy is established they may react one on the other in a vicious circle. In his opinion, both are merely the local manifestations of one common cause; namely, persistent contraction of the cervical muscles. The ultimate result of this contraction is a dorsocervical lordosis, with a close proximity of the atlas and occipit with corresponding reduction in the atlantooccipital space. This results in persistent irritation of the cervical nerves that lie in or adjacent to the contracted muscles and chronic venous congestion of the neck. The result on the circulation may be varied: a large number of vasomotor changes may ensue, their exact nature and extent depending upon which set of nerves are stimulated. The fact that arteriosclerosis has commenced may further complicate matters by tending to increase the blood pressure still further in already elevated areas. Under normal conditions the blood pressure in the brachial artery is a perfectly reliable index to that of the cerebral. For some reason or other this has been considered to be true of pathological conditions. Recent investigations, however, have brought to light a fact which definitely proves that in a large number of pathological states the brachial pressure cannot be the same as the cerebral. It has been established that in unilateral conditions, whether in arm, trunk, leg, or head, whether from disease or trauma (and even in some middle line or bilaterally equal conditions) the blood pressure in the two arms varies considerably. Obviously the cerebral pressure cannot simultaneously correspond to different values. The possibility of there being considerable difference in the brachial and cerebral blood pressures may sometimes account for two sets of cases which are somewhat puzzling; namely (1) those in which a cerebral hemorrhage occurs with a practically normal brachial blood pressure, and (2) those in which no hemorrhage occurs in spite of greatly augmented brachial blood pressure.

14. Tumors of the Heart.—Hyman I. Goldstein reviews the literature on this subject and reports ten cases, seven of metastatic sarcoma, two of secondary carcinoma, and one of primary sarcoma of the heart. He concludes that tumors of the heart are not common. Primary tumors of the heart are rare, there being only 150 cases on record in the literature. Primary sarcoma of the heart is very rare, there being about 40 cases recorded. There are probably many cases of secondary sarcoma of the heart that are never reported in the literature. They are not comparatively much less common than secondary cancer of the heart. Myxomata, rhabdomyomata, and fibromata of the heart are met with occasionally. The correct diagnosis of cardiac tumor has never been made clinically. Electrocardiographic, fluoroscopic, and *x*-ray examinations may be valuable aids in making such examinations. All cases of cardiac tumor should be reported.

1. Bone and Joint Changes in Congenital Syphilis.—Leon H. Dembo, Harry R. Litchfield, and John A. Foote observe that the pathology of the bones in congenital syphilis has been less emphasized, though not of less common occurence and importance than rash, snuffles, rhagades, eye changes, hutchinsonian teeth and a visceral changes. Bone lesions present themselves in a variety of forms. Probably the most frequent of these are epiphysitis; osteitis; painless hydrops articuli; periostitis, including dactylitis, and changes in the skull, such as craniotabes, thickening of the parietal and frontal bones with softening, known as caries sicca. In the differential diagnosis of various syphilitic bone lesions a number of conditions must be considered. Acute epiphysitis (Parrot's pseudoparalysis) must be differentiated from (1) Erb's paralysis, (2) scurvy, and (3) acute poliomyelitis. The first condition appears shortly after birth and the palsy is characteristic. Scurvy occurs usually in later infancy, the feeding history is suggestive, tenderness and swelling are marked, there is bleeding from the gums, and the roentgen ray examination reveals a subperiosteal hemorrhage with the characteristic "white line." Regarding poliomyelitis, in an infant under six months, the age itself suggests a syphilitic process. Acute osteitis of the tibiæ with saber deformity is to be differentiated from a similar deformity due to rachitis. The former is a curve due to periosteal new formation and thickening of the bone, while the latter is a curving of the bone due to a deficiency of calcium and phosphorus. Rickets is rarely present in the bones during the first few months of life.

Syphilitic epiphysitis and osteitis are seen at an early age. The ribs are rarely affected in syphilis and commonly in rickets. Syphilitic bone enlargements have a tendency to involve the shaft by periosteal implication; rachitic enlargement is usually limited to the epiphyses, and there is seldom pain or tenderness except in acute cases. The periosteal thickening and tendency to involvement of the shaft aids in differentiating syphilitic from tuberculous bone lesions. In the latter there is usually surface ulceration of the bone, with localized thickening of the bone around the ulceration. Other conditions involving the bones which have to be differentiated from those of syphilis are infections and Still's disease. The writer's observation bear out those of other clinicians to the effect that in some cases of hereditary syphilis the Wassermann reaction may be absent, and rather emphasize the importance of the contributory evidence of syphilitic bone disease which may be furnished by the *x*-ray. They also bear out Hochsinger's observation that in practically every infant dying of syphilis gross bone lesions could be observed.

8. The Serum Prophylaxis of Measles.—Morley D. McNeal, in a short series of cases, presents convincing evidence of the efficacy of serum from patients convalescing from measles. Sixteen children exposed to measles received intramuscular injections of 5 c.c. of serum obtained from healthy donors between the fifth and ninth days after the disappearance of the fever. Twelve of the sixteen children injected remained free from measles, and four developed a mild form of the disease. One child contracted measles two months after successful injection; this suggests that the immunity does not persist longer than sixty days in some cases. The method recommends itself most highly for the prevention of measles during the period of danger, between the ages of five months and six years, in tuberculous children, and in those below normal. McNeal also recommends that the procedure be used in institutions in which large numbers of frail children are intimately associated.

9. Basal Metabolism and Ideal Weight and Pulse Ratios.—Anne Peterson and Will Walter make a preliminary report on more than 2,500 observations on about 1,200 subjects. This research was undertaken to determine the following points: (1) The reliability and possibility of errors in the technique employed. (2) Whether the assumed interrelation of weight and thyroid activity is warranted; *i.e.* to study the possibility of diagnosing thyroid dysfunction by the weight of the subjects before one. (3) To check up on the ratios of pulse rate and basal metabolism in order to find, if possible, what might be the probable diagnosis from the determined pulse rate of the subject. (4) Similar relations of blood and pulse pressure, which also seemed desirable. They have reached the general conclusions that the basal metabolism test is necessary for diagnosis and for therapy. Its determination by tried out portable apparatus is reliable. The test is best made at the bedside of the subject, and the portable apparatus makes feasible its use in the home when a proper technique is employed. The mass of evidence is against weight being influenced to any considerable degree by thyroid activity alone as evidenced by basal metabolism tests. Obviously, in some cases the thyroid is the hormone at fault; but the promiscuous employment of any thyroid therapy is dangerous, and had best be done under basal metabolism control. It seems fairly established that pulse rate and basal metabolism are closely associated generally. It seems evident from the observations as a whole that a pulse rate over 82 in men or 90 or over in women in a resting state is cause for suspicion of hyperthyroidism, and that a basal metabolism test is indicated for final judgment and is likely to show plus. Several observations have shown that when the pulse rate drops from a high normal in action to a normal or low "basal" rate, the basal metabolism is most likely to show normal or low.

10. Butyn, a New Synthetic Local Anesthetic.—Albert E. Bulson, Jr., presents this special report of the Committee on Local Anesthesia of the Section on Ophthalmology of the American Medical Association, in which the following conclusions are drawn: (1) Butyn is more powerful than cocaine, a smaller quantity being required. (2) It acts more rapidly than cocaine. (3) Its action is more prolonged than that of cocaine. (4) According to the experience of the members of the committee to date, butyn in the quantity required is less toxic than cocaine. (5) It has no drying effect on the tissues. (6) It produces no change in the size of the pupil. (7) It has no ischemic effect and therefore causes no shrinkage of tissues. (8) It can be boiled without impairing its anesthetic efficiency.

1. Some Obscure and Rare Pulmonary and Pleural Conditions.—Robert Hall mentions seven conditions as being the most interesting that he has experienced in the 35 years that he has been interested in the diagnosis and treatment of pulmonary conditions. The first two conditions are those simulating pneumothorax and only met in advanced phthisis. In the first of these the simulation of pneumothorax was due to the pleura being everywhere adherent, the upper lobe being excavated to the pleura, a valvular action of a damaged bronchus permitted air to enter but not to leave the cavity. The side became an air-sac which, preventing collapse of the ribs, gave the physical signs of pneumothorax. The second condition simulating pneumothorax was a ballooning of the lung. Hall has seen a number of these cases, and though the physical signs may justify the diagnosis of pneumothorax, they may all be transitory and clear up in 24 hours. A third condition is broncho-pleural fistula. As it is impossible to tell where the rupture may be situated, and as it is a question of relief, not cure, this class of patients may be made more comfortable by aspiration than by any other form of treatment. Occasionally a case of pleural effusion is encountered in which vocal fremitus is still present and a large bronchial breath sound can be heard all over the side. The pleural cavity must be full in these cases. In a case presenting this picture on the third day after aspiration there was a suspicion of air in the pleura, and on the fourth day a splash was quite distinctly heard. At autopsy at least four quarts of fluid flowed out of the right side. The lung was tested and no leak found. The question is raised whether it might have been that the inspiratory pressure of the air was greater than the resisting power of the lung and pleura, permitting the air to diffuse slowly into the pleural sac. A fifth condition is interlobar effusion, which it is important to keep in our mind's eye. The sixth condition is loculation of fluid or pus which is frequently very puzzling. Cases are cited which show how constitutional trouble may be caused by a very small quantity of pus or fluid under tension, and the value of using the aspirating needle, boldly, if necessary, when there is reason to think fluid exists. The last condition discussed is a type of acute congestion of the lungs which, in the writer's experience, is very rare. The chief symptoms are a sensation of tightness about the chest, temperature a little over 100, pulse about 100, breathing faster than normal but not hurried, a short cough, and uniform impairment of resonance, with râles over the whole lung from apices to bases. Possible causes of this condition are discussed and the conclusion reached that it is a primary acute congestion of the lungs, attacking without apparent cause, of short duration, and always fatal in two or three days. In four cases of this kind coming under the writer's observation secondary causes, such as edema of the lung, back pressure from cardiac disease, abnormality of kidney function, new growths, and inflammatory trouble in the lung, could be excluded.

5. Percussion and the Width of the Heart.—W. Gordon states that, in spite of the insistence of many able observers for many years on the value of digital per-

cussion in determining the width of the heart, supported by careful post-mortem verification, it has recently been suggested that percussion has no such value. It has also been stated, and even officially laid down in instructions to medical boards, that the size of the heart can be more exactly determined in the recumbent position than in the upright. As he regards the first statement as a grave retrogression in cardiology, the outcome of defective percussion, and the second as contrary to recently established fact, it has seemed to him important to devise some means of immediate verification or correction of our percussional estimates of the heart's width. The *x*-rays obviously lend themselves to this purpose. The cardiac limits of dullness to right and left are carefully ascertained and marked on the skin with a pencil. Over these marks short pieces of wire are placed and fastened to the surface with adhesive plaster. The chest is then screened and photographed. The results enable Gordon to say: (1) That in the erect position it is possible by percussion to define the rightward and leftward limits of the heart with sufficient accuracy to make this means of diagnosis at least as valuable as it has always been considered, and (2) that in the recumbent position no such accuracy can be obtained—indeed, no accuracy at all, since the results of perussion fall far short of the true width. The statements which the writer has repeatedly published on this subject are fully borne out by radiography. Certain precautions are necessary, however, in photographing such cases: (a) The patient must stand quite square to the plate; (b) the chest must not be allowed to press against the back of the screen; (c) in the case of women with much mammary tissue the attachment of the wire is difficult, and for purposes of investigation such patients have been avoided.

1. Specific Sensitiveness and Anaphylaxis.—H. H. Dale presents a theory which he believes explains specific idiosyncrasies such as hay fever, many cases of spasmodic asthma, and specific urticaria, and is the only one that brings the facts of clinical experience into coherent relation with those of laboratory experiment. The experimental basis of his conception must be sought in anaphylaxis, which is not to be regarded as a weakened resistance to a natural poison, but rather a condition produced by previous introduction into the system of a foreign protein, in which the same protein, but not any other, acts on subsequent injection as an acute poison, whether it has normally any poisonous properties or not. A satisfactory interpretation of the facts of immunity and anaphylaxis would be provided by the supposition that the antibody must get out of the blood and into the living cells of the tissues before it can render the animal sensitive. On this supposition the occurrence in the living cell protoplasm of an aggregation of its colloidal particles, of a reaction analogous to the precipitin reaction of an immune serum, as seen in the test tube, would constitute the poisonous action. The fact that an animal is violently and even lethally poisoned by a normally innocuous protein would be explained by the fact that an antibody, which in contact with that protein forms a precipitate, is located in the cells of vital organs. A characteristic of the anaphylactic reaction, in the guinea-pig especially, is stimulation of plain muscle. If the effect is due to antibody fixed in the cells, we ought to find that the plain muscle of an actively anaphylactic guinea-pig, removed from the body and freed from all blood, will respond by contraction to application of the protein to which the guinea-pig was sensitive, but not to any other. We ought to find that plain muscle from a guinea-pig rendered passively sensitive behaves in the same way, and that the same antibody as conferred the sensitiveness, if present in excess in the fluid surrounding the plain muscle, will protect it from the protein to which it has been made sensitive, so that it no longer responds. Another condition which we ought to be able to illustrate by such experiments is desensitization, which must be clearly differentiated from immunity. It is very simple to demonstrate all these phenomena on a slip of plain muscle taken from the guinea-pig after death. Dale traces the points of similarity in hay fever and asthma in man to the condition of artificial sensitiveness or experimental anaphylaxis in animals. Some of the differences, he believes, are due to the fact that we do not, by experimental procedures, succeed in producing such extreme sensitiveness as that which appears in certain human patients. Time alone will show what proportion of cases of hay fever, asthma, and urticaria will ultimately be referable to anaphylaxis. At present the tendency is for the proportion to increase, as investigators gain experience in the application of the specific tests, and have a growing range of animal and vegetable proteins available for use.

2. Diagnosis and Treatment of Intrathecal Tumors of the Spinal Cord.—William Thorburn considers certain aspects of this subject which, though familiar to the neurologist, are not so well known as they ought to be to the body of the profession. After considering certain features on the negative side of the diagnosis, he emphasizes the diagnostic importance of a history of *pain* long precedent to paraplegia, of varying intensity and associated with remissions, which may not be localized in the back but extend vaguely along one or more spinal segments. Such pains are almost invariably present as early symptoms of intrathecal tumors. The writer has traced back their history to as long as two years before any paraplegic symptoms were noted. They may or may not be associated with paraesthesia or with a certain amount of anesthesia. They may be bilateral or unilateral. They are generally described and treated as "rheumatic" or may be regarded as due to visceral disease, as in one case in which an eminent surgeon advised operation on the gall-bladder and the writer removed an intraspinal growth. In the localization of the level of the growth it is not sufficient to accept the upper limit of what may be called gross anesthesia. The line of limitation is often very ill defined and only careful and repeated examinations will enable one to find it. Symptoms closely simulating those of tumor of the cord may arise from excess of cerebrospinal fluid, thickening of the arachnoid, "matting of the nerve roots," and compression of the cord. In doubtful cases, which are not obviously hopeless, exploration is more liable to do good than harm should a diagnosis of intrathecal tumor prove incorrect. There is strong probability that many cases of transverse myelitis may be arrested and cured by incision and drainage of the dura mater—a possibility fully in accord with the view that such myelitis is often due to infection spreading along the spinal nerves and then necessarily crossing the meninges and the intradural space before the cord itself is attacked and irretrievably damaged.

Wiener klinische Wochenschrift.

December 22, 1921, xxxiv, 51.

Experimental Tar Cancer.—Lipschütz obtained positive results in 45 per cent. of his cases of mouse inoculation with coal-tar pencilled on the skin. Often the skin inflamed but necrosis was not seen. The period of latency was from 88 to 112 days. The initial manifestation was a small pin-head sized lesion which when followed up showed more than one form of behavior. In some cases a wart-like growth developed, in others a papilloma with both broad and pedunculated attachment, and these again showed differences of surface—as granular or fissured or with finger-like projections. The author succeeded in transplanting these formations into other animals, the period of taking being about 19 days. A tendency to form secondary nodules on the skin without inoculation was noted in some of the mice so that one could speak of "mother" and "daughter" nodules. It seemed immaterial whether these grew in the immediate neighborhood or at a considerable distance. The lesions were usually small and superficial.

Book Reviews.

Die Lungentuberkulose in Rontgenbilde. Von Dr. Max Cohn, Leitender Arzt der Röntgen-Abtheilung am städtischen Krankenhaus Moabit, Berlin. Leipzig: J. A. Barth, 1921.

This small brochure of 48 pages is No. 2 of the Tuberkulöse-Bibliothek, a series of volumes which are supplements to the *Zeitschrift für Tuberkulöse*. There are 10 text figures and three plates, which comprise 12 individual radiograms, a total of 22 illustrations. There is neither preface, table of contents or index. The text contains a brief introduction, a section on technics, sections on miliary tuberculosis, lung cavities, apical lesions, pleurisy, therapeutic pneumothorax, progress of the disease as shown by radiograms (including arrest and recovery) and, pulmonary tuberculosis in children. There is very full explanation of the plates.

La Función de los Cuerpos Amarillos By Armando F. Quinterro (Buenos Aires) Tesis de Doctorado en Medicina. Buenos Aires: Luis L. Gotelli, 1921.

This is a book of 190 pages from the pen of a graduate of chemistry, and professor of microbiology of the National University. The chief chapters are devoted respectively to histogenesis of the corpus luteum, physiology of the same, experimental proofs of internal secretion of the corpora, Fraenkel's theory, puberty and ovulation, menstruation, pregnancy, correlation of glands of internal secretion, biological chemistry, experimental action of extracts of the corpus luteum, isolation of its active principles, and protocols of the author's own investigations. He finds active principles extracted by chloroform which influence the growth and also determine congestion of the uterus and vagina, but which are without influence on the ovary or mammary gland and exert no constant action on the external genitals. There are also acetone-soluble substances which exert no action on the genital organs but have an influence over the adrenals. Both groups of active principles are vasodilators. These activities are exerted in intravenous and intraperitoneal exhibition, but apparently not otherwise.

Infektion und Immunität. Von Dr. M. Loewit, weil. o.ö. Professor der allgemeinen und experimentellen Pathologie an der Universität in Innsbruck. Nach dem Tode des Verfassers herausgegeben von Prof. Dr. Gustav Bayer. Price M.80. Berlin & Vienna: Urban & Schwarzenberg, 1921.

This work was completed by the author and was ready for publication in 1914 but its appearance was prevented by the outbreak of the war. During the war the author attempted to keep it up to date and at the time of his death in 1918 much of the manuscript was ready for the printer. The editor has added but little to the work as then written and it is almost wholly the production of Loewit. It was originally intended to be part of a work on general pathology. It consists of a satisfactory presentation of the subject of immunology as a whole but suffers in comparison with other modern works in that there is very little reference to the literature since 1914 and practically none to that of the last three years. It does contain the results of the author's own work in this field and to that extent bears the stamp of originality. As a whole however it may be classed as a fairly good text-book on the subject which is at least three years old at the time of its publication.

Pennsylvania Hospital Unit in the Great War. By Various Writers. Price $5. New York: Paul B. Hoeber, 1921.

This volume constitutes a complete record of the organization, preparations for departure, activities in France and return trip of the Pennsylvania Hospital Unit, which functioned in France as No. 16 General Hospital (Base Hospital No. 10) from 1916 until the signing of the Armistice. In all, the unit cared for about 50,000 sick and wounded soldiers. Attention is called to the fact that the Pennsylvania Hospital was the first hospital in Pennsylvania to be selected for a Base Hospital, and most justly so since it is the oldest hospital in America and cared for the sick and wounded in all wars in which the country has been involved. Among those who have contributed to telling the story of the unit are Colonel Richard H. Harte, who describes the organization and mobilization of the unit; Margaret A. Dunlop, who relates the story of the nursing corps of the unit; John H. Gibbon, Edward B. Hodge and John B. Flick, who describe the work of surgical teams in various British Casualty Clearing stations. Other contributors to the volume are Lieut. Co. William J. Taylor and J. Clifford Rosengarten. Fifteen hundred and five copies of this book have been printed from type and the type distributed. This record is one in which the Pennsylvania Hospital and the members of the unit may well take pride, and one that will be read with interest by all those connected with the medical and surgical activities of the war.

Veröffentlichungen der Robert Koch-Stiftung zur Bekämpfung der Tuberkulose; herausgegeben vom Vorstand der Stiftung; Band II, Hft. 3. Price, 48 Marks. Leipzig: Georg Thieme, 1921.

The first two articles in this issue are by Prof. Dr. Georg Lockemann and deal exclusively with the morphology and biology of the tubercle bacilli. He speaks of the influence of the various culture mediums on the growth of the tubercle bacilli and draws an interesting conclusion from his experiments. This is that the concentration of one culture medium did not influence the growth of the bacilli, but that, on the other hand, with the increase in quantity of the substance used as culture medium, whether concentrated or diluted, the growth of the bacilli augmented. Another interesting article in this issue is by Professors Jos. Koch and B. Möllers, on the method used in their experiments to determine the rapidity and direction of the tuberculous infection. When the bacilli were injected in the small intestines the tubercle bacilli were found after one hour and a quarter in the blood of 60 per cent., in the liver in 40 per cent., in the spleen in 50 per cent., and in the mesenteric glands in 80 per cent. On the other hand, when the injection of bacilli was made directly into the stomach, the infection was so relatively rare that it would seem that the gastric juice either kills the bacilli or at least impairs their virulence. Dr. Bruno Lange, an assistant at the Koch Institute, describes a number of acid-fast bacilli, non-tuberculous but closely related to Koch's tubercle bacillus. Dr. E. Rumpf describes his methods of finding the tubercle bacilli in the blood and maintains that their presence can be demonstrated not only in miliary tuberculosis but also now and then in ordinary types of pulmonary tuberculosis. Dr. Kurt Stromeyer discusses the treatment of various kinds of surgical tuberculosis by x-rays and arrives at the conclusion that although heliotherapy is certainly followed by the best results in surgical tuberculosis, it is by no means infallible and x-rays should be considered a valuable adjuvant. He further maintains that if patients could be cared for in the clinics of large cities for a long period of time and the home environments be improved to correspond with the comforts and hygienic and sanitary conditions as found in the sanatorium, the results of x-ray treatment in surgical tuberculosis would approach those obtained with heliotherapy in special health resorts.

Om Blödning Ved Placentas Lösning. et Klinisk Arbeide av Trygve Hesselberg. Kristiania: Steenske Boktrykkeri, 1921.

This volume of 180 pages consists of two parts, the first devoted to post partum hemorrhage due to detachment of the placenta and the second to premature detachment of the normally inserted placenta. The first is a phenomenon of the third stage of labor, while the second part does not touch upon placenta previa. The author gives tables of 63 cases of post partum hemorrhage due to placental detachment and in a special table of 42 cases of eclampsia shows the amount of blood lost which varied from 20 cm. to 1700 cm., the average being 300 cm. In a series of 1000 miscellaneous labors the loss of blood was less than 100 cm. in about a third and less than a pint in over 83 per cent. In 11.4 per cent. it was between a pint and a quart and in about 5 per cent. more than a quart. In the second part there is a series of 35 case histories of premature detachment of the normally situated placenta.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 23, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Symposium on Infection of the Gastrointestinal Tract in Relation to Systemic Disease. Medical Viewpoint with Special Reference to Classification of Cases. The Importance of Advanced Bacteriology and Biochemistry.—Dr. GEORGE REESE SATTERLEE read this paper, in which he asserted that there was no such thing as a "medical case" in gastrointestinal diseases. Every patient should be studied by the surgeon and internist conjointly. Most cases needed minor surgery of some sort, but few needed major abdominal operations. Infection played an important rôle in every case. In the past and still, unfortunately, in the present, many abdominal operations had been disappointing, due to the fact that focal infections in the teeth, tonsils, mouth, and elsewhere in the body had been overlooked, or to a disregard of the fact that the abdominal pathology might itself constitute a focal infection and require further investigation. Morphological defects in the gastrointestinal tract should be studied from the bacteriological standpoint. When the stomach or duodenum were involved, cultures from the contents removed through the duodenal tube, according to the fractional analysis method, were frequently of value, not alone for the diagnosis but for vaccine therapy. Cotton and Satterlee had noted the high bacterial content in gastric contents that were deficient in free hydrochloric acid and also the converse. After a course in autogenous vaccine or serum therapy, the gastric contents had in many cases returned to normal. The medical treatment of chronic intestinal toxemia consisted of diet, massage, hydrotherapy, and vaccine or serum. The diet consisted of animal protein-free food, principally vegetables, fruit and cereals. The diet at first was very strict, no eggs and little milk being allowed. Bran was an essential article, one to two ounces being given daily. Where the food was dry and hard agar was given in the food, a liberal diet was permitted and encouraged, but it was often wiser to underfeed rather than overfeed. All laxatives and cathartics were forbidden. Castor oil, enemata, and colon irrigations were only given when specially indicated. Colon massage was of great value. Its use should be systematic. Hydrotherapy in the shape of eliminating cabinet baths followed by Scott's douche helped the physical welfare of the patient. Electro- and mechanotherapy were also of great value. It must be constantly borne in mind that the constipation in most of these cases was of toxic origin, probably protective, and it was probably for that reason that laxatives and cathartics were harmful. It was with this idea in mind that they had practiced vaccine and serotherapy. The routine procedure for the colon vaccines was to obtain the stool after a purgative dose of castor oil. The third stool was preferable. These vaccines were given every four days in doses of from 100,000,000 to 300,000,000, depending upon the general reactions. For the serum they were using they were indebted to Dr. Cotton's researches. It was obtained from a horse that had been immunized by the various strains of streptococci and colon bacilli obtained from cultures from infected foci in the patients at the New Jersey State Hospital. His own results with this serum had been very gratifying in the few cases in which it had been given. Of other therapeutic agents generally employed there was little to recommend. Their clinical experience seemed quite in sympathy with Rosenow's theory of the selective action of bacteria, so much so that they used it as a working premise. This lead followed directly into a most important field, that of *preventive surgery of the mouth.* The removal of obvious foci, provided the remainder of the digestive tract was free from focal infection or permanent changes, would frequently clear up the intestinal symptoms and restore, without further intervention, the physical and mental equilibrium. From a study of over 1000 chronic intestinal invalids, medically treated, and of over 200 similar patients in whom a portion or all of the colon had been removed, they had come to the belief that many of these advanced cases with infected colons would not recover until the diseased portion of the organ was removed together with every other local focus. Medical treatment with vaccines and sera was needed in every case. After discussing the routes by which gastrointestinal infection might take place, Dr. Satterlee said it had become his belief, based on a prolonged study of chronic intestinal toxemia, that the colon bacillus, perhaps the pathogenic forms only, was the primary cause of the lowered resistance found in these cases and that other types of bacteria, notably the streptococci, were secondary infections. This view was based on the study of over 500 cases of chronic intestinal toxemia treated by autogenous colon vaccines obtained from stools after catharsis. A suitable case, one with symptoms and signs of a chronically diseased cecocolon, would invariably improve after the administration of autogenous colon vaccines, and also, as they had discovered lately, of an anticolon and anti-streptococcus serum, prepared under the direction of Dr. Cotton. These principles were applicable to other diseased conditions as, for example, in syphilis, Cotton had observed chronic cases that could not be improved until the obvious foci of bacterial infection were removed. One of the most puzzling aspects of gastrointestinal infection was that it might produce the most profound mental or nervous disturbances with little or no direct gastrointestinal pathology. The writer had called attention to this fact in 1917. Careful neurological study of these patients would reveal no etiological factor until a complete study of the gastrointestinal tract was carried out and a thorough search for foci in other parts of the body had been made. Eradication of the diseased areas had brought about a return to normal or a great improvement, provided deterioration had not progressed too far. The organisms noted in 80 cases where dental extraction and bone operations were performed were tabulated. It was thus shown that the most frequent streptococcic organisms recovered were the *Streptococcus mitis* and *salivarius* of non-hemolytic type. Next in frequency were the *Streptococcus angiosus* and *pyogenes* of hemolytic type. *Streptococcus subacidus* and *equi* had not as yet been found in their cases. Cultures from the antra, directly on opening through the mouth, corresponded quite closely to the cultures from teeth and bone.

Neurological Viewpoint with Special Reference to the Relation of Clinical Symptoms to the Regional Distribution of Focal Infections.—Dr. HENRY A. COTTON of Newark, N. J., presented this contribution, in which he stated that in presenting a psychiatrist's viewpoint of the relation of focal infections to systemic disorders before an audience of general practitioners, one must at the outset disabuse the mind of the physician of the time-worn theories regarding the psychoses. One of the most prevalent errors as to the causation of psychoses was that of heredity. This fact arose from the rather loose way in which records of heredity were gathered in the old state hospital statistics. Any patient in whom there was "insanity in the family" was noted as suffering from hereditary taint. This occurred in sufficient numbers to substantiate the opinion that the psychoses were hereditary in origin. It was needless to go into the various arguments from a biological standpoint to show that this theory was erroneous. Not only were we in serious error regarding heredity, but such a doctrine was extremely fatalistic, for if a patient was born with the potential elements of mental disorder, then there was little use in trying to prevent the psychosis, or to successfully arrest it if it had appeared. The result of five years' intensive study of the hereditary factors in the psychoses led the writer to the belief that while we might not eliminate the hereditary taint entirely, at the same time it should not be given the exalted position it had previously held. As it had no bearing on the prognosis of a given case he believed that discussion at present was merely academic. Another error was with reference to psychogenic factors. For many years the psychiatrists, in common with the profession at large, voiced the opinion that the psychoses were purely mental disorders caused entirely by hereditary insta-

bility, plus psychogenic or mental factors. The physical condition of the patient was absolutely neglected. This gave rise to the fundamental error in that they assumed the psychoses to be diseases of the mind caused by mental factors almost exclusively. With an improvement in the methods of studying brain tissue and the results of their work of the last four years, they had slowly arrived at the conclusion that the so-called functional psychoses were in reality caused primarily by disease of the brain and not of the mind, and that the mental disorders were merely symptoms of a diseased brain. This did not mean that they minimized the part played by such psychogenic factors as grief, worry, anxiety, shock, and a host of others that undoubtedly played an important rôle in precipitating the psychosis. Their investigations in the last four years had shown conclusively that the psychotic individual harbored multiple foci of infection which often could be located and eliminated only with the greatest difficulty and persistence on the part of the physician. In order to properly locate and eliminate these multiple foci of infection the psychiatrist had had to call to his assistance the specialist in other branches of medicine so that to-day a well-equipped clinic for nervous and mental disorders was only adequate in so far as this principle was carried out. The so-called functional psychoses they believed to-day to be due to a combination of many factors, but the most constant one was the intracerebral, biochemical, cellular disturbance arising from circulatory toxins originating in chronic focal infection situated anywhere throughout the body and probably secondary to disturbance of the endocrine system. The psychosis then, instead of being considered a disease entity, should be considered as a symptom and often a terminal symptom of a long-continued masked infection, the toxin of which acted directly on the brain. If the profession at large could accept this viewpoint, which he and his coworkers felt had been demonstrated beyond a reasonable doubt, then their attitude would be changed from the hopeless fatalistic one, previously in vogue, to a hopeful one wherein they themselves could not only arrest many cases after a psychosis had developed but, better still, might prevent their development by elimination of chronic foci of infection. They had found that the source and type of chronic infection in the psychotic patient was the same found in many of the systemic disorders. They were of the opinion that the methods adopted by them were extremely valuable in ridding the patient of multiple foci of infection until better methods were devised. They had come to regard infection of the teeth as the most constant focus found in their patients. Without exception the functional psychotics all had infected teeth. While the progressive men and leaders of the dental profession were awake to the various types of infection to be found in and about the teeth, unfortunately the rank and file were not sufficiently acquainted with these many forms, consequently the physician who attempted to rid his patient of focal infection must become acquainted with modern dental pathology. In their younger patients, from 16 to 20 years of age, no matter what the psychosis that might be diagnosed, they found unerupted and impacted third molars in a large proportion of the cases, and they would unhesitatingly advise, when there were clinical evidences of systemic infection and intoxication present, that these should be removed. They had found these teeth always infected and the infection was in some way related to the fact that the tooth was unerupted and impacted. All crowns and fixed bridge work had been condemned by the best men in the dental profession, and they voiced the same opinion. In order to rid a patient of focal infection a very thorough job must be done and no suspicious tooth allowed to remain; this did not mean that every patient should have all his or her teeth extracted. The removal of foci of infection in the tonsils was equally important. It was a striking fact that very rarely was a patient admitted to the State Hospital at Trenton whose tonsils had been previously removed, so that over 90 per cent. of the patients had to have their tonsils enucleated after admission. Whatever might be the effect of treating infected tonsils with the *x*-ray or local therapy they felt that to-day enucleation was the only method permissible. From the fact that the elimination of infected teeth and tonsils produced marvellous results in some cases and in others no results whatever, it was logical to conclude that the infection had spread to other parts of the body, through either the lymphatic circulation or the blood stream, and probably by the former. Secondary infection of the stomach and lower intestinal tract could also come from constantly swallowing the bacteria originating in the mouth. The genitourinary tract was frequently infected, not only by organisms of the streptococcic group, but by those of the colon group as well. In the females they had found that at least 80 per cent. had a chronic infection of the cervix uteri, and rarely the body of the uterus, but more frequently the adnexa were involved. In the males a certain percentage of the acute psychoses had an infection of the seminal vesicles. The prostate and bladder, as a rule, were not involved. Speaking of the results of their work, Dr. Cotton stated that in the so-called functional group which included dementia præcox, manic depressive insanity, paranoid conditions, and psychoneuroses, for a ten-year period prior to 1918 the recovery rate was only 37 per cent. of the admissions. Since 1918, when the methods described had been put into effect, the recovery rate had averaged 70 per cent. in the same group. In 380 cases classified in this group in 1918 only 50 to-day remained in the hospital and nine of these were criminals. A recent survey of these 380 patients discharged since 1918 showed that after three years, with few exceptions, they were today normal in every respect. Over 1,000 patients had been successfully treated during the past three years, and the proportion of readmissions had not increased during this time. Their failures had been confined to patients with a psychosis of over two years duration. The cause of such failure they considered to be due to the fact that the brain had become permanently damaged and no amount of elimination of infection had any effect on such an individual. In concluding, Dr. Cotton said they had produced evidence, both clinical and pathological, which would set at rest any doubt as to the accuracy of their deductions. The fact that many individuals harbored infections and were not insane was no argument against the doctrine that focal infections could cause insanity. We knew that only a small proportion of patients contracting syphilis developed paresis; only a small percentage of those indulging in alcohol excessively developed a psychosis. One might argue similarly regarding a functional psychosis. The type, specificity, and severity of the infection, plus the patient's constitutional lack of resistance, determined whether or not psychosis would develop.

Surgical Viewpoints—Colectomy—Indications: Technique: (Lantern Slides)—Pathology, Mortality.—Dr. JOHN W. DRAPER discussed this phase of the subject. He stated that from the standpoint of infection of the gastrointestinal tract, that portion of greatest interest in surgical research was necessarily the colon. This terminal portion of the bowel was of much less vital need to the organism than the central portion, was frequently diseased, and could be dispensed with, entirely or in part, alike in human beings and in the lower vertebrates. There was a similarity between the stomach and the colon, particularly as regards their functions, those of storage and motility far outweighing in importance all others. After removal of the stomach in the lower vertebrates and in man it had been found that all its subsidiary functions, as well, apparently, as the two major ones just named, were taken on vicariously by other portions of the tract or indeed largely abrogated. The same was true of the colon. Between the stomach and colon lay the small bowel, a relatively short portion of which was essential for life. Save for the correction of small minor conditions this portion of the alimentary canal was inviolate for surgical intervention. This portion of the alimentary canal was notably free from cancer and infection, while both ends were the frequent seat of malignancy and of bacterial invasion as well. Was it not probable that the law of use and disuse was as applicable to the alimentary canal as elsewhere in Nature, and that we might properly seek an explanation of the well-known clinical fact that the colon and stomach were more liable to degenerative changes than the rest of the alimentary canal. Closely coupled with this was the

universally admitted effect of gravity upon the development of colon pathology. In spite of much recently acquired information regarding the colon, notably the fact that even its entire removal was compatible with health, growth, and development of the individual, its vital function being apparently nil, it could not be too strongly urged that the indications for its removal, either partial or complete, were rarely to be met with, most cases responding promptly to modern medical treatment. However, definite indications for total or partial colectomy were occasionally demonstrable, as was shown by the increasing literature on this very important subject. The subject of colon pathology, particularly in its relation to systemic disease, was at present little understood. This problem was beset with the greatest difficulties from the bacteriological standpoint, and although much was known about the occurrence of colon lesions in individual cases, no proof was as yet available that any particular group of symptoms could certainly be attributed to a given colon pathology. For this reason the record herewith presented of colon pathology found among 150 toxic psychotic patients at the State Hospital at Trenton was of the utmost importance. Before considering a partial or total colectomy in any given instance, it was evident that the indications, historical, physical, and *x*-ray, must be particularly well defined. There must be a long-continued history of chronic intestinal invalidism, with its usual, but not invariable, evidence of chronic appendicitis early in life; with "bilious attacks" and "belly aches"; often with oral infections later on; with the occurrence of right-sided abdominal rigidity and often with tenderness, pain, and superficial hyperesthesia; always with a colonic delay, defined and localized by *x*-ray study. Even in the presence of such findings, such intervention, in the writer's opinion, was not indicated except the also well-defined and serious subjective symptoms. It was now six years since, under the above conditions, their earliest cases were operated upon, and the continued study of these patients not only strengthened their belief in the very important relation of colonic infections to general health, but also afforded interesting ground for belief that in many cases there were personality changes associated with chronic intestinal invalidism, which ultimately became fixed in character, constituting definite toxic psychoses. Every practitioner was familiar with the mental depression which accompanied such invalidism. Mutation from a simple depression to a definite psychosis certainly occurred with sufficient frequency to interest the general practitioner, and to add to his already great burdens that of early physical diagnosis as an aid to preventive psychiatry. Finally, they felt that no patient should be subjected to a colectomy for chronic intestinal toxemia, except upon the collective decision of a medical group, it being, in spite of mortality, a far too serious operation to be decided upon by one physician alone. In the series presented the evidence for operation was based upon ample physical lesions augmented by the presence of a psychosis. The technique employed at the State Hospital at Trenton, for total or partial colectomy, was the direct outcome of the writer's experimental work in intestinal obstruction upon the lower vertebrates, so that for technique as well as for interpretation, the present research was primarily indebted to the laboratory. In 1919, 84 cases were operated upon with 13 deaths, a mortality of 40 per cent. In 1920, 59 cases were operated upon with 18 deaths, a mortality of 30 per cent. In 1921, 77 cases were operated upon, with 10 deaths, a mortality of 12 per cent. In all there was a total of 170 cases with a mortality of 24 per cent. The decrease in the mortality was due to operating on earlier less degenerated cases, and to the employment of serum before and after operation. Dr. Draper exhibited a number of lantern slides illustrating the pathology found in the colon in this series of cases, a number of which showed definite foci of infection in the colon.

The Application of Results Already Obtained at the State Hospital, Trenton, in Relation to the Conduct of Other State Institutions.—BURDETT G. LEWIS, Esq., State Commissioner of Institutions and Agencies for New Jersey, spoke on this topic. He said, in part, that it was naturally very gratifying for him to note the success in New Jersey of work he had undertaken in New York but which for want of time he was unable to carry through to completion. While Commissioner of Correction in the city of New York, he undertook to transplant to the old correctional institutions of the city and to the two new reformatories many of the routines and practices of the best hospitals for the insane. He discovered that many men and women in prison or in the reformatory were either insane or unstable, or were epileptics or feeble-minded, or were not able properly to conduct themselves as normal human beings. He also discovered that the disciplinary difficulties of correctional institutions were almost entirely due to the presence of persons belonging to these various groups who had been sentenced to prison or to a reformatory. By inquiry among the best hospitals for the insane and the best institutions for the treatment of the unstable, the epileptic and the feeble-minded, he found that the disciplinary difficulties of such institutions had not been solved by the club and the gun and by invoking horrible imprecations and profanity, but by the intelligent application of modern therapy and modern treatment, with which physicians had now become quite familiar. The organization of the New Jersey department was such that work which was difficult in New York, where the departments were under separate jurisdiction, was very simple in New Jersey, where all of the institutions were in a single department. This had made the transplantation of the best practices of the particular institution to all other institutions a much simpler problem. For example, for the conduct of the mental and medical work in the correctional institutions, he had organized a psychiatric clinic and placed the doctors and psychologists under the general supervision of Dr. Cotton, who held the position, not only of Medical Director of the State Hospital at Trenton, but also of Acting Director of the Division of Medicine and Psychiatry of the Central Department. This plan had hastened the application of the best tested results of the State Hospital to all the correctional institutions. Cases were discovered in the correctional institutions which were in need of treatment at the hospital, and under the New Jersey law they were transferred to the psychopathic division of the hospital long before they had become insane from the legal viewpoint. The methods of treatment carried out at the Trenton Hospital had shown the desirability of extending the benefits of such medical, surgical, and other treatment to all the population of each correctional institution. In consequence, the medical service and the appropriations for medical service had been more than trebled in all the institutions. The expense, however, had been reduced, by reason of the fact that the psychiatric clinic cut down the cost of overhead supervision of physicians and by reason of the fact that the increase in the amount of medical work in each institution had stimulated cooperation with the physicians of the various communities in which the various institutions were situated. The amount of voluntary work performed by the physician had been more than quadrupled in the past three years. They were therefore deeply indebted to the physicians in practice throughout the State for many of their good results. For instance, in the State Home for Boys, an institution for juvenile offenders, three and a half years ago, one out of each two boys released from that institution on parole failed; since the introduction of the new methods only one out of each ten failed. The development of research work at Trenton had stimulated similar work in other institutions and had won for such institutions legislative appropriations for treatment instead of mere custody of patients. Morris Plains State Hospital, for example, had under course of construction a 400 bed treatment hospital which would permit the carrying out of the very best types of medical treatment at that institution. They were attempting to extend to the people of their various communities the results of these achievements in the institutions, through the establishment of clinics. Without going into detail it would suffice to say that their physicians in their State institutions were to secure the advantages of handling the new cases in the communities long before they would ever reach a State hospital. On the other hand, the patients in the State institutions were to reap the benefit of the enthusiasm of doctors whose efforts were stimulated by contact with mental dis-

ease in the earlier stages of its development. In closing Mr. Lewis acknowledged their indebtedness to men like Dr. John W. Draper, who had so freely given up his time and his expert abilities in the promotion of their work, at no small sacrifice of time and strength. New Jersey was indeed fortunate in securing their help and was proud of the results achieved.

Dr. JAMES EWING stated that he had examined sixteen specimens of colon and ileum removed by Dr. Draper at operation. The great majority of the specimens showed very definite gross anatomical lesions which had resulted from chronic intestinal stasis and the ensuing catarrhal inflammation. In several cases the lesions were extremely marked, in many they were well marked, while in a few there were no definite changes that could be regarded as more than minimal variations from the normal. The most marked and constant lesion was pigmentation of the mucosa which rendered the inner lining brownish or at times dark chocolate in color. This change was most marked in the cecum, diminishing toward the sigmoid but often present throughout the section. Sections showed the pigment to be lodged in large polyhedral cells lying in the mucosa and at times in the epithelium. Pigmentation of the colon was fully recognized as a sign of chronic intestinal stasis and intoxication. It was sometimes associated with anemia and at times with severe and even fatal dystrophies of nervous and muscular systems. Pouching of the intestinal wall amounting almost to hernial protrusions was observed in most of the cases. These pouches were from one to two centimeters in depth. The wall of the pouches was generally thin, sometimes very much thinned, and the mucosa at the bottom was generally eroded, sometimes ulcerated. Through such erosions and ulcerations it was obvious that absorption of fluids and bacteria readily occurred. The usual contents of these pouches must have been fecal matter, and it appeared that such material must have been practically incarcerated and seldom emptied. About the lower end of the cecum the pouches were especially numerous and deep, and access to them was tortuous, especially when external adhesions held the wall of the colon fixed. The outer surface of the colon over the pigmented, and especially over the pouch district, was generally the seat of a chronic productive inflammation with the formation of very numerous small granules of vascular connective or denser fibrous connective tissue. This granular appearance was doubtless exaggerated by hardening in formalin. The loose serous coverings of the colon generally appeared as thin membranes extending from the gut over the mesentery. These coverings often showed diffuse opacities from thickened, abnormal bands and striæ, and occasionally definite cicatricial contractions. To what extent these changes were due to the conditions inside the gut it was difficult to say, but probably they were largely caused by the mucous membrane lesions. The lymph nodes in the mesentery accompanying the specimens were not as a rule enlarged, and often they were small and difficult to find. Sections of the nodes showed no inflammatory reactions of definite importance. It was noted that the lymph follicles were generally invisible in the colon, and were reduced to a trace in the sections. Well formed recognizable Peyer's patches were not found in any case. There was therefore a general atrophy of the lymphoid apparatus inside and outside of the gut. That bacteria were found by culture in the lymph nodes of the mesentery could have been confidently predicted on the lesions of the mucosa and the lymphoid atrophy. In general, the impression gained from the study of these specimens was that the clinicians were dealing with extensive and somewhat unusual grades of chronic intestinal stasis and catarrhl inflammation with its sequels. In a few cases the conditions were such as to be practically irremediable except by mechanical straightening of the intestinal lumen. Whether or not extirpation of the cecum was the most direct method of accomplishing this object was a matter of surgical judgment. In perhaps the majority of the cases, and certainly in some, the conditions were not so advanced that emptying of the colon was impossible by lavage or frequent catharsis. Here again the choice of methods was to be regarded as a matter of clinical judgment. As for the specimens of ileum submitted, they failed to show any lesions that would necessarily call for extirpation. The indications for this procedure had to rest entirely on clinical grounds. The isolation of various bacteria from the mesenteric lymph nodes did not appear to have particular significance, since bacteria passed the relatively intact intestinal wall under a great variety of pathological conditions, many of which had no connection with the clinical state of these patients. More important was the demonstration of hernias, pouching, thinning of wall, pigmentation, and ulceration of mucosa, which together formed an impressive anatomical basis for the theory of intestinal intoxication, which undoubtedly existed in severe degree in the cases exhibiting such lesions. Finally, Dr. Ewing said he would venture to express his personal opinion that extirpation of the affected portions of the cecum and colon was justifiable and probably the only effective means of relieving the condition found in the advanced cases, while in others with slight changes the condition could have been met by less radical means. The extirpation of considerable portions of the ileum seemed to him unwarranted if based solely on the anatomical condition of this organ.

Dr. OSCAR H. ROGERS, Chief Medical Director of the New York Life Insurance Company, stated that he had been very deeply interested in the papers which had just been read and believed that the work therein described opened up a field of medicine now too little cultivated. His own professional life had been spent almost entirely in life insurance medicine, in which the mortality rates among insured lives at various ages were matters of the greatest interest, and he had observed during the last 25 years a steadily improving mortality rate at the earlier ages. For example, at the present time the mortality rate at the age of 25 years was 40 per cent. lower than it was 25 years ago. Unfortunately, this striking improvement in mortality was not found at the later ages of life. Indeed, at the age of 55 there had been no improvement at all. It was his opinion that the improvement in the mortality rate at the earlier ages had been due to man's increased control over infectious diseases. This mastery of disease was less and less marked at the later ages and disappeared altogether before the age of 55. He was hoping that the science of medicine, possibly along the lines indicated in the papers of the evening, would presently master those infections that were still causing a high mortality at the older ages. He had come to the meeting with a feeling of skepticism, but was prepared to admit that some portion of that feeling had been resolved by the papers that had just been read. Some things he had heard, however, ran counter to his own prepossessions. One speaker, as he understood him, looked upon constipation as due to the fact that the human animal had assumed, in the course of his evolution, an upright position. Another speaker had referred to it as caused by toxemia. He was willing to accept the theory that the upright position had some effect in producing constipation, but that dental infection, or any other infection, was a clear-cut causative factor he had grave doubts. It seemed to him as if such a doctrine was putting the cart before the horse. He believed, on the contrary, that constipation was very much more often the cause of a toxemia than the effect of it; that the lowered vitality caused by constipation rendered possible the incursion of bacteria in other parts of the body. It must be remembered, he stated, that man was a "house-broken" animal; that from his infancy up the natural impulse to bowel movements was under restraint; that the restraint of clothing, of school, of play and of having to postpone bowel movements for a more convenient time and place, all tended to educate against natural impulse, until presently a daily bowel movement was looked upon as an expression of health, rather than, as it should be, an expression of disease. A single bowel movement a day was not adequate. Among animals in a state of nature, such restraint almost never occurred. We heard a great deal of the splendid work of the surgeons in various operations on the alimentary tract, but we heard too little of the teaching by medical men of proper care of the functions of the alimentary canal, so that the work of the surgeon should be rendered unnecessary. Almost every appendicitis, every gall-bladder infection, was a protest against this neglect of the

bowel function. Only recently he asked his own son, a graduate of a medical school in this city, what they were teaching in his school on the treatment of constipation. He put the same question to a young friend, who had recently graduated from Harvard Medical School. Both stated that these schools were teaching very little. Dr. Rogers stated that he would like to file an indictment against medical schools that taught "very little" on so important a subject, that did not emphasize the fundamental importance of correct bowel hygiene, but left to laxative drugs to complete the mischief which the restraints of civilization imposed. He felt that the proper care of the intestinal tract, if ever it could be widely taught, and the knowledge of it brought home to the people, would very largely do away with the high mortalities of the later years of life. Dental infection and other focal infections were important enough, and he was glad to see them emphasized, but he wished that men who were in a position to speak with real authority would give more attention to those infections which were caused by delayed bowel action alone.

Dr. Fenton B. Turck quoted from a report from the Woman's Hospital in which Dr. Ward had said that scientific research was very important. He would say that it was all important and that no positive knowledge was obtained except by scientific research. But no one by scientific research had found a single poison from bacteria in the gastrointestinal tract, in the respiratory diseases, or in the nervous diseases. This statement was confirmed by Davis and Rosenthal (America), who had shown that the intestinal flora were without any etiological importance. Blunderhorn admitted some intoxication, but held that it was not of bacterial origin. Gordon, working on respiratory diseases under the direction of the Metropolitan Life Insurance Company, came to the same conclusion. Helmholtz, Gobert (America), Sztark (France), and Balaffo of Italy had recently shown that cellular catabolism was the sole origin of the intoxication. Elis Lorengreen (Finland) had demonstrated that both acute and chronic disorders were due to constitutional factors. Dr. Turck referred to his work which explained what this constitutional factor meant. For the past twenty-five years he had been showing that whenever there was a lowered natural immunity the cellular catabolism that normally occurred might cause disease either of the alimentary tract, or of the respiratory tract, or of the nervous mechanism.

Cellular catabolism was seen in its classical form in tissue injuries such as wounds—and biologists and clinicians argued that traumatic shock was due to disintegration of the tissue. The poison thus formed affected the entire organism. The degree of shock and the variations depended on the degree of natural immunity. Every variety of disease occurred in chronic disorders resulting from tissue breakdown. Dr. Turck stated that he had extracted the tissue poison from the tissues and with it produced diseases of the alimentary and respiratory tracts and of the nervous system as well. He had also produced the tissue antitoxin, and used it in the prevention and cure of these diseases in both animal experimentation and clinical work with most satisfactory results. The active agent from ash produced what he had termed cytost, which excited cell division and metabolism in biological concentration, and he had produced an antitoxin, anticytost, also an ash. Furthermore, with this cytost he had succeeded in producing both active and passive immunity. The methods of colon lavage, of heat stimulation of the splanchnic area, etc., of producing elimination increased natural immunity, and then the employment of vaccine and foreign protein had been shown both experimentally and clinically to be of considerable value, and he was glad to see that this work so far as it went confirmed his own, though he had gone still further, and was now producing specific active and passive immunity to these toxins.

Dr. Anthony Bassler said, taking his cue from Dr. Turck's remarks, that because one could not feel the sun therefore the sun did not exist. We all knew that the entire world depended upon the sun for its existence, though the only means we had for substantiating the existence of the sun was indirect and because of its rays. The probabilities were the time was far distant when we would be able to isolate intestinal toxins in the blood. Dr. Bassler said he wanted to congratulate Dr. Cotton and his coworkers because they had entered into a field which was endless; they had plenty to study as long as they lived. The subject was too big for the Mayo Clinic. They recognized that the intestinal tract might be a most important focus of infection in the body, but even with their material their investigators and their methods of control they had not had the courage to go into this work. Dr. Bassler asked why it was that since there were definitely seven different forms of bacterial invasion one diet and one vaccine served for all. In some a vegetable diet was distinctly contraindicated and in some forms only a high protein diet was efficient. He believed with Dr. Cotton that the gut condition was the primary factor in many endocrine imbalances. He did not understand his remark, namely, that when the focal infection in psychotic individuals had existed over two years the prospect of benefit was not good. These were neurological cases that proverbially gave no gastrointestinal symptoms, though they had infected teeth, or infected tonsils or infected gallbladder. How could one say in these mental disorders that the focal infection had existed for any length of time with any fair degree of accuracy? Dr. Bassler said he did not believe the time would ever come when specificity of organisms would be understood in any etiological connection. He thought it a waste of time and money to go into that study in this connection. There were so many factors influencing the conditions under which one lived that were bound up with the question of intestinal infections and to these must be added the chemistry and motility of the intestinal canal and symbioses of different organisms; a flora of the intestinal canal might change inside of twenty-four hours. If one planned a special diet in a month's time the individual was often as toxic as ever because the organisms in the gut had become facultative. The question, Dr. Bassler said, was a big one and he felt that they had a much greater job yet to do.

Dr. Cotton, in closing, said Dr. Bassler had misunderstood him. He had not said that the focal infections were of two years' duration, but that the psychoses were of two year's duration. The focal infections were undoubtedly of many years' duration. In many cases chronic infections had been producing systemic symptoms for ten or fifteen years. As to diet and the changing of the flora of the intestinal canal, Dr. Bassler had answered that question. We had known for years that mental cases had been subject to gastrointestinal trouble. Diet, massage, etc., had been employed, and in special cases now and then good results were obtained, but not in the mass until they were able to demonstrate that infection was in the walls and in the mesenteric glands, and not in the lumen of the intestine. Proof was found in the fact that if the infection was removed the patients improved. Practically all the chronic cases were associated with colon infection, and it was only by removing infected areas that improvement or cure was brought about. Dr. Turck might doubt toxemia from bacteria being a factor, but if the removal of the colon was followed the next day by disappearance of the mental symptoms, then something had happened. It might be said that he was over-enthusiastic, but when the patients got well and stayed well one could not avoid being a little enthusiastic. Dr. Cotton said the whole question of intestinal treatment was a very large one, and they did not claim that they had solved the problem but felt that light had been thrown on one angle through Dr. Draper's experimental and operative work.

Dr. Draper, in closing, said that he did not mean to imply that toxemia had a single origin; he thought it had a triple origin. It might be the result of the breaking down and splitting of food proteins; it might come from a focus of bacterial infection in the mucosa, or, as Dr. Turck said, poisons might come, not from bacteria or food, but from abnormal metabolism of the epithelial cells. It was possible for a toxemia to exist in some cases without our being able to determine its cause.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held December 2, 1921.

DR. SEWARD ERDMAN IN THE CHAIR.

Shoulder Girdle Amputation for Sarcoma of Scapula.—Dr. FENWICK BEEKMAN presented this patient, a boy 8 years of age, admitted to the Children's Surgical Wards of the Fourth Division of Bellevue Hospital, on August 7, 1921. Examination showed a tumor involving the scapula. The growth was of about six months duration, had been growing gradually, and was constantly tender. The father stated that the boy had fallen downstairs previous to the appearance of the tumor. Previous to his admission to Bellevue Hospital an incision had been made and a portion of the tumor removed for diagnosis. A large tumor mass involved the outer surface of the left scapula and there was dilatation of the superficial veins in that region. The skin was firmly adherent to growth. The radiologist's diagnosis was osteosarcoma. The child was operated upon on August 27, an interscapular thoracic amputation being performed. Flaps from the anterior and under surface of the arm were used to cover the area left after removal of the arm. At the time of operation the *x*-ray showed no involvement of the lungs. On September 11 the boy was found to have a recurrence at the upper angles of the scar in the skin. The new growth was removed and the boy discharged from the hospital on Sept. 29. Two weeks later he returned with a recurrence in the granulating area of the wound and a metastasis was discovered in the lungs. It was then decided to start *x*-ray treatment. Under this treatment it had been a most remarkable thing to see the metastases fade away. The improvement was especially remarkable in view of the fact that the boy had not come regularly for the treatment. Not only was there a disappearance of the metastases but the boy had put on weight and improved in every way. Dr. Beekman stated that he showed the case because of the rapidity with which the recurrences had disappeared under *x*-ray treatment. He was not treated with radium because it was difficult to get the proper amounts of radium and to place them properly, so it was decided to try the *x*-ray. The pathological diagnosis was round-cell sarcoma, probably periosteal in origin.

Primary Closure of Wound of Chest.—Dr. FENWICK BEEKMAN presented this patient. He said the case was shown because some years before the war he saw a stab wound of the chest packed to control hemorrhage. A defect in the pleura developed which was operated upon several times and he did not know that the man ever got rid of the open thoracic cavity. During the war the surgeons closed many chests primarily, but he did not know whether such wounds were usually being closed in civil life. The patient, a child who had been struck by a fragment of a bomb during a block party, was admitted to the City Hospital September 6, 1921, a short time after the injury, with a temperature of 97°, a pulse of 136, and respirations 36. She had sustained a lacerated wound of the left forearm which fractured the radius and a second wound of the arm which involved the brachial artery and nerve. She also had a large sucking wound of the chest, which had been packed tight. Under ether anesthesia the wound was debrided. Then the incision was carried forward along the fifth rib and four inches of the rib resected. The ribs were retracted and the fragment of the bomb removed together with blood clot. The chest was swabbed out, great care being exercised to remove every particle of blood clot and dirt. There was a small laceration of the lower lobe of the lung. The chest was closed tight, two sutures being carried around the fourth and sixth ribs and the muscles closed over the closure of the pleura; the skin was closed with silk worm gut. The following day there was a subcutaneous emphysema extending up on the neck and down to the abdomen. The signs of hemothorax cleared up within three weeks and the child made a good recovery. Dr. Beekman said he felt that all penetrating wounds of the chest should be closed primarily, because if it was found that they were infected they could be opened later and drained from a more dependent portion of the chest; one lost nothing by having closed the wound and frequently gained a great deal. The child also had a radial nerve paralysis which had not as yet been operated upon.

Dr. CHARLES EVERETT FARR said he had not had an experience just like that of Dr. Beekman, but he wished to congratulate him on his excellent results in this case.

Dr. SEWARD ERDMAN said he was sorry Dr. Beekman had not brought the *x*-ray photographs of the chest as it would have been interesting to see the development of these metastases in such a short period of time. It was possible that the metastases were present before the operation and were overlooked. That brought up the question of the indication for operation in sarcoma of bone, when it had attained the size of this tumor, so near the chest wall and with the probability of lung metastases already present. Dr. Erdman asked Dr. Beekman what type of sarcoma this was.

Dr. BEEKMAN, in reply to Dr. Erdman's question, said that Dr. Symmers thought the growth was a round cell periosteal sarcoma. The sections showed many mitotic figures and cells which stained very irregularly. The slides of the recurrences showed many islands of round cells in the muscles which were excised at the second operation.

Malignancies of the Colon.—Dr. JOHN F. ERDMANN read this paper. (See MEDICAL RECORD, December 3, 1921, c, 23, p. 1006.)

Dr. GEORGE H. SEMKEN said his first impression after hearing Dr. Erdmann's paper, was one of amazement at the large amount of material that Dr. Erdmann had observed in a comparatively brief period of years; and secondly, he appreciated the excellent grouping and plans of treatment that had been followed in these cases. The diagnosis of cancer of the colon was not always so simple as had been believed. Subjectively, the cardinal symptoms of constipation and hemorrhage were not usually present; and the highly suggestive symptom of recurring "teasing" abdominal colics was often mistaken for appendiceal or renal colic. The *x*-ray examination also was by no means conclusive. As between the barium meal and the barium enema, the latter was the more likely to reveal the presence of the tumor. If the malignancy had progressed to the point of causing almost complete occlusion, the barium meal might reveal the obstruction and the dilatation of the proximal segment, especially of the cecum; but the usually associated hypertrophy of the distal segment and the hyperperistalsis of the colon usually caused the meal to pass through even a small lumen without great delay. With the barium enema, fluoroscopic examination and the study of stereoscopic plates had given more definite information. On the other hand, in three cases of cancer of the colon that had come to operation several months after an *x*-ray examination had been reported as negative by competent roentgenologists, a later examination of these plates aided by the surgical knowledge of the location of the tumor, showed definite evidences of the disease at that point, but the filling defect was too slight to excite suspicion at that time, or the diseased segment had taken an antero-posterior axis and was not shown in its lateral outline. So far as the surgical procedure was concerned, Dr. Semken agreed with Dr. Erdmann that the emptying of the bowel was an essential preliminary to resection. It was also essential to keep the colon from becoming distended with gas after the anastomosis had been completed for this distention had probably been a more frequent cause of failure than any other single factor. To avoid this difficulty, a colon tube or a Paul-Mixter tube was inserted through a colostomy or enterostomy opening proximal to the anastomosis. If this was sutured in place by Kader's method (for gastrostomy), the opening closed promptly after the tube had been withdrawn. Soiling of the inner suture line by feces did not seem to be very injurious; and this observation paralleled the experience in wounds in the rectum, which could be inspected, and in which healing seemed to progress without much difficulty. Dr. Semken regretted that Dr. Erdmann did not give greater consideration to the related lymphatic structures, since these also should be included in all radical operations for cancer of the colon, even though such tumors tended to remain localized for a long period. The work of Jamieson and Dobson, published in 1909 in the Pro-

ceedings of the Royal Society of Medicine of London, showing the location of the lymph nodes related to the colon, was a classic that deserved the closest study in this connection.

Dr. FARR asked Dr. Erdmann how he treated perforating growths in the lower bowel. He said he had had one or two perforating carcinomas and two instances of perforating diverticulitis.

Dr. BANCROFT asked Dr. Erdmann whether he understood correctly that Dr. Erdmann as a rule did not make a permanent colostomy. Did he always bring the sigmoid down to the anus? He had seen patients with an artificial anus on the left side who suffered very little discomfort. He would like to hear Dr. Erdmann express his opinion on this point.

Dr. ERDMANN, in reply to these questions, said he had evidently read his paper too fast as the reply to both questions might be found in his paper. He had said that when a patient came in and a diagnosis of obstruction due to a tumor was made he did a preliminary cecostomy. As a rule he put the artificial anus in the right side, making the incision sufficiently large to permit him to put his hand in and palpate the colon and learn just about what he had to deal with. Just that day he had had a patient come in who gave a history of having had colic since July. In fact, some discomfort had been noticed since April or May. This patient was distended and had succussion sounds in his cecum, making it evident that he had to be operated upon. Fearing that he was going to have a fearful time with adhesions due to a previous appendectomy the incision was made on the left side and the growth was found at the splenic flexure. He decided then to make an opening on the right side, and after making the incision spent twenty minutes breaking up adhesions. Finally he succeeded in mobilizing the cecum and making an artificial anus. The last thing he closed, whether in a cecostomy, an appendocostomy, or what not, was the gas vent.

Dr. BANCROFT said that in his question he referred to the disposal of the proximal end of the bowel after resection.

Dr. ERDMANN said in a large number of these cases the anastomosis was made down below so as to make an ordinary anus, because he felt that the patient was more comfortable where this could be done. In regard to the perforating cases, Dr. Erdmann said he did not handle a perforation in the sigmoid due to carcinoma differently than he did a perforating diverticulum or a perforating appendix.

Dr. FARR asked Dr. Erdmann how he treated an acute spreading peritonitis associated with malignancy and perforation.

Dr. ERDMANN replied that he brought the colon with the tumor out through the abdominal wound if possible and allowed the infection to clear up before proceeding.

Dr. SEWARD ERDMAN asked whether he was correct in the impression gained from the paper that he did not usually make use of a permanent abdominal anus but preferred to bring the stump down to the perineum, after resection of the rectum and anus. He asked whether such an artificial anus was more convenient for the patient. Furthermore, in a case of complete acute obstruction from a malignant growth, would Dr. Erdmann proceed with resection and anastomosis at the primary operation, or did he merely relieve the symptoms by some form of colostomy and defer the resection to a later date?

Dr. ERDMANN replied that that was true where it could be done. If one could bring the proximal portion of the gut down he thought that was preferable at the present time. He was not having the disturbances and dissatisfaction that some were having when this was done. He had one woman now in whom he had operated six years ago in this way and she was employed in the cloak department of a large store and no one knew that there was anything the matter with her.

Oblique Anastomosis of the Colon. (With Lantern Slides.)—Dr. A. L. SORESI presented a patient upon whom he had performed a colonic resection and anastomosis according to this method. It was thought that this patient was suffering from intestinal obstruction. At operation carcinoma was discovered. The operation was performed two years ago, the patient made a good recovery and thus far had had no recurrence. Dr. Soresi exhibited lantern slides illustrating the procedure he employed after the growth had been removed. He called it an oblique anastomosis. It consisted in the application of the same method of suture to the colon and sigmoid that he had devised for gastrojejunostomy. He emphasized that the cut ends of the gut must not be traumatized by the fingers or in other ways and no cautery was used. With this oblique anastomosis there was no danger of pocketing, of leakage, or of stenosis. Specimens of portions of the intestine of dogs in which this form of anastomosis had been performed were shown. Catgut was to be preferred as a suture material because there was a tendency for calculi to form about a silk suture in this location. The oblique suture was indicated in every case in which an anastomosis was to be made. The technique was not difficult. He had employed it in some forty cases in all parts of the intestine and in no case had he had leakage.

Dr. ERDMANN said he was very glad to have heard Dr. Soresi describe this method of anastomosis. However, he would not call it an oblique anastomosis but a lateral anastomosis. It was simply splitting a rectangular flap. It required exposure of the operative field for a longer time and the exposure of a greater amount of surface to infection. However, the danger of infection was very slight. As Dr. Downes had said, the abdomen could take care of a considerable amount of healthy feces without becoming infected, and if infection did not occur this was a very excellent method. Dr. Erdmann said he did not fear an end to end anastomosis in the small intestine. He had done an end to end anastomosis again and again and sewed the abdomen up tight and he had had no infection.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINERS OF WYOMING.

Cheyenne, June 6-8, 1921.

(*Concluded from page* 217.)

GYNECOLOGY.

1. Discuss the etiology, diagnosis, and treatment of acute and chronic salpingitis.
2. Give the diagnosis, etiology, and treatment of carcinoma of the cervix.
3. What are the indications for and technique of abdominal hysterectomy?
4. Describe the symptoms, signs, and treatment of acute gonorrhea in the female.
5. Differentiate extrauterine pregnancy, ovarian cyst, and pyosalpinx.
6. Discuss the physiological processes of ovulation and menstruation.
7. Discuss the diagnosis and treatment of fibromyomata of the uterus.
8. Describe the surgical repair of a bilaterally lacerated cervix and a complete perineal laceration.
9. Give the principal causes and treatment of sterility in women.
10. Give the indications for ventral fixation of the uterus, and the technique of the operation.
11. What is endometritis? Give its causes, classification, and treatment.

ANSWERS.

GYNECOLOGY.

1. *Salpingitis* is inflammation of the Fallopian tube. *Causes:* Gonorrhea, septic infection, subinvolution, fibroids, uterine displacements, lacerated cervix, taking cold at menstrual periods, and certain diseases such as the eruptive fevers and syphilis or tuberculosis. *Symptoms:* Pain or discomfort, made worse by pressure, examination, defecation; or colicky pains over the tube; dysmenorrhea; increased menstrual flow; tubes are found to be dilated and swollen. *Varieties:* Hematosalpinx, when tubes are distended with blood; Pyosalpinx, when they contain pus; Hydrosalpinx, when they contain serous fluid or exudate. *Diagnosis:* A drag-

ging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain. *Treatment:* Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary.

2. *Cancer of the cervix:* "Laceration and erosion are predisposing factors. It occurs most frequently between the ages of 35 and 50. The symptoms are hemorrhage, pain, and discharge. The diagnosis is made on the physical and microscopical examination. The cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. These nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable and bleeds upon touch. The prognosis is unfavorable unless a radical operation is performed. The treatment consists in removal of the entire uterus, but is contraindicated when the disease has extended to inaccessible organs. The palliative treatment consists in relieving the pain by morphine and in the removal of the diseased tissue by the scissors, curet, or caustic for the relief of the hemorrhage and discharge."

3. The INDICATIONS FOR ABDOMINAL HYSTERECTOMY are given as follows: All solid or cystic tumors of the uterus; cancer, uterine rupture during labor; certain conditions of puerperal sepsis; pregnancy complicated by pelvic deformity, cancer, or other serious obstacle to the passage of the child; uterine prolapse or inversion, and incidentally as a step in the removal of complicated suppurative conditions of the uterine appendages.

Abdominal Hysterectomy.—"The patient must be carefully prepared as for any other abdominal operation, but in addition the pubes and vulva must be shaved and thoroughly purified; the vagina should be douched for some days previously, and an antiseptic dressing worn, and if need be the uterine canal should be curetted and disinfected with some powerful antiseptic.

"After anesthesia has been induced the Trendelenburg position is adopted, and an incision of suitable length made in the median line. The parts are then carefully explored, and if no adhesions exist an abdominal cloth is packed in over the intestines in order to protect and keep them from exposure and injury. If adhesions to omentum or gut are present they must be carefully divided: it is, of course, most desirable that a complete peritoneal covering should be secured for any adherent organs; omental grafts may be sometimes useful in this direction. The broad ligaments are then examined, and a decision made as to whether or not the ovaries and tubes are to be saved.

"A pedicle needle carrying a sufficient length of well-boiled silk is carried through the round ligament so as to secure the ovarian artery and veins, and tied as far away from the uterus as possible. A broad ligament clamp may then be placed in position close to the uterus, so as to prevent venous regurgitation, and the broad ligament is divided halfway down. It is often possible and desirable to pick up the divided end of the ovarian artery on the face of this section and secure it separately, while the little artery which accompanies the round ligament should also be carefully secured. The ovarian artery on the other side is next dealt with in a similar fashion. A transverse cut is now made across the front of the uterus, involving merely the serous membrane and connecting the two ends of the incisions in the broad ligaments: the peritoneum below this transverse cut is detached, together with the bladder, from the cervix, and the intraligamentary space is thereby opened up on either side. In this will be found the uterine vessels, and it may be possible to see and isolate the uterine artery before securing it by ligature. Care must be taken in this part of the operation to keep close to the uterus, as the ureter comes forward from behind under the uterine artery to reach the bladder, lying about the level of the os internum. The uterine vessels are in this way carefully secured and divided.

"The uterus is now merely held by the connection between the vagina and cervix and the peritoneal reflection in Douglas' pouch. If a supravaginal operation will suffice, the surgeon cuts across the neck of the uterus in such a way as to fashion two flaps, and finally the peritoneum behind is divided. A few small vessels will probably need to be secured on the face of the uterine stump. This having been effected, the uterine flaps are stitched carefully together so as to bury the open cervical canal; the uterine stump is then covered in by uniting the divided portions of peritoneum. This line of sutures is carried up on either side so as to secure the two layers of the broad ligament; the final result is that the pelvic floor is covered in by a continuous layer of peritoneum, showing a sutured incision which runs transversely from one side to the other. The usual peritoneal toilette follows, and the abdomen is generally closed entirely, no drainage being required."—(Rose and Carless' *Surgery.*)

4. GONORRHEA.—*Symptoms.*—Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge.

Treatment: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position.

5. In *extrauterine pregnancy*, there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *pyosalpinx* the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), backache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender. In *ovarian cyst*, no signs of pregnancy, the tumor may grow to enormous size, fluctuation generaly distinct, emaciation, not painful, facies ovariana.

6. *Ovulation.*—In the process of development in the ovary, the individual Graafian follicle increases in size and gradually approaches the surface of the ovary. When fully ripe or mature, it forms a little projection on the exterior. Coincident with the increase in size, which is caused by the augmentation of its liquid contents, the external envelope of the distended vesicle becomes very thin and eventually bursts. The ovum and fluid contents of the vesicle escape on the exterior of the ovary, whence they pass into the Fallopian tube.

Menstruation is a periodic discharge of blood from the mucous membrane of the uterus, due to a fatty degeneration of the small blood-vessels. Under the pressure of an increased amount of blood in the reproductive organs, attending the process of ovulation, the blood-vessels rupture, and a hemorrhage takes place into the uterine cavity; thence it passes into the vagina. Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days interval, until the menopause; it is absent during pregnancy and early lactation.

The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other.

The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

7. UTERINE FIBROIDS are very common. "They are benign, but are harmful on account of the disturbance produced by them when enlarged, and also on account of the various degenerations which they are likely to undergo. Menorrhagia, metrorrhagia, and pain are the common symptoms of the growths, although in patients with large intestinal and subserous fibroids hemorrhage may be absent. In cases of the submucous tumors (fibroid polypi) bleeding may be extreme. The tumors are usually of slow growth, but sometimes they increase very rapidly in size, causing serious pressure symptoms. The diagnosis is sometimes very difficult and always impossible without physical examination. Uterine fibroma may coexist with pregnancy.

The treatment consists in removal. In cases of subserous fibroid the snare may be used when it is pediculated, and when sessile the capsule may be cut and the growth enucleated. In the subserous and interstitial variety if the patient can be kept under observation and the tumor is small operation should be postponed; otherwise a choice should be made between removal of the uterine appendages, ligation of the uterine arteries through the vagina, myomectomy, and hysteromyomectomy."—(Gould and Pyle's *Pocket Cyclopedia.*)

8. *To repair a lacerated cervix:* "A general anesthetic is administered and the patient placed in the lithotomy position. *Step* 1.—The cervix is exposed by a weighted vaginal speculum and two lateral retractors. The anterior lip of the cervix is grasped by a bullet forceps. *Step* 2. —With long rat-tooth tissue forceps and a long curved scissors, the edges of the laceration are made raw by excising a strip of scar tissue the length of the tear and well down into the angle of the laceration, taking care to remove the plug of scar tissue in the angle. The utmost care must be exercised in the process of denudation for fear of removing the mucous membrane that is to form the cervical canal. For this purpose a strip one-fourth of an inch wide is left in the middle of either lip. *Step* 3.—Sutures of No. 2 ten-day chromic catgut are now passed to unite the opposing denuded surfaces. The first suture is passed near the angle. A short cutting needle (Emmet's preferred) is passed from the outer margin of the line of denudation underneath the denuded surface and emerges at the margin of the strip of mucous membrane. The needle is then carried in an opposite direction through the opposite lip of the cervix. The remaining sutures are passed at intervals of one-half inch until the external os is reached, when they are all tied.

"To demonstrate the patency of the cervical canal a sound should be passed through the cervix. A gauze pack is now placed against the cervix and a sterile vulvar pad adjusted and held in place by a T-binder." —(Findley's *Diseases of Women.*)

Operation for lacerated perineum: "The labia are seized with Allis' forceps at the level of the lowest carunculæ myrtiformes. A guide stitch is placed in the posterior vaginal wall directly under the external urinary meatus. By pulling one Allis forceps and the guide stitch in opposite directions outward and downward, the posterior sulcus is exposed; denudation is required, even in a recent tear, for a part of it is always submucous. The other sulcus is exposed and denuded. Then by holding the guide stitch upward in the middle line and pulling the forceps apart the mucous membrane between the sulci is denuded or freshly torn surfaces covered with granulation-tissue are scraped with the edge of a knife. The ruptured levator ani muscle in the posterior sulci is united with a double tier suture of chromic gut, two half hitches being taken in the stitch as it turns upward after coming down from the apex of the wound, in its deeper portion to the base. One knot at the apex of the sulcal denudation secures the stitch. The retracted ends of the transverse perinei and bulbocavernosus muscles are brought together by silkworm sutures. Finally, a single stitch at the top of the perineal wound unites the posterior commissure of the vulva, restoring the fossa navicularis. The perineal stitches are knotted; they are removed on the twelfth day."—(Hirst's *Obstetrics.*)

9. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. The cause may not be in the woman, but in the man.

Treatment consists in removing the cause, if possible; curettage has been recommended; in the presence of developmental errors little or nothing can be done; atresia of cervix can be treated by dilatation; if the uterus is misplaced it must be replaced.

10. *Ventrofixation.* "This is a procedure that must be cautiously undertaken in married patients who have not reached the climacteric. An incision two or three inches in length is made immediately above the symphysis, and the fundus uteri is drawn forward by a volsellum. The silkworm gut stitches are inserted through the abdominal parietes and peritoneum, and also through the body of the uterus just posterior to its axis. The stitches should include about three-quarters of an inch of the uterine wall in their grasp, and go about one-eighth of an inch deep. On drawing them tight, the uterus is fixed forward against the abdominal wall and contracts adhesions. In some cases it may be desirable to scarify the uterine wall before tying the stitches, so as the better to determine adhesions. As a general rule the adhesions stretch somewhat, and hence allow a certain degree of play, but without the likelihood of a return of the displacement."—(Rose and Carless' *Surgery.*)

Ventrofixation is indicated in cases of prolapsed uterus uncomplicated by uterine tumor, and when subsequent pregnancy is not expected to occur.

11. *Endometritis* is inflammation of the mucous membrane lining the uterus.

"Acute endometritis is the result of the introduction into the uterus of septic microorganisms. This usually occurs during labor or miscarriage, or it may result from operations, such as dilatation, or from the introduction of an unclean sound. It sometimes occurs as a complication of the exanthems. If the process is severe enough, it may involve the muscular tissue underneath the mucous membrane, when it is called metritis; or the peritoneal covering of the uterus may be invaded, when it is called perimetritis. *Symptoms.* —Acute corporeal endometritis is usually attended by considerable pain, of a dull, aching character. There are constipation and vesical irritability. The pulse is rapid and temperature in some cases is very high—from 104° to 106° F. Vaginal examination reveals a patulous cervical canal with a profuse purulent discharge escaping from it. The uterus is enlarged, boggy, and tender.

Treatment.—Acute corporeal endometritis following miscarriage or labor should be treated actively. The uterus should be thoroughly curetted, in order to remove any portions of decidua or membranes remaining after parturition. If the symptoms do not subside in the course of 24 hours, intrauterine douches of sterile water may be given 2 or 3 times daily. Free purgation, hot stupes to the lower abdomen, a generous diet of milk and broths, and an abundance of stimulation will be required. In the gravest cases hysterectomy will have to be performed. In less severe cases of acute endometritis rest in bed, v aginal douches of hot, sterile water, and purgation will be sufficient.

"Chronic endometritis may result from an acute attack or it may be chronic from the beginning. One of the most frequent causes of this condition is gonorrheal infection. Chronic endometritis accompanies a variety of pathological conditions of the uterus, such as displacements, subinvolution, laceration of the cervix, and fibroid tumors. Two varieties of chronic endometritis have been described—glandular and interstitial. The *symptoms* of chronic endometritis are usually well marked. There is pain, of a dull, aching character, most evident in the back and extending down the thighs. Leucorrhea is constant, and is quite characteristic. The discharge is thin, purulent, and blood-streaked. Menstruation is profuse, and lasts usually from 5 to 7 days. The patient's general health suffers; she loses weight and becomes anemic, there is a sense

of great reduction in physical strength. Headache is a very common symptom. Nervous, digestive, and circulatory disturbances appear sooner or later. Physical examination reveals an enlarged, tender uterus. The cervical canal is patulous; the external os is eroded. The characteristic discharge can be seen escaping from the cervix."—(*Cyclopedia of Medicine and Surgery.*)

Treatment of chronic endometritis. The general health must be attended to; rest is indicated; constipation must be avoided; tonics are of slight use; ergot is useful for the menorrhagia or metrorrhagia; vaginal douches, pessaries, hip baths, and counter-irritation have all been recommended; curettage may help; and one or both lips of the cervix may be amputated. Foreign bodies, such as polypi and fibroids, must be removed; and any causative factors must be treated.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	S. W. Welch, Montgomery	Montgomery	July 11
Arizona*	A. Martin, 207 Goodrich Building, Phoenix	Phoenix	April 4
Arkansas		Little Rock	May
California	C. B. Pinkham, Sacramento	San Francisco	June 26
Colorado	David A. Strickler, Empire Building, Denver	Denver	April 4
Connecticut*	R. L. Rowley, Hartford	Hartford	Mar. 14
Delaware	H. W. Briggs, Wilmington	Wilmington	June 20

Death of Exner.—Professor Alfred Exner died in his 47th year on November 8 last of a malignant tumor of the kidney. The tumor cells penetrated at an early period into the vena cava and numerous metastases were set up, notably in the bones. He developed a spontaneous fracture of the right thigh from one and from the spinal metastases he developed paraplegia. The deceased, who had always been a glutton for hard work, began his surgical career as assistant to Gussenbauer and after the death of the latter he was associated for 13 years with Hochenegg. At the time of his death he was surgeon in chief of the Merciful Brothers Hospital in Vienna. He wrote some 60 papers on surgical subjects, largely those with an experimental bent, such as the absorptive capacity of the peritoneum, the genesis of gallstones, etc. He was interested in the surgical uses of radium.—*Wiener klinische Wochenschrift.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

AN INTRODUCTION TO BIOPHYSICS. By DAVID BURNS. 435 pages with 85 illustrations. Published by the Macmillan Company, New York.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints Vol. XXXIX. 662 pages with illustrations and colored plates. Published by The Rockefeller Institute for Medical Research.

TREBALLS DE LA SOCIETAT DE BIOLOGIA, 1919. Published under direction of A. PI SUNER. 314 pages with illustrations. Price, 10 ptes. Published by L'Institut D'Estudie Catalans, Barcelona.

SYSTEM DER NEUROSE. By Dr. EMIL KUGLER. 188 pages. Price, 84 M. Published by Urban & Schwarzenberg, Berlin.

GRUNDRISS DER GESAMTEN RÖNTGENDIAGNOSTIK INNERER KRANKHEITEN. By FRITZ MUNK. 297 pages with 193 illustrations. Price 180 M. Published by Georg Thieme, Leipzig.

THIRTY-SECOND ANNUAL REPORT OF THE STATE HOSPITAL COMMISSION, July 1, 1919, to June 30, 1920. 372 pages with tables. Printed by J. B. Lyon Company, Albany.

THE MEDICAL DEPT. OF THE U. S. ARMY IN THE WORLD WAR. Vol. XV. STATISTICS, Part 1, ARMY ANTHROPOLOGY. Prepared by CHARLES B. DAVENPORT, under direction of M. W. IRELAND. 635 pages with tables. Published by the Government Printing Office, Washington, D. C.

A PSYCHIATRIC MILESTONE, BLOOMINGDALE HOSPITAL CENTENARY. 215 pages with frontispiece. Privately printed by the Society of the New York Hospital.

THE MEDICAL CLINICS OF NORTH AMERICA, November, 1921. 363 pages with illustrations. Price, $12.00 per year (6 numbers). Published by W. B. Saunders Company, Philadelphia.

REPORT OF THE PHILIPPINE HEALTH SERVICE, January to December, 1920. 497 pages with illustrations. Published by the Manila Bureau of Printing.

THE EVOLUTION OF MODERN MEDICINE. By Sir WILLIAM OSLER. 239 pages with illustrations. Published by Yale University Press, New Haven.

EPISCOPAL HOSPITAL REPORTS, Vol. 5. 506 pages with illustrations. Published by Wm. J. Dornan, Philadelphia.

DISEASES OF THE DIGESTIVE ORGANS. By CHARLES D. AARON. 904 pages with 164 engravings, 48 roentgenograms and 13 colored plates. Price, $10.00. Published by Lea & Febiger, Philadelphia.

AIDS TO MEDICINE. By BERNARD HUDSON. 370 pages. Third Edition. Price, $2.00. Published by William Wood & Company, New York.

COMMUNITY RESPONSIBILITY. By COURTENAY DINWIDDIE, with Statistics by BENNET L. MEAD. 171 pages. Price, 35 cents. Published by The New York School of Social Work, New York.

THE SURGICAL CLINICS OF NORTH AMERICA, December, 1921, Vol. 1, No. 6. 295 pages with illustrations. Price, $12.00 per year (6 numbers). Published by W. B. Saunders Company, Philadelphia.

THE SURGERY OF THE PERIPHERAL NERVE INJURIES OF WARFARE. By HARRY PLATT. 49 pages with illustrations. Price, $1.25. Published by William Wood & Company, New York.

COMPEND OF BACTERIOLOGY. By ROBERT L. PITFIELD. 297 pages, with illustrations. Published by P. Blakiston's Son & Company. Price, $2.00.

MEDICAL ELECTRICITY FOR STUDENTS. By A. R. I. BROWNE. 231 pages, with illustrations. Published by Henry Frowde and Hodder & Stoughton. Price, $4.25.

BOWEL DISEASES IN THE TROPICS. By Sir LEONARD ROGERS. 475 pages, with illustrations. Published by Henry Frowde and Hodder & Stoughton. Price, $9.00.

MIND AND ITS DISORDERS. By W. H. B. STODDART. 592 pages, with illustrations. Published by P. Blakiston's Son & Company. Price, $7.50.

Medical History.

NEW BOOKS AND OLD.

XXIII. WALTER MOXON AND HIS PILOCEREUS SENILIS.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

(*Concluded from page* 264.)

In 1868 Moxon delivered the introductory lecture at Guy's Hospital. He chose for his topic "How Should We Study Medicine." A rather long lecture full of good advice and quaint phrasing.

Don't let what you hear from me stand to you in the place of your own thoughtful observation and inquiry. Think out your own view of the profession honestly, liberally, and truthfully. . . .

Before we commence some trade or profession we are like social fœtuses. The progress of social development is also from the general to the special. There is an absence of what is called differentiation in boys, corresponding exactly to what physiologists tell us of in the early development of mammals. They tell us that a rather clever man cannot at first say whether the little creature is going to be a cat or a monkey, and this doubtful state hands about it until it gets it teeth and nails, and the rest of its means of working for its living, and then any one can see what it is. You see, the characteristic qualities come when a thing has to do its real work in the world; and when these come out, the more general (and hence useless) qualities, which had been upon the surface hitherto, go out of sight, to be hunted after by comparative anatomists. Now, in just the same way we are, as boys, all one with the rest of boys, and show the same general but useless characters which we share with young clergymen, and lawyers, and merchants; but now that we are to differentiate into doctors, those boyish appearances and manners must recede into the depths of our nature, and we must develop the qualities of physicians and surgeons.

It would be a fine thing if our school teachers, they call themselves educators and pedagogues these days, could be made to read over a few lines on the subject of learning. The more I see of the present day school child, and alas, the present day medical student, the more I feel that their heads are crammed with facts rather than ideas. But back to Moxon:

Why, the very words I began with are examples. I said you would have to *get* a *store* of knowledge. And again, for another instance out of many, we speak of a man's *capacity*. These are bad words, gentlemen. We must learn not to look upon knowledge as stuff to store into capacities as if the relation of knowledge to the mind were the same as the relation of old curiosities to a lumber-room. No! It is not capacity and storage. The knowledge that enters does not find room, it makes room. It is poor, stunted stuff if, when it gets in, it does not grow. It will make poor growth if it does not grow in harmony and adaptation to what is already there, and unite and develop with it. The educated mind is not a stuffed bag. It is true of the mind as it is true of the body. "It cometh forth like a flower," though it is never cut down. The mind is a growth. . . .

Take care of your freedom, and, with all your getting, get understanding. Understanding is the organization, the digestion of your knowledge, the mastery of it, so that you are in possession of its central and cardinal points, its seats of government and control.

What we want to do is, to inquire into, and grasp intelligently, the principles of every science you study; you will not keep all the details, but when the details fall like leaves, then the principles shall remain, as the stem, and boughs, and branches, to give form, and strength, and permanency to your tree of knowledge. Let over the door of memory be written, Nothing unmethodized enters here. Don't cram with ill-arranged knowledge. Don't cram for your examinations. The examination is not you real trial; you only find *bail* there to appear again before a higher court, where your worth and usefulness will be vindicated or condemned without appeal. DON'T CRAM!

It is pitiful to see those poor creatures who, without putting out vital power of mind, suck, and imbibe, and swell out into shapeless lumps of unorganized learning which dies down and decomposes in them, till they go about putrescent heaps of decaying knowledge, on which theories and -opathies, and other low growths sprout and flourish like funguses on a dunghill. Don't cram. Don't fear your examinations. A wise examiner does not "pluck" for what you don't know, but for mistakes which show confusion and error in principle. Don't suppose you can "get up" in the last few months of your study such a knowledge of principles as will save you from confusion and error. You can't. Consider the limits of your acquiring intellect. Your intellect cannot take photographs; it is just one single individual indivisible point, that, like your discerning vision, can only attend to one thing at one tme.

Your intellect, like a single pencil-point, will go, throughout each day, over the page of memory; and it will write deeply and durably, as attention keeps it down firmly. Please let it now write down this indelibly: *Bad Memory is another name for Inattention!*

Moxon was practical and he realized the futility of striving after the unattainable. He believed in doing the task at hand and not in dreaming about the endless possibilities of some distant future:

Don't be dazzled by brilliant aims. Keep your minds fixed on today's duty, for your life is not lived to an aim. *Sine missione nascimur*, we live to a duty. Don't let us think and act as if we were here to sweep disease and death off the face of the earth, or to give life for half a crown a bottle. This is rather our humbler, yet our truly nobler, service—it is, to be to each individual sufferer under our care all that a man can be to his fellowman in sickness. . . .

For why is it we are only honored in the sick-room, or as the old saw has it:

"God and the Doctor they alike adore,
"Just in the hour of danger, and no more;
"The danger o'er, both are alike requited;
"God is forgotten, and the doctor slighted."

There is much plain truth in both sides of that old comparison.

He gives a piece of advice which all medical students,—I speak of them both before and after they are graduated M.D.—would do well to follow. It is infinitely more true today than it was in his time. There are so many of us who forget that we have eyes and ears and fingers and brains of our own.

Get an independent, well-grounded familiarity with diseases for yourself, or you will never escape from the crowd of experts that will thrust their help upon you, to aid you with all sorts of -graphs, and -scopes, and -ometers. They will importune you—these multitudes of guides—to start on the old labyrinth from their new start-point, and to follow their thread, which will put you at their mercy; but do you start from some ground you know yourself, and take your own thread. Use the new-fashioned instruments rather to guide and educate your old and trusty five senses than to replace them.

Moxon would be a wonderful man to have about in these days of specialized and rationalized medicine. I should like to hear him on the subject of the man who went into a barber shop to get shaved. The barber persuaded him to have a hair-cut, singe, massage, tonic rub, manicure, shoe shine, and what not. At the end the barber said your hair is falling out, you need a bottle of Eau de Quinine which I have here in the shop. But the good man said

him nay, "I shall go," said he, "to my physician and have him prescribe." So to the learned man he hastened. "Aha!" said the doctor, "We will examine you thoroughly, this alopecia may indicate some deep seated endocrine lesion, some forgotten infection, something of which we are not now even cognoscent. We will examine you." So he *x*-rayed him, and had electrocardiograms taken, and blood, and stomach contents, and everything which could be examined was subjected to a careful scrutiny by a corps of highly trained and highly priced specialists. In the end the doctor after summing it all up said to the poor man—poor if he paid his bill—"We have ascertained that your hair is coming out and advise the use of some stimulating lotion such as Eau de Quinine."

Now hear our author:

Cannot you fancy the lecturer in 2874, of the threatening ear of what I may call Panteutonic Buddhism, beginning somehow thus: "The earliest age is known as the Scopes-age, from the name of the many kinds of instruments worn by physicians. Thus they had on their eyes things called microscopes, the nature of which is now unknown, as the records of the period were printed on bad paper, and were worse bound; but they could make the smallest trifles come to sight. To spy through these at the excretions was supposed by the ignorant patients to have a magical healing virtue. These instruments were said to magnify, a word meaning to make great; but it was afterwards found out that the things put under were really made no greater than they were before. How this strange error prevailed we cannot now understand, but it has been suggested that the constant wearing of microscopes prevented the physicians from being able to see the real relative size and importance of things. At the same early period doctors were not considered full-dressed unless they wore on their ears pipes of wood of ornamental design, called stethoscopes; and it is said they would crowd in dozens to hear an unusual squeak or whiz, which had in itself no real relation to the patients' suffering and danger; but the poor patients thought all the while that they received great benefit from this. Besides this, there were many other scopes; but for mention of them I must refer you to the historical lectures, in which you will find it shown clearly that these delusions were but part of the universal trust in machinery which led to the downfall and decay of civilization, to which I must apologize for so long directing your attention."

Moxon was not a therapeutic nihilist, quite the contrary. I cannot quote much more but he said:

A doctor without physic is like a priest without a creed or a poet without rhyme. It is only the other day that the *Times* said: "If there be anything which nature abhors, it is a doctor without medicine or advice. . . ."

It is not only from the ancient physicians themselves that we know they were sensible doctors; indeed, physicians have always had an unfortunate way of leaving the most useful part of their advice out of their writings, and filling these with technicalities and trash more or less obscure.

Only too often do we doctors imagine we are dealing with enlightened men and women, educated, sceptical, free from superstition and ignorance. Far from it. Man has not changed appreciably since the beginning of written records. His environment has changed, he has invented much but he thinks and feels as always. Listen to the lecturer on this subject:

Do not be led by the rational atmosphere at this hospital to thing the world is led by reason. Do you think that charms and spells are effaced, and that people do not hold to and long for them? Do not make such a mistake; they have not departed at all, nor been done away; they have only a little changed their shape, and are recognized without much difficulty. You will find the old and natural trust in spells and unknown agencies to be embodied, often very plainly, in the faithfully exact and almost worshipful deglutition of the orthodox dose three times a day. You may know it is only ammonia and gentian. They may half know it. But never think they take it as they would take a "pick me up" of brandy and soda; they swallow it as if to Æsculapius, and in the gulp their eyes sparkle with all the old ineffaceable longing for help from the unknown. The time-honored potion carries with it the undying power of the medicine-gods and medicine-man, of Fairyland, and of the witches, as real as ever. The conditions of emotional overstrain and tendency to unwonted credulity are naturally present around the sick-bed, and often are the more urgent in proportion as the occupant of it is more beloved. The calamity came from the unknown, and they will have help from the unknown. No education or civilization will ever refine or develop them out of that, for education and civilization carry nature farther, while it remains the same as before. This insatiable demand on unknown forms of help keeps therapeutics unstable. The demand from the unknown is answered, and the -opathies come out of limbo hungry, but smiling and full of promise, and patients encourage and favor their mysterious aid, and are ready to believe that what they have taken produced all the feelings that happened since, and hope made these feelings more pleasant. Thus pretentious quackery thrives parasitically on the sufferer's faith and hope.

And now we must leave Walter Moxon and his Pilocereus Senilis and his lectures and essays. If you see his work in a second hand shop give the man the quarter or half dollar he will ask for it and carry it away with a straight face but joy in your heart.

Semicentennial of the Union Médicale du Canada.—This periodical was founded in 1872, the initial number bearing the date January 1 of that year. The first editor-in-chief was J. P. Rottot. This enterprise was doubtless due in part to the organization in 1871 of the first medical society in Montreal. There were at the time under 600 physicians in the city and vicinity, and 400 of these subscribed for the new periodical. The journal was the official organ of the medical society and Hotel Dieu. In 1876 Dr. Grenier, who had succeeded to the editorial chair, succumbed to an illness and was succeeded by Dr. Persillier Lachapelle who conducted the journal at his own expense until 1882 when he transferred the editorship to Dr. Lamarche. In 1893 two French medical schools and two French medical journals were consolidated and the *Union Médicale* absorbed the *Gazette Médicale*, which had been organized in 1887. The editor-in-chief of the consolidated journal was H. Desrosiers, who resigned in 1895 and was succeeded by E. Benoit. In 1900 the present incumbent, Albert Lesage, assumed control of the journal. In noting the large number of editors—seven in all—it should be borne in mind that one of them, Grenier, died in office, at the age of 31, while Desrosiers was forced to resign on account of illness, dying shortly afterwards.

Work of the Pasteur Institute, Paris, During the Great War.—When hostilities first broke out the institute supplied 10,000 packages for serodiagnosis and 5,000 ampoules of antityphoid vaccine. Early in September the serotherapeutic headquarters were transferred to Toulouse with most of the horses used in manufacturing. Another laboratory was improvised in which 67,000 doses of vaccine were

manufactured. Then, as all of the supply on hand of tetanus serum, amounting to 140,000 doses, was used up at the front the new laboratory had to manufacture anew. During the entire course of the war the total number of horses used in the laboratories mounted to 1462. Over 6,000,000 doses of serum of all kinds were used up in France alone, while there were also supplied to Italy 1,000,000, Servia 10,000, Belgium 70,000, Roumania 40,000, and to the American Army and Red Cross 800,000, the grand total amounting to about 8,000,000 doses. After the German push in the spring of 1918 there were supplied 20,000 vials of antitetanic serum daily from the Institute, while in the Louis Martin laboratory were manufactured 34,000 liters of diphtheria and tetanus antitoxins. There were also supplied 390,000 vials of meningitis serum and 518,000 vials of dysentery serum. A laboratory under the charge of Legroux made a specialty of antityphoid and antidysenteric serum, supplying hundreds of thousands of doses, while Dujardin-Beaumetz, specializing in plague, furnished 78,000 vials of plague serum and vaccine jointly. Salimbeni and Fernbach had charge of the supply of mallein for veterinary practice, and during the entire course of the war supplied 1,200,000 doses. By 1915 aniline dyes for tinctorial purposes having been almost exhausted, Agulhon succeeded in devising over 40 new stains for bacteria. M. Nicolle worked in the direction of a pneumococcus serum, Weinberg and Seguin devised an antigangrenous serum for gas gangrene, Delezenne prepared snake antivenoms for colonials and Bertrand was active in the domain of poison gas.—*La Presse Médicale.*

Sanitary Supervision of Brandy in Cuba.—*Sanidad y Beneficencia,* the official health magazine of Cuba, contains an account of the official inspection of cognac, by Dr. Villamil. The word Cognac, applied originally to brandy from a locality of that name in France, now denotes in Cuba any kind of spirits distilled from wine or from fermented grape sugar, the latter being known as an artificial cognac. There are many varieties in the market, some of which are the product of rapid distillation. True cognac is aged in wood while artificial brandy is made by adding to grain alcohol various substances with or without further distillation. Actually in the market are imported French brandy, wine distillates or distillates of grape sugar, artificial brandy made by distilling alcohol with other substances, and simple synthetic brandy made by mixing alcohol with essences, etc., in the cold. In Cuba all of these articles are known as cognac. One of the substances present at times in synthetic brandy is vanillin. The number of substances which are actually added to brandy is very large, and this kind of spirit has always been subject to much sophistication. In some varieties the addition is in the form of fruits or leaves and in others fruit juices or essences, according as the spirit is to be redistilled or merely mixed in the cold. To make a rapid diagnosis of a sophisticated brandy one should test for the presence of vanillin, coccinic ether, or caramel.

Sovietism in the Buenos Aires University Medical Faculty.—Prof. Marcel Labbé of Paris was in charge of a French mission to take part in this ceremony and has written to *Le Temps,* the Paris daily, as follows: This anniversary of the Medical School was celebrated on the occasion of the presentation of students' diplomas by a special address given by Professor Fernandez, councillor of the university. The number of students and graduates has steadily increased during the century elapsed, both in medicine and pharmacy. There has been a process of evolution going on and now the students have a franchise in connection with university administration. This movement has been regarded as sovietistic, although some of the faculty regard it as due simply to straight sociological development untinged by the lunacy in Russia. It is more or less an experiment. Will the students choose professors and studies which will force them to work hard or will they make it as easy as possible for themselves? Again, the members of the teaching body may lose their dignity and stoop to flatter the students to obtain their suffrage. Thus far there are no signs of abuses. Certain professors are very popular who are also exacting. It does not appear to the editor that this innovation of student *rapprochement* with the faculty is anything more or less than the elective system of our undergraduate colleges applied to professional schools, although since the curricula of medical schools are quite rigid and subject in part to the administration of state examining boards, it is difficult to understand how an elective system can be carried out except by a vote on two or more competing professors for the same chair.—*Gazette des Hôpitaux.*

The Tranquilizing Balsam.—The socalled *baume tranquille* of the Abbé Rousseau is the subject of an article by Leclerc in *La Presse Médicale* for June 18, 1921, xxix, 49. The Abbé, it is claimed, also devised laudanum, but the credit for the latter was later given to Sydenham. He very nearly lost the credit for inventing the tranquilizing balsam as well, which was associated with an ecclesiastical colleague named or nicknamed Pêre Tranquille. This preparation from its emerald green hue and the great number of vegetable ingredients contained suggests a mixture of the absinthe type especially as the narcotic ingredients were commingled with many aromatic essences. The formula includes stramonium leaves, belladonna, and even the tobacco leaf. Other ingredients were henbane, poppy, nightshade, mandrake, phytolacca, etc.—apparently always the leaves, rather than other portions of the plant which might be of much greater activity. The original formula, also called for live frogs. In the modern Codex the formula is greatly simplified, comprising the dried leaves of belladonna, stramonium, henbane, nightshade, and poppy with essences of rosemary, thyme, lavender, and mint. Rousseau with Pêre Aignan, who was later known as Pêre Tranquille, were medical missionaries in the Levant and Abyssinia, in the XVII century. The above was but one of a number of remedies which they employed among the natives of those regions and which later became popular in France. Rousseau became physician to the King of France and seems to have retired from the Capucin order of which he had long been a member. He professed the then new science of chemistry, which he chose in part to gain access to Turkey, his proselytizing campaign evidently requiring a blind of some kind.

TRANSIENT HEMIPLEGIA.*

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

ONE usually is called upon to make a definite prognosis, not only at the onset of a hemiplegia, but also during its course, as to the degree of improvement to be expected, as well as the possibility of a recurrence of the seizure. The patient commonly being of advanced age, it often happens that family and business or other interests of considerable importance are at stake. The suddenness of the attack, moreover, makes the family more importunate in demanding a definite forecast of the outcome which is not easily met by generalizations. While much may be predicted, through knowledge of the patient's age, the condition of the vascular system, the presence of long-standing disease such as chronic nephritis, syphilis, etc., there nevertheless remain many cases in which it is exceedingly difficult to offer an accurate prognosis. Are there, then, any general principles which may guide one to a conclusion for any considerable number of patients? Before discussing this matter, reference to the following unusual cases will illustrate some of the difficulties encountered:

The most striking case of transient hemiplegia which I recall I met with many years ago, but it made a lasting impression, for, being recently out of Medical College, I had heard the symptoms and course of hemiplegia thoroughly emphasized, but this case was nothing like anything I had been taught to expect, and, in fact, it mystified four of my college professors who were in consultation.

The patient was Dr. "X," who was professor of physiology at the time of the seizure. He was then a few years past sixty. He was in apparent good health, when, while lunching at his club, he was attacked by hemiplegia, and by the time he had reached his home, where he was promptly carried, he was in profound coma. It was as typical a case of complete, right-sided hemiplegia as one possibly could see. Four of his colleagues being summoned in consultation, quite naturally made the gravest prognosis. As I was one of the professor's assistants I was sent there to be near his bedside, while the four eminent professors went away to return in the evening for further consultation. "Unless," they said, "I should have occasion to notify them of the death of the patient in the meantime," as none of them had any idea that he would recover. His breathing was stertorous, there was complete unilateral facial paralysis with deviation of the axes of the eyes, and the entire right side of the body was in absolute paralysis. After an interval of two or three hours I went to the patient's bedside to pass a catheter, which I was in the act of doing, when, with great suddenness, he hit me a round blow in the chest with his *right* arm! This was a new kind of hemiplegia to me, so I went into his library to read up the subject anew. Shortly after the nurse came running in and said that Dr. "X," whose eyes troubled him in a bright light, had jumped out of bed and walked over to turn out the light, which was annoying him, he being unable to speak. I hurried in to examine him and found him completely aphasic and apparently much bewildered in mind, like a drunken man. He had almost entirely recovered the power of motion in the right limbs after an interval of six hours. His mental confusion and complete aphasia, however, lasted throughout the evening, when the four professors returned, and I was greatly edified to witness their astonishment and hear their attempted explanations of the total breakdown of their prognosis! The next day Dr. "X" wrote we, with his previously paralyzed hand, a very courteous note, apologizing for his treatment of me because he did not recognize me and resented my intimate ministrations with the catheter! His recovery was absolute. He lived for several years and never had a recurrence of the attack, although, while in fair general health, he was known to have a moderate degree of chronic interstital nephritis and arteriosclerosis, with enlarged prostate gland.

Another case of this type was that of an Irish woman, aged forty-one, who entered my service in the Presbyterian Hospital. She was a chronic dipsomanic, being seldom sober for any length of time, although rarely ill from any cause. She was brought to the hospital in a semi-conscious condition with convulsions. She had complete aphasia and beginning paralysis of the entire right side of the body, which shortly afterward became complete, and there was also unilateral facial paralysis. The patient soon became profoundly comatose. The hemiplegia remained complete for about thirty-six hours, when a rapid improvement in the functions of the paralyzed muscles took place and she was able to speak distinctly. A week later she had a general convulsion, most marked, however, on the *left* side of the body. There was entire loss of consciousness after a short time. A right-sided hemiplegia recurred and lasted throughout the day, when it wholly disappeared, after an interval of about twelve hours. In this case it seemed evident that the chronic alcoholism was the cause of the temporary cerebral irritation. The patient had a considerable degree of arteriosclerosis. As she was discharged "cured" from the hospital, after a fortnight's treatment, no further information has been obtainable about her. The general physical examination of the patient showed no abnormality in any of the viscera. Her nutrition was good and she was not anemic.

A third patient I saw quite recently in consultation with two other physicians, and his case further illustrates the hazard of too hasty and definite prognosis. He was a man sixty-six years of age, who, for more than a decade had had diabetes, the sugar recently measuring as much as four per cent. He passed into sudden coma with quickened respiration which was evidently of a diabetic origin, but soon became totally hemiplegic on the right side. We all agreed that he could not live through the night, as he was developing pulmonary edema, and his entire condition was extremely critical, and we so informed his family. I was, therefore, surprised to be recalled to see him again twenty-four hours later and found that he had so far regained

*A paper read before the New York Clinical Society, November 25, 1921.

consciousness as to ask for food and to inquire who the strange nurse was who had arrived during his coma? He again lapsed into coma, however, and died a day or two later. In this case the primary coma was no doubt mainly of diabetic origin and the temporary improvement was due to the antidiabetic treatment which he received. Having assured the family that he could not possibly regain consciousness, it was somewhat embarrassing to find him able to speak intelligibly the following day!

A fourth case which I lately saw was that of a man 66 years of age with a marked arteriosclerotic condition and systolic pressure of 210 mm. He had a sudden right-sided complete hemiplegia and profound coma with a temperature of 103° F. I apologized to the hospital where I transferred him from his hotel, for sending in a moribund case. Next morning I found him wide awake and he greeted me with a "Hello Doc" and a hearty handshake with his right hand!

Two of these illustrative cases obviously were of toxic origin due respectively to alcoholism and acidosis and possibly the first one was also of some toxic origin, although it would have been difficult to discover its exact nature. In cases so plainly accompanied by profound toxemia, the prognosis had better be based upon the degree and nature of the toxemia rather than the extent of the paralysis, for while it is difficult to reconcile such distinctly unilateral loss of function involving a widespread area with the operation of a toxemia, cases of this type nevertheless are quite common, and if the toxemia can be overcome there is no ground for expecting continuance of the hemiplegic symptoms. In the case of the professor of physiology the existence of any definite organic lesion is also difficult to believe in view of the prompt recovery. The interference with cerebral circulation by either a thrombus or hemorrhage, however small, could scarcely in so short a time be compensated so fully by collateral circulation as to result in entire restitution of function within a few hours. The condition, therefore, in such cases would appear to be functional rather than structural. There is the theory of localized arteriospasm which has been advanced to explain intermittent claudication, angina pectoris, migraine, and various muscular cramps. This has much in its support, although in many such instances the symptoms usually do not last without remission for so many hours as do some of these cerebral cases. There are, however, many other transient cases in which the symptoms do not go on to complete hemiplegia, but are confined to incoordination of speech, oculomotor symptoms, partial loss of consciousness, and sometimes more or less facial paralysis. Such a condition I saw recently in a man 60 years old who had decided arteriosclerosis, an inactive liver, and prolonged constipation. He had half a dozen attacks of the nature described and in the one in which I saw him coma had lasted for several hours so that it was feared the attack was the forerunner of an apoplexy. Attention to diet and elimination of waste products entirely cured him, so that when I saw him a year later he had had no further seizure. In cases of this type, which rarely present a total hemiplegia, the possibility of infection from decayed teeth must not be overlooked, for sometimes it has bearing upon etiology and prognosis, as the following history illustrates:

Mrs. "A," aged forty-one, a nervous, active woman, had been feeling perfectly well, when, while singing in a church choir, she suddenly felt faint and went out into the fresh air. She at once experienced difficulty in speaking, her tongue feeling "thick," as she described it. She also said that she felt as if she had had a slight blow over the left parietal region. She managed to walk to her home, one block distant. The doctor who was summoned found she had a complete right facial paralysis, was strabismic and unable to speak intelligibly, although she knew what she wished to say. Her systolic blood pressure was only 130; examination of the eyes showed no abnormality; urinalysis was negative; blood examination was normal, excepting a slight anemia. The patient went to bed and within twelve hours her paralysis had wholly disappeared. Two weeks later I saw her and found her physical examination negative. She showed some evidence of fatigue and slight loss of weight with the moderate anemia above mentioned, otherwise she was not abnormal excepting that the teeth were found in exceedingly poor condition, there being several old decayed stumps and several capped-over ones. The systolic blood pressure was 128, and diastolic 84. The patient felt perfectly well and greatly resented insistence upon leading a less active life.

In this case there would appear to be two possible explanations for the paralytic seizure: (1) That it was of the nature of an arteriospasm, and (2) that it was due to a small thrombus of septic nature, the origin of the trouble being absorption from decayed teeth. The condition of the patient's heart and blood vessels should exclude cerebral hemorrhage. The Wassermann test was negative and the anemia was insufficient to be a factor in thrombosis.

In such a case where general directions could be followed, like properly regulated rest and exercise, diet, and the restriction of social and domestic activities, prognosis should be entirely favorable as regards the possibility of recurrence and the condition of the teeth should be remedied.

Heredity as a factor in inducing hemiplegia is a question which naturally greatly interests the laymen, and there are many persons who are firmly convinced that, because a parent or grandparent died from "apoplexy," they necessarily are foredoomed to the same fate. There are, however, several factors which enter into this matter which, in the absence of very definite statistics regarding it, merit consideration.

Apoplexy is a fairly common cause of death in the sixth and seventh decades of life, and the more lives which are saved in earlier decades through the conquering of infectious and contagious diseases the more survivors there necessarily are to die later on of something else. Moreover, apoplexy being common, the laws of chance would often give rise to more than one death from it in the same family quite independently of any hereditary predisposition. The same argument applies to deaths from carcinoma which formerly was so universally believed to be strongly hereditary. Sometimes, indeed, the inheritance of means to live in a certain environment is a more potent influence than actual physical inheritance. Thus in former times a man who inherited his father's wine cellar might acquire habits leading to alcoholism or gout, or of debauchery leading to syphilis, all of which might be antecedents of arterial changes favoring apoplexy. On the other hand, in a large number of cases of hemiplegia, particularly those occurring in women of good social class, no hereditary history of the disease is obtainable.

It is a very interesting fact that the incidence of hemiplegia, whether due to thrombosis or vascular rupture, tapers off very rapidly after the eightieth

year, so that in centenarians it is rarely observed. I have collected the medical biographies of over 100 persons who lived to be 100 years of age or over, and not one of them was hemiplegic, but seemed merely to die from a general deterioration—the clock runs down and stops, unless, as quite often happens, they die from acute gastritis from overeating or other forms of dietary indiscretion.

It is, therefore, quite safe both to reassure patients that they are not necessarily foredoomed to die of apoplexy, because of such a case in the family, and, if they be very old, that they are immune.

Another matter which greatly worries many patients in this sphygmometric era, is that because the blood pressure is high, they necessarily are going to burst a cerebral vessel. Of this it may be said that many hemiplegics do not have extreme hypertension and, on the other hand, we all see many patients with systolic pressure above 200 mm. who never have hemiplegia.

A man of sixty-seven years, whom I have been watching for some time, two years ago had a slight numbness and very slight diminution in power in the right arm and leg accompanied by quite transient loss of memory. He unfortunately discovered that he had an increase in blood pressure and acquired the sphygmomanometer habit, coming to me at frequent intervals to record his blood pressure. In fact at one time the systolic pressure rose to 210 mm., but has since then not exceeded 180 mm., and he cannot be persuaded that he is not doomed to hemiplegia. He is neither syphilitic, gouty, nor alcoholic. The kidneys are normal and he is really in excellent health. I do not suppose any insurance company would consider rating him in view of such a history, and he may yet die from an apoplexy, but I have felt justified in trying to assure him to the contrary. This case is typical of many which present great difficulty in prognosis, but I have been inclined to regard it as belonging to the group of transient toxemia cases, above described, with possibly an arteriospasm. The fact that his only vice is overindulgence in rich food lends support to this view.

It may be stated with regard to hypertension that patients in whom the diastolic pressure remains low are in much less danger of hemiplegia than the opposite group.

A very puzzling matter to be certain of concerns those mild attacks which may or may not prove the forerunners of apoplexy or hemiplegia, and this again is a subject one is liable to be cross-examined upon by both the patient and the anxious family. The following history is typical of a condition frequently regarded as a definite warning of what is popularly called a "stroke" soon to be followed by fatal termination:

A woman of seventy-eight with decidedly sclerosed arteries, slight corneal opacities in both eyes, and other evidences of senility, became suddenly confused, asking the same questions four or five times in succession. When I saw her she complained of feeling dazed and repeatedly passed her hand before her face as if to brush aside a veil. On being questioned she said the room looked natural and she recognized persons, calling them correctly by name, but she felt estranged and memory was much impaired. She had a very dazed searching expression, like one suddenly blinded, and speech was slow and thick. There was a slight deviation of the tongue toward the left. The pupils and all reflexes were normal and there were no sensory disturbances. After four or five hours the attack subsided, although it was not until the following day that the mental confusion wholly disappeared. Systolic pressure was 210, and obstinate chronic constipation had long been present.

This case seemed more like the forerunner of apoplexy than the preceding one, mainly on account of the evidences of senility and the marked arteriosclerosis, but more than fourteen months have passed and the patient has remained in excellent health. There may have been an arteriospasm, or possibly a miliary hemorrhage, or the attack may have been purely toxic, and yet I think one might more decidedly anticipate an apoplexy than in the preceding case.

In still another example of this symptom complex the patient was twenty years younger. After three or four attacks of sudden mental confusion in which, while at the dining table, he suddenly began to repeat the last word he was speaking and then stopped conversation altogether, having a vacant stare, he finally had an attack of coma lasting twenty-four hours. In this case the urine presented the picture of a sclerotic kidney and there was a tendency to intestinal obstruction with great abdominal distention. But two years have passed without the occurrence of any genuine apoplectic seizure.

The instances of hemiplegia which are clearly embolic as a sequence of vegetations upon the mitral value when non-septic at the time of impaction are not necessarily immediately fatal, and the chief danger lies in repeated attacks.

I saw a woman forty-six years of age who six years before had acquired a complete right hemiplegia without loss of consciousness, yet she entirely recovered by the end of a week. In girlhood she had had a rheumatic endocarditis which left her with a serious mitral lesion and decided compensatory cardiac hypertrophy. When I saw her six years after the first hemiplegic attack she was again hemiplegic upon the same side as that originally affected. She passed into coma immediately and died in thirty-six hours from pulmonary edema.

I do not believe that one who has had an embolic hemiplegia of such origin can ever be regarded as free from the liability of an ultimate fatal attack, although, as in the case just cited, the interval may be prolonged. However, when one considers the large number of cases of serious mitral lesions which there are, the wonder is that embolic hemiplegia does not more often result.

In the syphilitic cases of cerebral thrombosis which do not yield to neosalvarsan, and especially when complicated by alcoholism, the prognosis is uniformly bad. I saw lately a man 30 years of age who had had six neosalvarsan treatments without benefit. He had been drinking more than a quart of whiskey a day. One evening his masseur called to treat him but found him alone in his hotel room in a coma which he mistook for an ordinary drunken fit so he left him. Everything in the room was in disorder, with glasses broken and furniture overturned, and the patient's body was bruised from head to heels, in evidence of previous maniacal delirium. When I saw the patient next day he had a complete left hemiplegia. The systolic blood pressure was only 130 mm. and the spinal fluid was negative. There was Cheyne-Stokes respiration with a temperature of 104°, and in a few hours the man died.

Writers upon hemiplegia while entering fully into minute pathological descriptions of cerebral hemorrage, embolism, localized edema, thrombosis, and obliterating endarteritis, usually pass over very casually the question of arteriospasm of the cerebral vessels, causing temporary localized cerebral block. Necessarily this is quite empirical, as the cases are not fatal, being capable of neither postmortem nor

experimental demonstration. Yet some explanation is needed of the very transient duration of many cases of definite hemiplegia or of partial attacks which affect only the facial, ocular, and lingual muscles with mental disturbances. The absorption of a clot from either a hemorrhage or thrombus can scarcely be rapid enough always to account for the prompt recovery, and it is similarly questionable whether collateral or anastomotic circulation could become adequate in such brief periods of time. Moreover, it is difficult to conceive how mere toxic interference with brain function can produce such well-defined localization without the aid of mechanical interference with the circulation which arteriospasm implies, and this, compared with the analogy of arteriospasm elsewhere in the circulation, such as is claimed in explanation of intermittent claudication, etc., must constitute the chief basis of the argument.

At all events, this conception is a fairly satisfactory one for the physician, and it may be used to afford great relief to patients who are terrified by the dread of genuine apoplectic seizure. There is one other possible explanation of the curiously transient yet very definite attacks of hemiplegia, and that is pressure from a localized cerebral edema of toxic origin which, being capable of more prompt reabsorption than a blood clot, restitution of normal function quickly ensues. It is also conceivable that certain brains, more readily than others, from some minute anatomical difference, develop prompt compensation, so that when particular fibers or cells are put out of commission, either through sudden interruption of the circulation which supplies them or through localized pressure, others soon take over their temporary function for them.

In this connection I may refer to the very interesting localization of a brain lesion due to a definite toxemia which has so often been observed in fatal cases of carbon monoxide poisoning that it may be regarded as pathognomonic. In six out of nine fatal cases of illuminating gas poisoning which I have elsewhere reported, the brain showed marked generalized congestion of the white matter, pia, and arachnoid, the cerebral arteries being greatly congested, and, in addition, in those cases in which the patient lived long enough for it to result, there was softening of the lenticular nucleus which, as Otto H. Schultze has pointed out, is due to the peculiar curvature of its nutrient vessels in which thrombosis frequently occurs. None of these patients in this series was hemiplegic but the autopsies illustrated an interesting brain localization of the effects of toxemia.

Where experimentation and post-mortem demonstration must necessarily be lacking, the field is still open to cumulative clinical experience and impressions, and it is from the latter point of view that I have given these illustrations, the main conclusion being: First, that clinical definite transient hemiplegia is of frequent occurrence in middle life without necessarily implying the existence of any threatening permanent deterioration in the cerebral circulation. Second, that patients are not invariably foreordained to genuine apoplectic stroke through either heredity, excessive hypertension, or the occurrence of transient hemiplegic symptoms.

142 East Sixty-second Street.

TREATMENT OF GONOCOCCAL INFECTION IN THE FEMALE.*

By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S.,
NEW YORK.

The treatment of any disease depends on a correct diagnosis. In no affections is this more important and in few is it equally as momentous as in venereal infections. The frank cases cause little doubt but there is hardly a just measure of the difficulty in the masked forms of gonococcal disease. In taking the history no respect of persons must be had because any person of the community may have acquired the disease innocently or immorally. The establishment of infection in fact and in form is the first essential because nongonococcal cases are often as difficult as the gonococcal cases. Luys on the subject of nongonococcal organisms says that the most important are the streptococcus, staphylococcus, pneumococcus, *Micrococcus fullax, Micrococcus pyogencs aureus, Micrococcus cereus albus, Bacillus typhosus, Bacillus coli communis, Bacillus diphtheriæ, Bacillus tuberculosis,* and various sarcinæ. To these may be added the influenza bacillus, pseudodiphtheria bacillus, *Micrococcus catarrhalis, Treponema pallidum,* and bacillus of Ducrey. Norris gives the following six Gram-negative cocci: *Micrococcus catarrhalis, Micrococcus intracellularis* (meningococcus), two forms of coccus from nasal discharge in Hartford's case of influenza-like epidemic, another coccus from the urethra (unidentified) and the *Micrococcus melitensis* (Malta fever). From this it will be seen that the accurate diagnosis of gonococcal infection is not easy. I believe that in the female at least eight slides should be taken in pairs from the urethra, vulva, vagina, and cervix.

The second set of four slides controls the first set. Cultures are of supreme importance. Cultures cannot be omitted if real accuracy is aimed at. Reimplantation is often required to prove the exact nature of the infection. As in diphtheria of the throat, the local condition may be very favorable but the possibilities of the dormant organisms are very great if they are of nocuous type.

The most favorable time is during the congestion just before and just after the menses, because organisms in the depths of the mucosa are more apt to appear on the surface than when the parts are quiescent. If douches have been taken by the patient they should be stopped for forty-eight hours before the specimen is taken. Pressure on the mucosa with a blunt instrument, such as a hairpin in the urethra or a dull curette in the fornix and cervix, will often express a good specimen.

A few years ago I noted the following in literature but have not been able to trace it. If any hearer or reader of this paper knows of the correct reference I shall be glad to receive it. The French took a number of prostitutes, examined them for infection and found a small number apparently free. These negative women were then subjected to intercourse. The men wore covers so that infection from them was impossible. Immediately after the intercourse another examination showed many of these women to be infected because the congestion

*Read before the Alumnæ Association of the New York Medical College and Hospital for Women, December 16, 1921.

of intercourse had brought the gonococci to the surface. This important observation shows how difficult it is to make a final diagnosis from specimens alone and also how one man will escape infection and another receive it from the same woman a short time apart.

An interesting case in private was that of a young woman who on her return from Europe accepted the sexual embraces of her fiancé who a few days previously had become infected by another woman. Of the eight slides taken, only those from the urethra contained the gonococcus which was destroyed by proper abortive measures. The girl had had an old injury of the vulvovaginal gland on the right side which caused physical inconvenience. After the gonococcal infection was destroyed the gland was dissected out and examined and found to be free of gonococci. In this case the absence of all acute symptoms in the gland ruled out gonococcal infection, although my staff were of the opinion that such might nevertheless be the case until the microscope proved otherwise.

The difference in diagnosis between the female quiescent or excited, is revealed by the following case: A shop girl infected a man who was supporting her very soon after their liaison began. Eight slides were taken. Only the urethra was apparently involved. She menstruated in a few days. Eight slides then prepared revealed the gonococci in the cervix and cul-de-sac, although active treatment had been given. She did not have acute disease but chronic disease, masked except directly after menstrual flow and during intercourse, because the normal congestion of each of these processes brought the gonococcus within reach of the examining instrument.

There are certain clinical facts about cases which predominate over microscopical findings, at least until one or several reexaminations are made. On this basis I recently disputed the diagnosis of gonococcal infection in a young woman who had given birth to a child two weeks previously. A discharge developed which was said to contain the gonococcus but the clinical progress of the case was such that the condition could not be the gonococcal. I think one should be very cautious about giving an opinion when the clinical and the microscopical factors do not agree.

In another case venereal excesses were denied by a girl engaged to be married. I saw her in the midst of a gangrenous appendicitis, operated and found a double pus tube as well as the appendix. The right tube was as large as the adult thumb and the left as large as a lead pencil. Both were nonadherent but exuded typical gonococcal pus. There was little vulvovaginitis. The facts were probably that, having been in the Bedford Reformatory for Women, this girl knew how to keep her vagina and vulva clean but could not prevent extension of the process upward. Later it was found that the cervix and fornix contained the gonococcus. Here the clinical conditions prior to the operation were deceptive but at operation no question of the lesion remained.

Another postpartum case was accused of gonococcal infection and about to be discharged from a nursing home in disgrace. Because the disease had not run like wildfire into the uterus, tubes, ovaries, and peritoneum I decided that the case was probably not gonococcal. Six slides and four cultures proved that the discharge was due to an overgrowth of ordinary organisms. On account of the patulous cervix I omitted its specimen lest penetration of it might also infect it.

A woman of refinement had become inoculated by a clubman who was suffering from an old infection supposedly cured. There were hardly any clinical suggestions of the disease because the patient was seen so early. Suggestive subjective symptoms prevailed on me to make numerous smear and culture specimens which proved the woman to have the incubation period of urethritis. It was stopped by proper abortive measures.

These cases show the need of simple common sense in making and interpreting specimens and serve to introduce the importance of the social aspect of the disease. The diagnosis is so important that it can never be slighted and that it places on each physician the moral obligation of putting himself into the position of the patient. No error will then be invited by carelessness. If the disease exists it must always be known at least to the physician and in most instances to the patient.

The medicolegal aspect is another important phase. The followup systems in hospitals and the welfare work of social agencies at the present time is bringing lay-workers into contact with the venereal disease secrets of individuals and sometimes families. It becomes necessary to draw the line strictly between such information or part thereof which belongs to the official records of the case in the hospital or social agency and that which must remain professionally sacred. In point is the young woman, just noted above. The social worker in charge of her case wished to tell her future husband of the existing gonococcal disease. I convinced her that her duty and our duty consisted solely in relieving the patient of the operative and nonoperative results of the disease and that all moral obligation toward her future husband was her own. We could not possibly interfere with it any more than we could possibly betray her on the witness stand unless the girl under oath had waived her rights to professional privilege. I hope that the social worker obeyed my injunction not to converse with the fiancé unless she previously obtained the girl's consent under oath before a notary. I added that it would be better to have the interview in the patient's presence, and best of all to have her talk with the man herself in the presence of the social worker.

Treatment is preventive as a sociologic method and abortive or curative according to the age of the infection. The preventive measures are largely educational. Perhaps the most difficult lesson to impress is that no matter how fine looking and attractive a man may be he is not safe because these very characteristics make him much more apt to be sought after by women of all classes. I find it very difficult to teach young men that the pretty women are almost sure to be infected. Young women will not remember that the man who seeks them sexually is rather sure to have done it with other women of whom any one may have infected him. Conversely I find it almost impossible to have the young men understand that the girl who accepts one man

sexually is almost sure to have had a number of others, any one of whom may have infected her. Lastly it is difficult for the community at large to understand that this biological equality of the sexes exists. I am of the opinion after many years of practice in this field that only one thing makes the average woman less promiscuous than the average man and that one thing is fear of pregnancy.

I have often been asked the question "Is venereal disease increasing?" I do not believe that it can be answered because there are so many factors to influence final judgment, but I am morally certain that clandestine intercourse is rapidly increasing. There are several reasons. The birth control campaign is rapidly removing the aforesaid fear of pregnancy and prophylactic measures are rapidly dispelling the dread of venereal disease. Civil conditions are such that young people are required to wait for marriage until they are nearly thirty instead of uniting in marriage about twenty. It is not thinkable that many accept in sexual idleness the loss of the best years of their sexual life, namely those between twenty and thirty. On this point a shop girl, herself the common-law wife of a decent man, told me that she believed that fully 75 per cent of shop girls were guilty of clandestine sexual life. I am rather inclined to agree with this opinion whose terms do not mean commercial prostitution.

The chemical means of birth control are being handed about from woman to woman in a way that is appalling. Only this month I examined the wife of a college friend who used such means for the first few years of married life. A friend had passed her own prescription along to her. She has remained childless, so far as I can see only because she has induced a hyperacid chronic vaginitis. Whether I can ever restore the mucosa to its natural condition remains to be seen, but among other things I told her that she had only herself to thank for her state. I am old fashioned enough to stick to the doctrine that people who do not wish to accept parentage in the normal way should not get married. They will then leave that much more opportunity for men and women who have a better viewpoint. I have no polite language in which to condemn birth control, partly because it is adding materially to sexual immorality.

It is well to teach the young women as I teach the men that none of the well-known chemical means of avoiding infection is infallible. The infection may be drawn into the uterus before the application is made. Nearly every specialist sees gonococcal infection of the cervix which apparently precedes the disease elsewhere. There can be no other explanation. Must of these chemical measures are used in overdose: too strong, too frequently, or too roughly. Vaginitis ensues which is as hard to cure in some patients as the infection.

There are at least two forms of prevention—one concerns the patient (as already briefly stated) and the other society. The patient must receive written or printed instruction concerning the dangers to her eyes from infected fingers and the dangers to innocent persons, especially children, from the same source. No matter what the quality of woman may be she must be instructed about the absolute unfairness of having intercourse until she is known to be cured. Therefore wives who have erred from the path of virtue, business women who are practising clandestine relations, and professional or semi-professional prostitutes all fall within the same category requiring the same instruction. In the last analysis society loses as much through an infection of the male as it does through an infection of the female no matter what the circumstances of said infection may be—innocent in wedlock, more or less innocent in perhaps a real love affair, or guilty in a purely commercial relation. I do not believe that the average woman will ever see the problem in exactly this light, no matter what her social standing may be, any more than the average man is able to see it, so far as my efforts at instruction have indicated.

Under prevention must be classed the all-important detail of reaching and curing the carrier. Almost insurmountable barriers cross the path of this scientific duty. Of course women cannot tell who infected them among several lovers any more than men can answer the same problem. The family doctor of the carrier is in duty bound to pronounce his patient "all right." Sad to relate, he often does so in ignorance bound because his diagnostic technic is very indifferent or inadequate. His diagnosis is all too frequently of the snap type.

The woman does not wish to betray her lover in any way. A reversal of chivalry occurs in which the man is the object not the subject.

It is the duty of every physician, in my opinion, in public and in private work to endeavor to reach the carrier because he is often guiltless—in the sense that a "quick, sure cure" treatment has been given him without any bacteriologic diagnosis of the exact nature of the infection, or a bacteriologic decision of his cure. This repeats exactly the circumstances in women said to be well who infect large numbers of men.

At a recent clinical meeting two men with gangrene of the skin of the penis were shown and fully discussed. When I asked what effort to reach the woman responsible for the disease had been made, the answer was none. My rejoinder was that in the cure of the men without reaching the woman hardly half the professional duty toward society had been done. I never expect to alter that opinion. It may be a generation ahead of the times, but it is the coming opinion if the medical profession is ever to gain control of veneral disease.

Under the heading of prophylaxis falls the proper concept of what constitutes a "cure." This is noted in the last part of this paper.

The abortive treatment requires application within twelve hours after possible inoculation. I remember one patient of the ultrafastidious class who was such a fool that she would leave her husband for six months at a time and then expect him to stay faithful. It never dawned upon her mind that she was basically and primarily unfaithful to him in leaving him. He became inoculated as part of a college celebration. Soon after her return, after several months' absence his wife requested intercourse, a thing which she had never before done. The man tore the cover he used and brought the woman to me about twelve hours later. I aborted the infection. Part of our social duty is to teach women that they have no right to leave their husbands many months at a time.

The chemical formula for abortive treatment is not important provided it is a recognized true antiseptic without great irritating power. I place a firm reliance on older pharmacopœial drugs in preference to the newer semiproprietary and proprietary preparations. The main difficulty is to have patients remember and follow warnings to continue this treatment for at least five days, because they represent half the ordinary incubation period.

In the female there is no sealing-in method as in the male, but light tampons soaked in appropriate medicine are a good substitute.

As in the male, I doubt if it is wise to paint the vulva and vagina of a suspected case with strong silver nitrate. The reasons are alike in both sexes. One may not reach all the infection. The reactionary inflammation becomes a wonderful soil for extraordinary extension of the disease.

In the curative treatment there is no single quick cure or sure cure remedy. In my opinion the greater science leads away from proprietary and semiproprietary remedies and impresses the value of older drugs. Antiseptic douches must be frequent, copious, hot, and retained. Their strength must not be irritable to the normal mucosa. Such douches are better than douches infrequent, scanty, lukewarm or cold, and concentrated and irritating. Lying down is the only position, and the douche should be followed by rest on the back for thirty minutes. I therefore prefer hot potassium permanganate, 1 in 8,000, increasing to 1 in 4,000, four times daily one or two gallons at a time, 110 to 115 degrees Fahrenheit within tolerance. A long douche nozzle reaches the utmost limit of the vagina. The fifteen to thirty minute rest on the back for retaining the douche is analogous to holding the hand injection in the male urethra for ten minutes. But how many business women clandestinely infected can carry out these steps? How many married women about whose infection there is suspicion can do it? We are all familiar with the irremovable obstacle comprised in the struggle between civil conditions and professional requirements. What millennium will be ours if we could only carry out treatment with total disregard of civil conditions. If the disease is well established I have been told that under an anesthetic the vagina may be painted thoroughly with 10 per cent. nitrate of silver. Most women whom I see either have the disease too early or too late for this step, namely a mild vulvitis has begun suggesting the wisdom of not causing an active chemical inflammation or a cervicitis is present from which reinoculation of the vagina would occur if this silver nitrate wash were to succeed.

In the uterine lesions, cervix or body, mucosa or muscularis, the more serious forms appear. Rest in bed is desirable but rarely possible in vaginitis, but it becomes essential in upward extensions. No measure will definitely limit the disease from such progress on account of continuity of mucosa until even the tubes, ovaries, and peritoneum are involved. Expectant measures give the best results and excite the fewest later complications. Antecedent urethritis, vulvitis, and vaginitis must be included in the measures.

Gonococcal cervicitis must be distinguished from syphilitic, chancroidal, neoplastic, and tuberculous forms. Space eliminates the familiar details. In the management of these cases absorption must be prevented or controlled and good health maintained or restored, otherwise the case will be obstinate. Abortive treatment is possible only in early superficial cervicitis and consists of an antiseptic bath through the Ferguson speculum after mopping the mucosa clean. The curative measures apply chiefly to the chronic stage because little can be done in the acute stage. Clinging discharge and granulations are removed down to the bare mucous membrane foci of the disease. Instillations and applications are much safer than injections, augmented by tampons. Granulations require caustic and curette and cysts incision, drainage and mild caustics.

Endometritis must be diagnosticated from tubal disease and suppurating fibroids and other suppurative infections of the linings. The expectant management with ice bags, hot douches, perhaps in the sitting posture to avoid penetration is best. According to the position of the uterus, the patient may sometimes be placed in various postures so as to facilitate drainage. Not much else may be done until the chronic stage, when two things must be accomplished—drainage and the restoration of the lining to a healthy condition by the gentlest available measures. Curetting is done at the present time less frequently than in former times.

Tubal and ovarian complications are almost the last step in the progress of the gonococcus inward. Localized peritonitis is almost always present. More extensive peritonitis is not part of the purpose of this paper and will be therefore omitted. Gonococcal salpingitis must be recognized as different from catarrhal and tuberculous forms and from cystic ovary, solid tumor of the tube, extensive pelvic cellulitis, tubal pregnancy, and appendicitis. Acuteness, chronicity, and complications determine the forms of treatment. The patient is always sick enough for bed and is comforted by hot or cold water bags, coils, or douches. It is said that frequent changing of the posture of the patient may prevent adhesions. Opiates are required for pain, and elimination is indicated through bowels, kidneys, and colonic irrigation. Serum therapy is still in doubt. Operation is to-day almost always postponed until subsidence of all symptoms and then conservative measures have supplanted the radical ideas of twenty years ago, so that as much as possible of tubes, ovaries, and uterus are not sacrificed.

The foregoing sketchy remarks indicate that the older methods have not changed, chiefly because they cannot be improved each in its own particular sphere, but with the development of better electrical generating apparatus and better electrical instruments for applying the current, electrotherapy is to-day demanding more and more attention and is receiving more and more respect.

There are a few basic principles which are altogether too often neglected. The patient must not be hurt or frightened; electrotherapy must be employed to augment all other measures and not necessarily to supplant any; the current must produce profound circulatory effect of creative character and it must be opposed to the circulatory condition of indolent character due to the disease; the modalities must be varied so that similar circulatory effects will be produced through somewhat different influences; and finally the electrotherapeu-

tic measures must leave no evil aftereffects. If these simple principles are obeyed little trouble will be encountered.

For the maximum results the treatment must continue for not less than twenty minutes, preferably thirty minutes and often forty-five minutes. Their frequency must vary from every day to once a week, according to circumstances. Their potency is to be measured by clinical results rather than by meter alone. In general it is probable that there is little choice of current provided the circulatory influence just spoken of is obtained. I am convinced that in some patients a particular current will be of greatest value, contrary to the average experience or clinical expectation. For example, I have two male patients each with prostatic disease. The one finds great benefit from diathermy and the other from sinusoidal combined galvanism and faradism. In each the results are about equal. I cannot explain why currents so different should produce equal results in about the same character of disease.

In urethritis, vulvitis, and vaginitis the glass electrode adapted to the part is serviceable. Its vacuum should nearly equal that of the standard *x*-ray tube in order to obtain maximum actinic effect. The correct tube gives a bluish white fluorescence and the incorrect tube a reddish blue or bluish red. Helium gas pumped into the tube after the vacuum is said to increase its efficiency. When properly applied, the actinic effect will aid in destroying the infection, in allaying congestion, and in decreasing bleeding. These tubes are best activated from the negative pole of a 16-16 high speed static machine, with spark gap 1 inch and I milliampere of current. The positive side of the machine must be grounded. It is possible to alternate the high frequency current with the static current resulting in a more heating and a less actinic influence.

In the uterine complications during the acute stage the *x*-ray obtained again from the static machine is of value, alternating with light as a decongestant of the deeper parts and a corrective of the irritation of the skin. The value of *x*-ray produced in this way is high penetration, deep actinic influence, and little burning power of the skin. The best tubes back up a spark gap at least 5 inches, which with the accumulating ball electrodes, is equivalent to a 10-inch gap in the ordinary *x*-ray induction coil machine. From 2 to 2^1_2 milliamperes of current are used. Therefore during thirty minutes of application the patient receives 60 milliampere minutes under a voltage which is said to be not far from 127,800 by Harris and Riess, independent and competent observers, using a 15 centimeter gap and balls 0.866 inches in diameter.

In the chronic uterine lesions drainage is secured by opening the cervix with the native galvanic pole using a current of 5-10 milliamperes for a few minutes, until the cervix relaxes around the instrument. Then a larger one is used until the cervix admits one a quarter-inch in diameter and drainage is free. A granulating mucosa is easily removed with a light packing of 10 per cent. zinc chloride solution over night. Thereafter applications are made with the positive pole wound with cotton, dipped in mild strengths of such electropositive elements as zinc and copper. The negative pole must be used with such electronegative elements as iodine, chlorine, and the radicals of salicyclic acid and sulphuric acid. For subinvolution and allied conditions diathermia is of great value, using 750 to 1200 milliamperes within tolerance. Electrodes of equal size must be employed, otherwise a burn may be made at the small electrode. One electrode is placed on the abdomen and another on the buttocks. A third may be placed in the vagina, connected with either of the other two, or the other two may be connected together. X-ray treatment is greatly augmented if diathermia is used before it in this manner. Likewise diathermia will augment other treatment. If spasticity is present diathermia tends to relax it and if the muscular coat is atonic it tends to restore it.

The tubal and ovarian and peritoneal complications require about the same electrotherapeutics as the uterine. Although much progress has been made in electrotherapeutics within recent years it is certain that still greater progress will be made in the ensuing years of the present generation through improvement in apparatus for producing the current and instruments for applying these measures.

I trust that at least some of the straws scattered in this paper will point the direction of the scientific wind of the present time. Undoubtedly a larger and larger number of specialists are beginning to realize that operations are not unmixed blessings, and further that they are the last resort and no longer the first resort.

I have personally had two interesting tubal cases recently. A nineteen-year-old girl had been impregnated illegitimately and later infected with gonorrhea. After the baby was born she had rapid onset of uterine and tubal conditions. Fortunately they were relatively mild. In a person so young operation was out of the question unless totally unavoidable. I gave her the foregoing treatment and had the pleasure of seeing the infection in the tube on the right side almost totally disappear and the tube on the left side evacuated spontaneously into the uterus. When last seen the girl still needed treatment but these two successes had made her wonderfully better than at any previous time, and vastly better than any operation could possibly have left her. Since this paper was read, this patient has reappeared at my office about 4 weeks pregnant.

Another woman had had one pus tube and ovary removed and had a certain amount of uterine disease left behind. She did not desire any more children but she wished relief from the chronic discharge. After about three months of the same treatment practically all discharge had been eliminated. Then to my surprise and her own unspeakable annoyance she conceived again. She was uncontrolled in her anger when I refused to induce an abortion because she held my treatment responsible for the pregnancy. She put me into the position of the Presbyterian salvation. I was foreordained to be damned if I did and damned if I didn't.

A statement of the standard of cure has a prophylactic value as well as a restorative value. The destructive quality of the gonococcus makes complete cure in the sense of restoring the mucosa more or less universally to its former normal condition almost impossible. Nevertheless, a physiological standard of cure is fortunately in a great number of cases possible. This should be aimed at to the

limit of our own ability and the willingness of the patient to follow advice. Of course bacteriological cure is always to be reached in terms of destruction of the gonococcus or its allies as revealed in many tests by smear and culture made at various intervals and under different conditions such as before and after menstruation, after intercourse if practicable and sometimes after mildly irritating applications. The disease as a bacteriologic manifestion must be abolished. It nearly always is. Failure usually follows the ignorance and disobedience of the patient rather than indifference of the physician.

45 West Ninth Street.

ANTISEPTICS IN THE TREATMENT OF INFECTED WOUNDS.

By RICHARD J. BEHAN, M.D., F.A.C.S.,
PITTSBURGH, PA.
SURGEON TO ST. JOSEPH'S HOSPITAL.

Before the Great War, treatment of wounds was usually directed towards rendering them free of débris and the removal of the discharge which had accumulated. During the war the pendulum swung back again to where it had been years previously, and the value of active antiseptic treatment of infected wounds was thoroughly demonstrated. In the treatment of infected wounds, as in the treatment of every other condition which occurs in medicine and surgery, it is well to thoroughly understand and appreciate the principles upon which the curative measures are based. As at present the antiseptic method of wound treatment is most in vogue, it might be well to review as briefly and as concisely as is compatible with thoroughness, the means by which bacteria are destroyed. I shall then review the mechanical, physical, and chemical methods which cause destruction of bacteria.

Among the mechanical methods may be grouped those which cause a thorough eradication of destroyed and devitalized tissues, with their contents of bacteria. These measures include scrubbing, excision (under the form of débridement) and active scraping away of harmful tissues. Among the physical methods are those by which the physical properties of bacteria are interfered with, or by which destruction of bacteria is caused by changing the osmotic relationship existing between the bacteria and the surrounding media. This activity is manifested in two ways: First, by plasmolysis and second by plasmoptysis. Under the physical methods we must consider the destruction, including the destruction by heat or cold. Under the third variety of bacterial destruction, that is, the chemical, we may include digestion by ferments or the destruction by chemical agents of one kind or another. Under chemical, we classify the nutritional changes which may take place in bacteria and lead to their destruction.

With the above brief indication of the methods of bacterial destruction, we shall now consider the destruction of bacteria more in detail. First, the destruction by plasmolysis and plasmoptysis and then, as we advance, further methods and more definite means will be defined.

To aid in the elucidation of antiseptics we may recall that bacteria are destroyed by:

I. *Plasmolysis.*—Should the solution surrounding bacteria be of a higher osmotic tension than the contents of the bacteria a dissolution of the bacterial protoplasm takes place. This reaction is termed plasmolysis. Because the molecular weight of the fluid outside the bacterial wall is greater than that inside the cell wall, in order to equalize the weight, fluid passes out of the bacteria into the surrounding media. The water passes from the cell through the cell membrane more easily than do the contained salts. Consequently the protoplasm retracts from the cell wall and protoplasmic devitalization, and even death, results. The following facts may be of interest, namely: (*a*) Old bacteria plasmolyse more quickly than young bacteria. (*b*) Gram stained bacteria cannot be plasmolyzed and contain more water; however, (*c*) Gram stained bacteria are easily digested in the gastric juice. Gram positive bacteria are (*a*) *tubercle bacillus*, (*b*) *Pneumococcus* of Frankel, (*c*) *streptococcus*, (*d*) *Streptococcus erysipelatis*, (*e*) *Staphylococcus aureus, albus, vitreus*, (*f*) bacteria of hog cholera. Because of these facts and the well-known resistance of living cells to digestive ferments, it may be possible in the above type of infections (Gram-positive bacteria) to combine an antiseptic with such a digestive ferment that the activity of either will not be neutralized by the other. As yet no such combinations have been devised.

In this connection it is well to remember that vegetable cells are very rapidly killed by 1/5 normal sodium chloride solution which is saturated with iodine. However, in this case, plasmolysis does not occur, for the iodine enters immediately into a chemical reaction with the surface layer of the protoplasm and abolishes its semi-permeability for the sodium chloride. On the other hand, one may produce plasmolysis of bacteria with this very same solution, if sufficiently weak in iodine, probably a ½ per cent. solution (A. Fischer). In this strength the iodine penetrates more slowly through the external membrane of the bacteria (Wells, p. 499).

II. *Plasmoptysis.*—A lower osmotic tension in the surrounding tissues causes fluid to pass from the cell into the surrounding media with the consequence that the cell contents swell, until the cell wall gives way at some point, then the contents exude as glistening drops which may become detached from the wall and escape free into the tissue juices. Not all bacteria can be made to undergo this change. Bacterial spores are so well protected by the membrane surrounding them that they are not affected by sodium chloride solution, distilled water, or concentrated alcohol. It requires days for a 4 per cent. carbolic solution to kill anthrax spores, while adult bacteria are killed in from two to ten minutes by a 1 per cent. solution corrosive sublimate. A 1 per cent. solution kills anthrax bacilli in ten minutes, but for the spores it requires two hours. (Wells, p. 499.)

III. *Digestion by Ferments.*—The digestive action of ferments (trypsin, etc.) and blood sera may recommend them as of mild antiseptic value in some cases. Müller and Gergo believe that methods of treatment in which digestive ferments are used are especially indicated in abscesses of the soft parts with the exception of the following: (1) A disproportionately large abscess; (2) those of deep loca-

tion; (3) in great weakness of the patient; (4) when the abscess is of an inflammatory tuberculous origin. Also, if there is no abscess, only a diffuse inflammatory infiltration, the antiferment treatment is of no value. Trypsin digests Gram-negative bacteria. Gastric juice digests Gram-positive bacteria. One per cent. potassium hydrate dissolves only Gram-negative.

IV. *Chemical Toxic Substances (Bactericides).*—If from the surrounding media a chemical toxic substance enters into the bacteria, death occurs. Such a chemical destructive agent is called an antiseptic. Its activity depends upon (1) its solubility in water or other suitable media. This is a determining factor. As a rule, the more soluble in water an antiseptic is the greater is its bactericidal power. Since bacteria are colloids and lipoids suspended in a soft medium containing different salts, therefore the antiseptic power of a substance varies according to:

2. Its solubility in the lipoids of the bacteria, when it is exhibited in the form of (A) organic combinations of mercury, iodine, bromine, chlorine; or (B) organic disinfecting media, such as phenol, cresolin, and alcohol*; preparations which are easily soluble in lipoids; (C) organic acids as acetic and formic acid; (D) alkalies as ammonium hydroxide.

3. The activity of a bactericide depends also upon its power to coagulate protoplasm. Coagulation may be produced by haloids, as iodine, bromide, chlorine; by corrosive metals, mercury, etc., by acids, as picric and osmic acid and by strong alkalies. Iodine vapor penetrates the bacteria the easiest and gives excellent antiseptic results. Mercury is the best of the soluble coagulating media at hand. One per cent. solution of the bichloride kills in a short time all varieties of pathogenic organisms. A dilution of from 1-100 to 1-500 will kill in a few hours, even the spores of anthrax. Usually an equal part of sodium chloride is used with the mercuric chloride, because the sodium chloride hinders the coagulation of the albumin by the corrosive and renders possible the permeation of the mercury deeper into the tissues. In old wound secretions there are formed small coagula, but these quickly dissolve as double salts of mercury albuminate and sodium chloride. The usefulness of mercury is limited, because in weak solutions it injures the tissues locally and in concentrated solutions, through absorption, it injures the kidneys and intestines, and the central nervous system. Silver salts are stronger antiseptics than mercury. They form a union with albumin. The soluble organic silver salts, as argonin and protargol are very active and serve as disfecting media for mucous membranes.

Antiseptics which act by disassociation or coagulation of the protoplasm may be classified as follows:

A. Salts of the heavy metals, as calcium in the form of quicklime, iron, copper, lead, silver, bismuth, zinc, arsenic, mangan, etc.

B. Inorganic, as nitric and sulphuric acid, which are not directly used as antiseptics: Sulphur dioxide (SO_2) was long used as a room disinfectant. Picric acid, which is very useful in the first dressing of wounds, where it seems to reduce greatly the tendency to infection: Chlorine in the form of acids or of salts acts very efficiently. The best known of these is the hypochlorite in the form of Dakin's solution, chloramine or dichloramine. Part of the effectiveness of the chlorine derivative is due no doubt to their ability to react with proteins with the formation of soluble products. However, as shown by Reiman and Magoun, dichloramine-T, in 7½ per cent. oily solution, does not kill intestinal bacteria. The experiment was as follows: The sigmoid was cut across and the anastomosed end to end, without clamps. Feces were allowed to contaminate the peritoneum. Then 7½ per cent. dichloramine-T was dropped on the infected field. All the animals developed peritonitis.

C. Organic antiseptics, as iodine, bromine, formaldyehyde-hexamethy lenetetramine, aromatic chloramines, phenols, naphthols and derivatives (lysol, cresol, creolin), dyes, as malachite green, acriflavine, etc. (Dakin and Dunham.) Lambert according to Fowler (*Annals of Surgery*, lxvi, 55, 92) has shown that iodine alone of various antiseptics tested will kill bacteria rather than tissue cells. A growth of cells occurred after exposure to a 1-2000 solution of iodine for one hour, a strength sufficient to sterilize the tissues completely in most instances. This I have repeatedly demonstrated to my own satisfaction and have found the most efficient antiseptic for continuous application (clinically) to be iodine 0.25 per cent. in a hypertonic salt solution (hot).

4. The bactericidal efficiency of a substance also depends upon its power to cause "de-emulsification of a colloidal suspension of some constituent protein, essential for the stability of the organism," according to Dakin quoting Cooper (*Biochemical Journal*, p. 175, 1913). This is the manner in which phenols act as antiseptics.

5. Ionic disassociation of antiseptic salts in solution partly determines the antiseptic power of the exhibited substance. If the amount of free metal in solution is very great the antiseptic power is high. This power is exerted through the chemical reaction of the metal with the "protein or the other constituents of the bacterial protoplasms."

*Alcohol in concentration and dilution acts in two different ways: A. In concentration, *i.e.*, absolute alcohol acts by withdrawing water from the cells, in other words, causes death the same as does drying. The spores, however, remain alive. B. Diluted alcohol, on the contrary, is directly absorbed by the cells and causes death by its poisonous properties. Alcohol is most active in a percentage from 50 to 80. According to researches which I have made the greatest activity is at dilution of 50 per cent. A loop full of alcohol at this strength killed staphylococcic colonies plated on agar, at 98.6° F. The method of experiment was to take a loop full of an active staphylococcic growth and implant it on a agar plate. It was then incubated for two hours and the size of the colony noted. A loop full of alcohol (using different dilutions) was then spread over colonies of the same size. The plates were then placed in an incubator. After 12 hours a subculture was made. It was found that 50 per cent. alcohol had the greatest antiseptic activity. After its use, there was no increase in size of the colony and no growth from a subculture. Alcohol also, because of its penetrating power is an efficient vehicle to carry antiseptic media in solution. This was demonstrated by Seelig and Gouls. (*Surgery, Gynecology and Obstetrics*, 1911.) They also found that the higher concentrations of alcohol penetrated animal membranes more quickly than the weaker concentrations. Ether or benzine also act upon the lipoids. Since acid fast bacilli contain a high percentage of fatty matter, they are easily acted upon by the above antiseptics. Tubercle bacilli contain 26.5 per cent. fatty matter. (Wells.)

6. The activity of the antiseptic substance depends also on the media in which it is dissolved; as in watery solution an antiseptic or disinfecting substance possesses the strongest activity. If albumin is present in the surrounding medium (say blood serum), it forms a firm union with the antiseptic (if in the form of metallic salts) much quicker than does the albumin of the bacterial cells, and consequently reduces the activity of the antiseptic. In the presence of albumin, the antiseptic must be used in a more concentrated form than when it is in a pure watery solution. However, there is at least one exception to this: Acriflavine will kill in 1/10 the strength in the presence of serum that it will when the organism is suspended in peptone solution. Some of the salts of blood serum, such as the phosphates, precipitate the antiseptic, especially if it is a metallic salt. Phenol and kresol dissolved in oil have little activity. Heat stimulates the disinfecting power of practically all disinfectants. The presence of pus or of serum usually retards the activity of an antiseptic, in some instances as much as two hundred times.

7. The activity of a disinfectant also depends on its power of oxidation as is seen in hydrogen peroxide, which may act as a powerful antiseptic. The more nascent the oxygen the greater the oxidizing power and the stronger the antiseptic activity. Other chemicals, as those belonging to the chlorine group, also are strong oxidizers.

8. The greater the concentration of the antiseptic solution, the greater is the destructive action upon the invading bacteria, but at the same time the body cells and the leucocytes are destroyed in increasing ratio. However, antiseptics in the concentrations ordinarily used, exert but little influence on either the activity of the leucocytes or the vitality of the tissue cells.

9. The solvent action on necrotic tissue is also a factor of importance in reinforcing the activity of an antiseptic. Antiseptics which dissolve necrotic tissue are more useful in bad infections than those which do not have this power. If instead of dissolving the necrotic tissue, the antiseptics coagulate the proteids an impermeable coating may form over the infected area and under this coating a favorable nidus arises for the growth of anaerobic bacteria. Salicylates and mercuric chlorides in strong solutions form impermeable coatings and are not so useful in deep wounds. Hypochlorites and chloramines are more useful, since they dissolve dead tissue, but because of their evanescent character they must be frequently renewed. The activity of dichloramine-T is not reduced, when it is in an oily solution. For cavities in which frequent renewal of the antiseptic is impractical, a paste of bismuth, iodoform, and paraffin (B.I.P.) introduced by Morison, has been extensively used by the British Army. In all cases of injury the wound should be cleaned as thoroughly as possible by surgical means (all the dead or devitalized tissue being cut away) before the application of the antiseptic.

10. The effectiveness of an antiseptic depends to a considerable degree upon the length of time the disinfecting medium remains in contact with the infected tissue, and the thoroughness with which it comes into contact with the bacteria. In case of evanescent action, as with the hypochlorites, etc., the antiseptic should be renewed frequently, as by the Carrel-Dakin method of application.

11. The rapidity and effectiveness of the action of an antiseptic depends largely upon the penetrability of the capsule of the bacteria to the antiseptic.

12. Some antiseptics in weak solution, and others only in concentrated solution, render the external layer of the protoplasm impermeable to disinfectants. For this reason, it is very difficult for an antiseptic to penetrate into the bacterial organism. After it does penetrate the organism, its activity is measured by the rapidity with which it is dissolved in the lipoids. The quicker and the greater volume of the penetration, and the greater the rapidity with which it is dissolved, the stronger is the antiseptic. Spores are more resistant and have a membrane of but slight permeability, so that they are very difficult to destroy by chemical agents. Depending upon the above factors bacteria may be classified into (1) those which most easily penetrate the external layer; (2) those which are easily dissolved in the lipoid contents of the bacteria.

The measure of the activity of a disinfecting substance, therefore, depends upon its solubility in water or other media, upon its ability to penetrate the external layer of bacteria, and upon its solubility in the lipoids of the bacteria.

13. The activity of a disinfectant may be enhanced by combining two or more antiseptics. Two disinfecting media of moderate strength will produce a greater disinfecting action than will either alone, in the strength of the two. One of these media may act as a carrier for the other, or it is probable that disinfectants have different points of attack on different bacteria. For this reason, we may use the elective action of different disinfectants against different bacteria.

14. For the maximum action of an antiseptic a proper degree of heat is necessary. "With metallic salts the mean velocity of disinfection increases 2 to 4 fold for a rise in temperature of 10 degrees, while with the phenol it is as high as eight fold, using the *B. paratyphosus* as the test organism in each case." (Dakin and Dunham.)

15. The activity of an antiseptic may vary, depending upon the type of the infecting organisms. It is quite likely that a particular antiseptic may not act equally well on all organisms. This, at least clinically, has been my experience, for I find that in streptococcic infections I have better results with iodine ½ per cent. in hypertonic 10 per cent., or saturated salt solution than with the hypochlorites or the chloramines.

The use of bactericides is not of itself devoid of danger. Should the death of a great number of bacteria suddenly occur, large quantities of toxin may be liberated and produce an extremely harmful reaction in the body. In this connection, it might be well to recall that toxins of bacteria are of two types: endotoxins and exotoxins. The endotoxins found in the bacteria are liberated only on the death of the bacteria, because the toxin is incorporated with the protoplasm and is liberated only when the bacteria are killed. The exotoxins produced in the bacteria rapidly pass out during the life of the micro-organism into the surrounding medium and cause very severe and early symptoms. Tetanus bacilli, in 24 to 48 hours produce an in-

tensely active toxin in the surrounding culture medium. It is not possible always to verify the exotoxin-producing power of a bacterium by cultural methods, because many bacteria produce their poison only in the animal body.

In using a bactericide, it might be of importance to know the kind of bacteria and the type of toxin which they contain. It would be very dangerous in an infection in which the causative bacteria contain an endotoxin to use an antiseptic in which the bacteria are suddenly killed and the endotoxin is quickly liberated in what might be an overwhelming dose. Toxins may be decomposed by the action of certain disinfecting groups, especially the chlorine group. In addition to bactericides, bacteria may also be destroyed by a reduction of their nourishment. For their vital processes bacteria need: (1) Water, (2)oxygen as a rule, (3) organic substances and salts, and (4) a proper temperature.

1. *Water.*—Before the food supply for the bacteria is available it must be in solution in the surrounding media, therefore a suitable degree of moisture is essential. Should this be lacking bacterial growth is greatly restricted. A practical application of this principle is made in the treatment of gangrene, where an attempt to keep it dry is made by the application of dry heat in the form of the hot air blast, the hot water bottle, or the electric light bath. If the gangrene is moist, an effort is made to keep the paste dry by radiant heat from electric light bulbs by the application of dusting powders, etc. The removal of water from the tissues is also affected by glycerin and absolute alcohol.

2. *Oxygen.*—For their growth most bacteria need oxygen in some form, carbon dioxide, and nitrogen which is absorbed in the form of nitrates. Depending on whether oxygen as found in the air is or is not necessary, bacteria may be divided into (A) aerobic, which are again subdivided into obligate and facultative. (The obligate absolutely must have free oxygen, while the facultative can get along without it.) (B) The anaerobic which thrive best where free oxygen is not present. These again may be divided into obligate which will grow only when there is absolutely no oxygen, and the facultative which will grow in the presence of a small amount of oxygen. The anaerobic separate the oxygen from the nutritive media, the aerobic from the air. The presence of aerobic bacteria in combination with the anaerobic will permit the latter to grow. A wound infected with aerobic bacteria may be rendered sterile or nearly so by restriction of the oxygen supply. This restriction of oxygen may be brought about by some non-pathogenic organism which is hardy and requires large quantities of oxygen for its support, for instance, yeast cells. They produce carbon dioxide which restricts the content of oxygen in the wound and at the same time the deeper layer of *Sarcinæ* removes the oxygen from the tissues, thus causing death to the bacteria. To restrict the absorption of gases from the surface of the wound and thus inhibit the growth of aerobic bacteria, an impermeable layer of some substance, such as charcoal which has the power of quick absorption of gases may be used. The development of anaerobic bacteria may be inhibited by suffusion of the tissues with oxygen under low pressure.

3. *Organic Compounds and Salts.*—Nitrogen is supplied in the form of organic compounds as broken down albumin molecules, serum or muscle waste products, etc. Salts, such as sodium or potassium, magnesium or calcium, phosphorus, etc., are necessary. These enter the bacteria by diffusion, as salts from the surrounding media. Therefore, the nutrition of the bacteria may be retarded by changing the constituents of the surrounding media. The presence of an excess of salts of these elements may act more disadvantageously than the presence of too little. For instance, more than 0.5 per cent. to 0.8 per cent. of salt in the surrounding media restricts the growth and spores are formed. Changing the reaction of the surrounding media may also affect the growth of bacteria. Some bacteria require, or flourish best in an acid media, while for others an alkaline media is the best. Therefore, the exhibition of an antiseptic-carrying-medium which of itself is inimical to bacterial growth will enhance the activity of a suitable antiseptic. Everything which causes a restriction of the diffusion rate of needed salts into the bacteria has a deleterious action on them, for instance: Neutral salts decrease the diffusion power of certain substances into cells. Acids retard the diffusion of substances into cells. Low temperature hinders the diffusion power of cells. (Cf. Ross, 2101.) Urea hinders the diffusion of substances into cells. Alkalies and alkaline salts cause a marked increase in the diffusion of other substances into living cells. Excess of sodium carbonate may act as neutral salts and so delay diffusion. (Cf. Ross 7075, and 101.) Therefore, the solution of an antiseptic in an alkaline medium would enhance the diffusion power of the antiseptic. However, since the diffusion power would be increased in the animal cells the same as in bacteria, such a combination might not be an advantage, unless one could find a substance with a selective action, that is, one which prevents diffusion into animal cells, but favors it into bacteria which are vegetable cells, with a cellulose capsule. We would then be closely approaching the realm of specific antiseptico.

4. *Proper Degree of Temperature.*—Bacteria grow best at a certain temperature. Elevation or lowering of this certain temperature mean has a deleterious influence on bacterial growth. Cold has a marked retarding influence. Heat to be equally efficacious, must be of such an intensity that if it destroys the bacteria, it must at the same time injure the tissue cells.

Another method of destroying bacteria is by the action of one variety of bacteria on another. This is called antibiosis and is the direct opposite of symbiosis. In this method, use is made of the destructive action of the ferments of one variety of bacteria on another variety, as is exemplified by the action of *B. acidophilus* on *B. coli.* Symbiosis is seen in the cooperative action of the influenza bacilli with either the pneumococcus or the *Staphylococcus aureus.* Some ferment producing bacteria can cause fermentation in hemicellulose and produce (1) acetic acid, (2) formic acid, (3) succinic acid, (4) alcohol. These substances may act as antiseptics.

Bacteria contain a gelatinous carbohydrate similar to hemicellulose. Therefore, the possibilities

of using the above ferment-producing bacteria as active antipyogenic bacterial agents is appealing.

Other bacteria act by chemical precipitating action on the protoplasm of adjacent cells; for instance, the *Beggiatoa* and the *Thiothrix* have the power of precipitating sulphur in the form of small amorphous particles in the protoplasm. This sulphur may be dissolved in the wound juices and act as an antiseptic.

One other antiseptic activity of bacteria may be the production of poisons destructive to one variety of bacteria by another. (So far, I have not been able to find record of such a variety.) The *Bacillus prodigiosus* may have such action. I have no doubt that ultimately bacteria with this attribute will be discovered.

The effect of light upon bacterial growth must not be forgotten. Bright sunlight has a markedly injurious action upon bacteria. The blue rays act most powerfully, the violet and ultraviolet with less intensity (Marshall). Radium and *x*-rays in proper dosage will destroy bacterial growths. Electricity has some bactericidal power, but is not applicable to the treatment of bacterial wound infection.

6079-81 JENKINS ARCADE.

WHAT THE SCHOOLS MAY ACCOMPLISH IN SOCIAL ADAPTATIONS.*

BY L. PIERCE CLARK, M.D.,

NEW YORK.

WE make progress slowly in education, due to the fact that in many instances we start at the wrong end. The educators alone are not at fault. The medical profession, for instance, has only begun within the past few decades to look to preventive medicine. Neuropsychiatrists considered the end-processes of defective mentation, and only in the last score of years have they applied mental hygiene to so-called normal persons in everyday life.

It has become increasingly obvious that antedating the formulations of distinct syndromes and symptoms known as disease, there are many evidences of maladjustments in the early physical and mental life of the individual which if taken in hand at the time of their development are much more modifiable than later. Thus many nervous disorders can be retarded or prevented. The facts brought out by these more intensive investigations show that we must consider the individual as a whole rather than piecemeal. We have grown to realize that the presence of defective eyesight, enlarged tonsils, etc., is but a part of the defective equipment and removal of these physical defects only helps the feebleminded individual to handle better his larger problem of life. In other words, an individual may be so feebleminded in all his life reactions that straightening out one or two of his physical defects will not radically clear up the situation. The other point is that precise methods of intellectual gradements fail to clarify the behavioristic faults per se. We will take up this latter point again. As in forestry culture where the big trees are cut down first, we get at the more obvious and immediately pressing issues before these other problems are taken up. We all know that an intensive concern to detect and remove imbeciles from the public schools does not cure idiocy and feeblemindedness, but it has made patent the prime necessity of considering the moron, the dull normal, and the socially unstable pupil, and now we are much concerned with the so-called normals with antisocial tendencies which are for the most part benign.

For a long time it has been popularly held that all the feebleminded are potential criminals. The essential intellectual defect disclosed is supposed in some manner to portend a weakness in their social adaptability. It is true that perhaps a larger number of social delinquents is recruited from those suffering from intellectual defect, but this is offset by the fact that the converse is not true. What is ordinarily known as character is not at all related to degree of intellectual endowment. This conclusion is now patent in the mental defective, in the moron, and in the dull normal group. It is likewise true for the psychopathic group as a whole, including the neurotic, the socially unstable, and the insane. Recent studies have shown that the socially defective youth is an individual of an entirely different sort. He is defective in the social instincts that underlie character. I will illustrate by an example:

My case is that of a boy of seventeen who had been stealing at the school in which he was preparing for college. His home life was apparently normal. He was a vigorous, overactive boy. In an outline of his personality we found that although possessed of a lively temper he could take disciplinary punishment fairly well. He had a keen sense of justice but seemed unable to combine courage and will to put into practice his ideals, which were rather strict for one of his years. He was very uneven in intellectual development, and for several years lacked power of concentration, and was easily diverted from his tasks. He had the play-impulse of one more youthful than his years, and from the age of twelve seemed unable or unwilling to repress this impulse for a more adult mental development. He was a born leader, and a bit toppy and egotistical in his boy set. He was very sociable, kindhearted, and generous. Both parents being deeply concerned in the formal religious aspects of their neighborhood life, the son embraced the same attitude and became a bit priggish in consequence. However, it took no deep hold of his moral nature and he did not seem to rely upon religious practices to hold his pleasure-impulse in check. At puberty his physical restlessness increased; he had a short period of sleep walking and frequently talked in his sleep of his search and pursuit of various pleasures.

When this boy first entered preparatory school he was struck with the extreme levity and rather insincere attitude many of the boys took toward the discipline and regulations of the school. This was not the general rule, but there was a sufficient number who indulged in profanity and made for a general laxity in moral atmosphere to materially lower his own standards. This not only concerned strictly moral issues but attitudes toward study, cribbing, cheating, etc. A number of the boys spent money lavishly and often through deception obtained money in excess of their actual needs. The boys were also allowed to visit one of the large stores and see the display of goods, and our patient found it difficult to curb his desire to purchase things which his allowance would not afford. This atmosphere was entirely opposite to what he had been accustomed at home; coupled with this fact he felt the need for more money to gain an equal footing with the other boys, besides satisfying his own personal wants, and he felt in a state of being chronically hard up. For instance, he coveted a new drill coat, which many of the boys also needed but the minority

*Read before the American School Hygiene Association, New York, November 16, 1921.

did without. He had not sufficient money, but nevertheless purchased the coat and borrowed the money from his father, whom he believed would stop part of his allowance in order to meet the expense; instead, he was required to do additional work during vacation to earn money to pay for it, cutting wood, attending to the furnace, etc. He considered this a hardship, and it caused him much annoyance. He failed to do his work promptly, to get home on time, and by various means avoided the painfulness of working. He said very frankly, "I am lazy and never wanted to work. I don't know anybody who does want to work."

In February two years ago an episode occurred in which he took money from his roommate, whom he liked, and as he states, it was an impulsive act. About this time he had been having an ineffectual struggle to repress his sexual life. This, combined with the chronic shortness of his funds, created a state of discontent and irritability. As a result of taking the money he felt miserable, his head ached, he was remorseful, humiliated at the exposure, etc. In the following May and June he successfully repressed his sexual desires; but they reappeared on going back to school in the fall. However, with much moral effort and special physical precautions, taking cold baths, exercising, etc., he was able to check his impulses. Still the need of funds was as keen as ever. He then roomed with a boy who had an abundance of money and who had no need for the extra clothing which our patient took. He then experienced the same disgust and humiliation after this act as when he had taken the money or when he had masturbated. In every instance it was the desire to get the desired object rather than money as such which really concerned him. At the time of this episode there was considerable sexual desire but no overt practices. Since that time he has been capable of suppressing his sexual desires entirely and has taken no money or property, and has no desire to do so. There is a retardation in the development of the emotional life and its inhibition, and as a result of an attempt to repress a too insistent sexual demand and the various inhibitions against it being ineffectual, it comes up by way of an impulse that is partially acceptable to consciousness in taking the things which he would buy if he had more money. At first he stole to spend money on foods and drinks.

Going more into details, we find that the first thing which strikes one about this boy is that he has been backward in the development of his emotional life, his feelings, ideas, and general attitude toward behavior and conduct. A reconstruction was necessary when he went to the preparatory school and had to make new adaptations. At school he felt he was in an atmosphere which no longer held him up to the innate idealism of the home, and as he put it, "It is harder when you have boys around you doing the things you never did."

It came out very strongly that he was violent in his hatred toward the school. He was attached to some of the boys, but when it came to the school discipline, he hated the "policemen", the spy system, the rules and regulations, and thought the scheme of things which made them necessary was "rotten". If he had obeyed the regulations of the home at an earlier period and made a satisfactory adjustment, he would have taken the severer discipline at school a little hard for awhile, then would have gradually adjusted to it. Each phase of development had not been properly met, and he was thus re-inflicted at a later period with mental indigestion,—of episodes, attitudes, and adjustments not properly met in the home, in the boy group, etc. He was chronically hard up, and it was very difficult for him to suppress his pleasure-impulses, his desire for sweets, dress, etc. These subinhibited youths suffer more, they cannot get these intense desires out of their minds or sidetrack them. This boy suffered a great deal from suppressed desire, especially when other boys spent money lavishly, often obtaining more than they actually needed. Seeing goods displayed increased this boy's desires and gave him moral cramps when he was obliged to go without.

In this boy the main moral fault was due to his bad handling of his sexual life. The situations were relatively benign. A few analytical talks and an arraignment of cause and effect were sufficient to correct both vicious attitudes. The boy is now entering college and is accomplishing his education with an excellent record.

By and large it makes little difference to society whether its individual members know more or less of the usual ingredients of a high school education. It is highly important, however, that the individual shall conduct himself with proper decorum and obey the ordinary customs and laws in common usage. In order that he may do this it is necessary that every individual shall have the training in the home or school of the socially adaptive instincts. It naturally begins in the proper instillation at home of what may be designated as nursery ethics, continued in the school training by both teacher and companions in learning to be a socially adaptive being in the group. Usually this training is supposed to be obtained by the youth in the course of natural observation and association with others, but is this hit-or-miss method sufficient? Boarding schools and colleges say it is not, and they wisely make considerable effort to give this training under the various terms, conduct, personal culture, morale, etc. Many times in the so-called finishing schools the chief duty of the school is to train the pupil in this field of social and adaptive education, ofttimes carried to an exaggerated degree. However, the principle is thoroughly sound, worthy of being rescued from the obliquy into which it has fallen, especially if the idea is genuinely sincere.

We are then forced to consider the kind and manner of training and the type of teacher qualified to give it. Should those engaged in purely intellectual teaching be called upon to do this quite different sort of training? Again, should not instructors in this field have a good deal more equipment than merely a natural aptitude and inherent sense of world culture? Can we afford to allow the public day school to go unequipped with a proper personnel for teaching social adaptations which the private school and college have so long given their pupils? We know in the future life work of these youths this training counts much toward success. The advantage is not to be reckoned in mere social terms, but is of great economic importance as well. The principle too intimately concerns the general welfare of all society to be denied proper concern. Those engaged in the broader applications of preventive medicine, that branch known as mental hygiene, recognize at once the importance of a social training for youths of all ages. It is in this province of education that the proper teachers not only help the easily guided youth to a better adaptation to life, but those who early show nonsocial instincts can be easily detected and given proper corrective training, or they can be referred to many of the mental clinics now being established in this State, whose main concern is to handle and direct the

benign cases of social maladaptations to the proper agencies. If the simple advices and directions which are given in these mental clinics are not efficacious, then more intensive correctional measures may follow. Thus a proper union of teacher and psychiatrist would be possible toward preventing a host of nervous invalidism in later life. I am informed that this sort of morals officer of the school system has been much further advanced in Europe than here. The French schools in particular make the simple ethical principles of conduct in all phases of life a part of the school curriculum. In brief, then, why should not our public schools incorporate more fully social adaptation as an integral part of the educational system? Perhaps the Truancy Department could be encouraged to do not only moral policing but psychologic social service of a more constructive sort than at present. If this truancy function of schools has already acquired too bad a name and feeling, why not attach this expanded function of social training into the regular intramural school curriculum? If the present teaching force is to be employed at this work, they need a more specific training in applied dynamic psychology. It would, of course, be better if this work were left to specially trained workers in this field and incorporated as a part of the regular teaching personnel of the school system.

2 East Sixty-fifth Street.

INDICATIONS AND CONTRAINDICATIONS FOR TONSILLECTOMY.*

By SAMUEL COHEN, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN LARYNGOLOGY, POST-GRADUATE SCHOOL, AND ASSISTANT INSTRUCTOR IN LARYNGOLOGY, UNDERGRADUATE SCHOOL, UNIVERSITY OF PENNSYLVANIA; ASSISTANT LARYNGOLOGIST AND OTOLOGIST TO THE HOWARD HOSPITAL; LARYNGOLOGIST TO THE SOUTHERN DISPENSARY.

It is a surprising fact that most men when questioned as to how long the tonsil operation has been performed, will answer, about fifty years. The fact of the matter is that the tonsil operation has probably been in use for several thousand years. Celsus, in A.D. 10, speaks of this operation with great familiarity; he says: "Tonsils which remain indurated after inflammation, should be loosened by working the finger round them, and then torn out; when this is not possible, they should be seized by a hook, and excised with a scalpel." Aetus speaks more cautiously of removing the tonsils, in A.D. 490. Paul of Ægina in A.D. 750, and Albucasis in A.D. 1120, speak of the operation, but have great respect and dread of hemorrhages. After this the operation fell into disuse and Ambroise Paré in 1509 advises tracheotomy. His pupil Guillemeau did not resort to tracheotomy unless the mouth could not be opened. In 1637, Servini, during an epidemic, the most important symptoms of which was great swelling of the tonsils, removed numbers of them by caustics when pedunculated, and by a knife when sessile. Dionus in 1672, opposed the removal of the tonsils saying, that they are of physiological importance. After 1740, operations came again in vogue by means of the tenaculum and bistoury. Meseati and Wiseman have the credit of reviving the operation. They first used a ligature round the tonsils and then cut off the projecting portion.

Medicine, from its incipiency in the minds of our savage forefathers until this present generation of scientific practitioners, has been and is continually undergoing changes.

Until a very short time ago, the doctors, for the treatment of various bodily ailments, decreed that fresh air, sunshine, and water, were dangerous elements, and should be kept from the sick. The practitioners of the last few generations, however, find these elements an absolute necessity in the cure of disease, and so instruct the public. The general public, being the first ones to resist any new ideas, and the last to take them up, have and are resisting the change of front of their family physicians. Having been trained to fear sunshine, air, and water, when treating disease, they (especially the elders amongst them) resist the complete change. Many times a physician cannot advocate his honest opinion and remedies, just because he fears the opinion of his patients, and knows if he insist, a loss in income and reputation would ensue. This is preeminently seen when treating such acute infectious diseases as measles, erysipelas, etc. Fresh air is excluded, the room temperature is kept far above that of normal, and water must not touch the body of the patient.

Some time ago, it was proven beyond a shadow of a doubt that the tonsils were in many cases the cause of local and general bodily ailments, and their removal, at first partial (a tonsillotomy) and then later complete, *i.e.* capsule and tonsil (a tonsillectomy) was advocated. The cry, wolf, of the physicians whenever a set of tonsils was seen, was after some public objections, taken up by the populace, so that the time has practically arrived, when to tell a patient that his child has enlarged tonsils, but the necessity of removal is not an absolute one, is to draw down public censure. To-day the public in most cases, demand the removal of the tonsils.

Dr. R. sent a child to my office for an examination of the tonsils. On examination I could not find any indication for their removal, and suggested to the mother to wait at present, and if any trouble developed pointing to the tonsils, to return and I would remove them then. I never saw this patient again, but found out later that she went elsewhere and had the operation performed. I was informed by her family physician that she believed I had found in these particular tonsils of her child something to make me afraid of operating, and I had therefore hedged about the question.

Recently my chief, Dr. G. B. Wood, had a similar experience. A druggist of this town, wanted to have his child's tonsils removed, but on examination, I did not see the absolute necessity for the operation. He wanted the opinion of another man, and I referred him to Dr. Wood, who also did not find the necessity of an operation. The child was taken to another specialist, and had a tonsillectomy performed.

Last year at a meeting of the Mt. Sinai Clinical Society, I made the statement that there were too many tonsil and submucous operations performed.

*Read at a meeting of the Southeastern Branch of the Philadelphia County Medical Society.

My friend, Dr. Moses Behrend, ably seconded me in this statement. I might add here that the probabilities are, that there are too many operations performed in general.

Last year after reading my paper on a similar subject before the Brooklyn Pediatric Society, where I advocated that a little more thought was necessary before advising tonsillectomies, a well-known physician arose and, raising his hands, said, "Thank God, no one has stolen my children's tonsils." Unquestionably the expression of a most extreme conservative. A physician of this city arose at a meeting and stated: "To advise against the removal of tonsils ought to be regarded as a criminal offense, punishable by law." The most extreme radical view I have ever heard.

Because a child's tonsils may even protrude a little in front of the anterior pillars, is no reason for their removal, although it seems to be the essential indication for our school doctors. Many parents whose children had been referred to the dispensary (many of whom can well pay for services, *school doctors please note*), when asked what ails the child, tell me "he has tonsils." When asked whether or not the tonsils bother the child they answer, "the tonsils don't bother the child, but they bother the school doctor." A typical conversation in my office or dispensary is as follows:

"What was your purpose in bringing the child here?"

"Oh, he has tonsils."

"What about the tonsils, are they troubling him, has he any attacks of sore-throat, ear trouble, does he sleep with his mouth open, has he rheumatism, heart-trouble, etc.?"

"Oh, no, he has tonsils and I want them out."

"But if they don't bother him, why run operative chances, be it ever so small?"

The answer is a peculiar stare, whose meaning I have learned, and the outcome of the matter is that the operation is performed elsewhere.

Physicians, as well as the public cannot be blamed for this present attitude. The fact is, that special text-books on the subject are very indefinite and vague, enumerating as indications all well-known diseases from brain-fever to bunions. We must not lose sight of the fact that it may be just as bad to err on the conservative side as on the radical side. Also, that the last word on this question has not yet been said. The pendulum is still swinging in the direction of more and more tonsillectomies, but like all other movements, it will probably swing the other way some day, and that, sooner than one might expect.

When considering the question of removing tonsils, and knowing the enormous amount of benefit the human race has gotten from it, we must not lose sight of the fact that patients subject themselves to a great many possible complications and fatalities. In the last three years, I have seen three deaths from such operations. The first happened immediately after the injection of the local anesthetic. In the second, the patient stopped breathing while being anesthetized, and all efforts at resuscitation were of no avail. (All this occurred prior to the operation.) In the third case, the child left the table following the operation in almost perfect shape, no bleeding, and still, five hours later, it expired. I feel very thankful that none of these cases were mine; however, no one is free from such a possibility. Besides fatalities, which, of course, are rare, complications, such as pneumonia, otitis, local abscesses, and lung abscesses, are met now and then by every operator. Each case is a law unto itself, and should be considered as if occurring in our own families, meeting the demand of the case in question at all times.

Let me also call attention to the fact that in a large number of cases it is impossible to state definitely, after looking at and feeling the tonsils, whether they are normal or diseased. Tonsils which have appeared to be ragged, enlarged, with adherent congested pillars have been found on microscopic examination to be normal, and some which appeared normal have been found full of pus pockets. You cannot say in many instances, on looking say in many instances, on looking at a pair of at a pair of tonsils, that they must come out or stay in; it is the *history of the case* that is most important.

To-night I want to attempt to give a sane, not too radical nor too conservative view on the subject. An absolute demarcation line cannot be drawn, each case must be studied from its own angle.

For general purposes of discussion, I have divided the indication of tonsillectomy under two headings: (1) The absolute indications, in which case I insist on the removal of the tonsils. (2) The questionable indications, where one can wait, watching the patient, before deciding one way or the other.

Absolute Indications.—1. Recurrent attacks of acute tonsillitis, whether of the suppurative or simple variety, call for a tonsillectomy.

2. When an acute attack of tonsillitis (even though it be the first) is followed by such complications as rheumatism or heart trouble the tonsils should be removed.

3. Tonsils that are so large as to cause any difficulty in breathing or swallowing call for a tonsillectomy.

4. All cases of acute suppurative otitis media (otorrhea), which have lasted more than six weeks call for a removal of the adenoids and tonsils.

5. Repeated attacks of pain in the ears of children who have a normal drum-head, and no near-by local conditions is found to explain the pain, call for the removal of the adenoids and tonsils.

6. Recurrent attacks of acute anterior cervical adenitis, especially when the "tonsillar gland" is involved, point to the tonsils as the origin of the infection and call for their removal.

7. Tonsils, which on pressure extrude cheesy matter or pus, complicated by symptoms of toxic absorption or a foul odor of the patient's breath, calls for their removal.

8. If the patient has had one attack of peritonsillar abscess, removal of the tonsils will prevent the recurrence of this condition.

9. Diphtheria carriers should have their tonsils removed. (Negative cultures are usually returned in two weeks after operation.)

Potential Indications.—1. All tonsils, being possible sources of trouble, should be looked upon with suspicion at all times, especially those showing some enlargement, irregularity, congestion, adherent pillars, or extraneous substances obtainable by extrac-

tion or pressure. When such tonsils are present in patients suffering with rheumatism, chorea, arthritis, etc., and when all other sources of infection have first been investigated and treated without avail, they should be looked upon suspiciously, and if no contraindication exists, they should be removed.

2. Cases in children of occasional nasal hemorrhage, without any local area found to explain this, or cases of chronic nasal discharge, should have their adenoids and tonsils investigated with the idea of removal. I purposely put the adenoids first, because they are probably at the bottom of these symptoms, and when removing the adenoids, it is well worth while to do a tonsillectomy at the same time.

Contraindications.—1. *Age*: Tonsils should not be removed before the age of two, unless some special indication exists. Tonsils should not be removed from people who show a marked arteriosclerosis, or in the old. The danger often overbalances the possible good that might result from such an operation.

2. Patients having fever or albumin in the urine, should wait until these are cleared up before being operated upon if possible.

3. During an epidemic I think it unwise to remove tonsils.

4. When vascular anomalies are seen or felt in the tonsillar region, pointing to large blood vessels, being in direct relationship with the tonsils, the removal of the latter is fraught with great danger.

5. Hemophiliacs, or those known to bleed very much after the slightest cut, are endangered by the operation of tonsillectomy. I always ask my patient before operating as to their bleeding propensities, and if possible have the blood coagulability taken.

6. Operating during an attack of acute tonsillitis or of peritonsillar abscess, I believe to be unwise. These patients take ether poorly and injection of a local anesthetic is rather dangerous, to say the least (pushing infection, as it may, into surrounding tissue and opening up nature's protective wall).

7. All conditions wherein the giving of a general or local anesthetic is dangerous, are to be classed as contraindications to tonsillectomy. The key to this part of the topic lies in the question, "Is the danger run justified by the possible benefits to be derived?"

8. I always try to avoid a tonsillectomy in cases of atrophic rhinitis.

9. Syphilitics should not have a tonsillectomy performed unless in the most extreme urgency.

10. Tonsillectomy in the presence of badly diseased teeth, or of an acute infection in or about the mouth, is to be avoided, when possible.

In conclusion permit me to again call to your attention the fact that it is often a very difficult matter to decide whether to remove the tonsils or to leave them alone. No rule of thumb can be laid down. Each case requires your own special painstaking, conscientious thought. The possible dangers and the benefits that the patient may derive, must all be carefully considered; and if this paper can bring the idea to us to be less hasty, and more careful before advising tonsillectomies, it will have served a worthy purpose. Last, but not least, let me say that in the operations that I have performed, ill results, if any, occurred in the three weeks following the operation. If none occurred during that time, the patient ever afterward showed no ill effects, and in a vast number of cases an improvement in their general health was noticed.

1626 Spruce Street.

"PERICARDITIC PSEUDOPNEUMONIA" IN CHILDREN.*

By MILTON SMITH LEWIS, M.D.,

NEW YORK.

During the past few years, our attention has been called to the fact that, associated with pericarditis with effusion, there are found definite abnormal physical signs indicating some sort of a pathological condition at the left scapular angle. Inasmuch as there has been but little written on this subject, it seems a very appropriate time to discuss the condition, and perhaps to arrive at a common understanding concerning the signs of apparent consolidation at the left scapular angle, associated with pericarditis with effusion.

A review of the literature for years back discloses but little information concerning this rather puzzling subject. Textbooks on physical diagnosis, such as Norris and Landis,[1] French,[2] and Cabot,[3] only mention that signs of apparent consolidation at the left scapular angle are met with in pericarditis with effusion. According to Musser,[4] there is increased pulmonary resonance at the left scapular angle, with increased vocal fremitus, and bronchial or bronchovesicular breathing. These signs are present when the patient is sitting up, but disappear on his bending forward.

According to Roberts,[5] when considerable pericardial effusion is present, the left side of the chest may give rise to a definite group of signs such as dullness, increased fremitus, bronchial or tubular breathing, bronchophony, or egophony.

In these cases Robey[6] calls our attention to a small area of dullness at the left scapular angle.

Christian[7] is the only author to date who has enlightened us on this subject to any extent. He reports that in his series of 53 cases, all of which were in adults, observed at the Peter Bent Brigham Hospital, 39, or 73.5 per cent., showed abnormal physical signs indicating some sort of a pathological condition in the left lower chest. Christian also mentions the very interesting fact which I have also observed, namely, that nearly all of the cases that showed the pulmonary signs had acute articular rheumatism on admission, or had an attack a very short time before admission. In our series of cases it will be seen that all gave a distinct history of rheumatism occurring a few weeks before admission, but there was no evidence of arthritis on admission. This would seem to indicate that the damage was done to the heart at or soon after the onset of the arthritis. Pericarditis is often overlooked for several days because it is usually entirely painless, and on auscultation the to-and-fro friction sound may resemble a valvular murmur.

According to Riesman,[8] a curious feature in pericarditis, and one that may cause error in diagnosis, is the presence in many cases of the signs of pneu-

*From The A. Jacobi Department for Children, Lenox Hill Hospital, New York City.

monic consolidation in the left chest. Distinct dullness on percussion, bronchial breathing and bronchophony suggest the presence of pneumonia, and Riesman believes that the deceptive signs are produced through compression of the left lung by the heart. The production of this condition he calls "Pericarditic Pseudopneumonia."

It appears that the above authors, with the exception of Christian and Riesman, lay stress on the fact that the pulmonic signs are due to large amounts of fluid in the pericardium, but I have found that the pulmonic signs are present when only a small amount of fluid is present with an enlarged heart, and is not dependent on large amounts of fluid in the pericardium, but is present in cases of acute fibrinous pericarditis as well.

The physical signs in these cases vary to some extent. In some the dullness is distinct and extends from the spine of the scapula to the left base, in others the dullness is limited to a very small area at the left scapular angle, while in others the dullness extends to the axillary line. Over the corresponding dull area there is heard distinct bronchial breathing of varying intensity, and bronchophony or egophony. In none of our cases were rales elicited except in Case III, in which the rales were scattered throughout the right side posteriorly but with absence of other signs of consolidation on the right side.

The majority of our cases of pericarditis on admission to the hospital, presented rather definite signs of apparent pneumonia, such as dyspnea, dilatation of the alæ nasi, fever ranging from 102° to 104° F., and a very rapid pulse. All gave a history of coughing profusely a few days before admission to the hospital. Two of them had been expectorating blood tinged sputum.

A common mistake in these cases is to suppose that a lobar pneumonia is present. Experience has shown that these signs are due to pressure exerted on the lung by the heart or by a pericardial effusion and not to an exudate in the lung.

During the past few months it has been possible to observe a number of children with pericarditis, and it has been found that nearly all of these cases showed definite signs of apparent consolidation at the left scapular angle.

Case 1.—B. S., female, age 4 years. Three weeks previous to admission to the hospital child had a rather severe attack of rheumatism with involvement of ankles, wrists, elbows, and shoulder joints. Since the onset of the rheumatism she had been running a temperature ranging from 101° to 103° F. Two days prior to her admission she began coughing profusely. There was present slight dyspnea which was exaggerated on exertion. There was no pain over the precordium. The patient was perfectly well prior to onset three weeks ago, except for frequent attacks of tonsillitis. On admission to the hospital the temperature was 102° F., pulse 162, respiration 36.

Physical examination revealed a poorly nourished child who appeared to be acutely ill but apparently suffering no pain. Color cyanotic, especially of lips and ears, the respirations were markedly increased and labored, and dilatation of the alae nasi was pronounced. A pericardial friction sound was audible over the lower end of the sternum, accompanying both systolic and diastolic phases of the heart not intensified by bending forward or in the erect position. Cardiac dullness was increased downward and to the left and slightly to the right of the midsternal line. The left border of the heart measured 12 cm. to the left of the midsternal line; right border 2 cm. to the right of the midsternal line. Total transverse diameter 14 cm. At the left scapular angle there were signs of apparent consolidation such as bronchial breathing, bronchophony or egophony, and a distinct dullness over the corresponding area. No râles were elicited. Bamberger's sign was not present.

A roentgen ray examination revealed evidences of pericarditis with effusion, but none of consolidation at the left scapular angle.

Case II.—F. C., female, age 8 years. Six weeks prior to admission she gave a history of a severe attack of rheumatism with involvement of right ankle and knee joints; both joints were swollen and red. This condition subsided in fourteen days. Seven days previous to admission she complained of pain over the precordium and dyspnea on exertion. Two days ago she began coughing but at no time was any blood-tinged sputum noticed. On admission the temperature was 103.2° F., pulse 132, respiration 32.

Physical examination revealed a child apparently acutely ill, with cyanosis of lips and ears. There was marked dyspnea with dilatation of the alae nasi. A pericardial friction rub was audible over the base of the heart which disappeared on resuming the erect position. Cardiac dullness was markedly increased. The left border measured 14 cm. to the left of the median line; the right border measured 4 cm. to the right of the median line. Total transverse, 18 cm.

Posteriorly at the left scapular angle there was heard distinct bronchial breathing with bronchophony, and there was dullness over the corresponding area. No râles were elicited.

Roentgen Ray Report.—The shape of the cardiac shadow would indicate a pericardial effusion. There is no evidence of a pneumonia at the left base.

Case III.—E. B., female, age 10 years. Gave a definite history of rheumatism four weeks prior to admission. Ten days ago the child contracted a severe cold and since then has been coughing continually. The mother has noticed blood-tinged sputum at times. There was marked dyspnea on exertion, but the child complained of no pain over the precordium. On admission to the hospital the temperature was 102.8° F., pulse 130, respiration 48.

On physical examination there was heard over the precordial area a distinct pericardial friction rub, with the physical signs of mitral regurgitation and stenosis. Cardiac dullness was increased downward and to the left and right of the midsternal line. The left border measured 13 cm. to the left of the midsternal line; the right border 5 cm. to the right of the midsternal line. Total transverse, 18 cm.

Posteriorly at the left scapular angle and extending down to the left base, there was bronchial breathing with bronchophony. Dullness was pronounced over the corresponding area and extending to the axillary line. Voice and breath sounds were somewhat increased over this area. No râles were elicited over the left side of the chest, but there were a few crepitant râles heard over the entire right side posteriorly, but with no other signs of consolidation. Bamberger's sign was not present.

Roentgen Ray Examination.—There is a shadow extending from the first rib to the base of the heart on the left side and is very suggestive of a left-sided pericardial effusion. The whole of the right chest posteriorly shows congestive changes.

Case IV.—J. B., male, age 10 years. Four months prior to admission to the hospital the child began to complain of pain over the precordial region which has persisted at intervals since the onset. Three days after the onset the child gave a history of rheumatism with involvement of both knees and ankle joints. This condition cleared up under treatment, three weeks later. Seven days prior to admission to the hospital the child began coughing but no blood-tinged sputum was noticed at any time. There was dyspnea on the least exertion. The temperature on admission was 101.2° F., pulse 140, respiration 30.

Physical examination revealed a child acutely ill, with labored respirations, marked cyanosis, and dilatation of the alae nasi. There was distinct bulging over the precordium. Over the lower end of the sternum there was heard a distinct pericardial friction sound accompanying both systolic and diastolic phases of the

heart, not intensified by bending forward or in the erect position. The left border of the heart measured 13 cm. to the left of the midsternal line; the right border measured 4 cm. to the right of the midsternal line. Total transverse, 17 cm. At the left scapular angle there was heard bronchial breathing with bronchophony. Over the corresponding area there was slight impairment of resonance.

The Roentgen ray report reveals evidence of pericarditis with effusion.

In explanation of this peculiar phenomenon, it is evident that the great frequency with which these signs of apparent consolidation occur with pericarditis indicates that there is some definite relationship with the heart.

There have been several theories advanced as to the cause of these signs:

1. A distended pericardial sac presses on the lung producing a mechanical atelectasis.

2. An inflammatory process extends from the pericardium to the pleura or lung causing changes that are responsible for the pulmonic signs.

3. Pressure is exerted on the lung by a dilated heart or a pleural effusion.

The area of solidification at the left scapular angle is in all probability due to pressure upon the lung either by a pericardial effusion, a pleural effusion, or a greatly dilated heart. The latter possibility is very rarely mentioned in textbooks.

In none of our cases was there evidence of pleural effusion.

Conclusions.—1. The signs of apparent consolidation at the left scapular angle are, in all probability, due to the compression of the pulmonary tissue either by the heart or by the pericardium, or by both.

2. The frequency of these signs and their location at the left scapular angle, indicates that there is some casual relationship to the acute pericarditis.

3. These pulmonary signs seem to have little influence on the course of the disease, as the signs at the left scapular angle disappear with the improvement of the pericarditis.

Digitalis in Tuberculosis.—Focke quotes literature 100 years old of English origin in which the statement is found that foxglove in small dosage is of value in the first stage of consumption and may result in recovery. It is of hardly any use in the second stage, but in the third exhibits some symptomatic value. He suggests that the drug be tried out in our sanatoria.—*Wiener klinische Wochenschrift.*

RESOLUTION IN PULMONARY TUBERCULOSIS.

By Owen Paget, M.D.,

Perth, West Australia.

Mankind is generally reluctant to hurry along the paths of progress. When I was a student in London the orthodox treatment for ovaritis and salpingitis was to paint a circle of tincture of iodine on the abdomen over the ovarian region. Our teachers for the most part, better casuists than classicals, sought to infuse our minds with the differences between "para" and "peri" metritis. An abdominal section was a sacrificial ritual.

My outlook was, however, influenced by a visit to Bordeaux, where the operating of a gynecological surgeon, who removed ovaries like picking plums off a tree, charmed me by its celerity, even though one wondered sometimes as to its necessity.

Presenting myself shortly afterwards for examination, I enthusiastically described the superiority of French to English methods. Unfortunately one of the examiners was one of my teachers, and I passed my examination by the merest margin and received a severe rebuke.

There is no question but that the time is close at hand, when pulmonary tuberculosis will be easily cured by the practitioner in a few days to six weeks. Three factors only dominate the prevention and cure of this disease—

(1) The circulation of the inspiratory current of air in the regions of the nose, superior to the level of the free edge of the middle turbinate bone.

(2) An appreciation of the physiological capacity of the epithelial cells in these regions to produce antibodies, potent enough to prevent and destroy the growth of tubercle bacilli in other parts of the body.

(3) The discarding of academic pedantry, which refuses to admit the presence of tuberculosis, until bacilli are discovered in the laboratory. For this must be substituted the dictum, that, lacking positive evidence of other disease, ninety per cent. of the diseases of the nose, tonsils, pharynx, and lungs are tuberculous, and should be speedily treated accordingly.

Future investigations in the morbid anatomy and pathology of pulmonary tuberculosis will be practically confined to such questions as: (*a*) The penetration and exfoliation of protective epithelium. (*b*) The not infrequent occurrence of fibrinous deposits, especially on the tonsils, as an expression of tuberculosis. (*c*) The penetration of the bacilli into the peribronchial lymph spaces. (*d*) The value of and reasons for serious effusions. (*e*) The development and resolution of consolidation.

The key of the whole proposition in the treatment of pulmonary tuberculosis is the artificially bringing about of the resolution of consolidated lung. In other words the sole difference between a pneumococcic pulmonary consolidation and a tuberculous pulmonary consolidation is that, in the former resolution of the lung nearly always takes place, whereas in the latter it more often does not.

Consolidation of the lung is the presence within the pulmonary alveoli of a firm or solid exudation. The process, before it ultimately resolves, passes

through the following stages: (1) Congestion. (2) Red hepatization. (3) Grey hepatization. (4) Resolution.

The following account from Zeigler's Pathological Anatomy well describes the final stages of Resolution. "As the coagulated exudation liquefies; its removal becomes possible. *This takes place chiefly by reabsorption, in part also by expectoration.* During this process the lung appears as if saturated by moisture; it is beset with leucocytes, but not in excessive numbers, and its tissue is easily torn. *In the great majority of cases complete recovery takes place, so that after reabsorption is complete nothing remains of the affection.*"

In tuberculosis this intricate process may stop at any point. As a matter of fact different parts of the affected lung usually respond in different manners. Thus some sections resolve and some remain congested. Others again sluggishly halt in various stages of red and grey hepatization.

The final stages of unresolved tuberculous consolidation, such as fibrosis, ulceration, caseation, cavity formation, and calcification, are simply expressions of either sullen resistance, or of complete capitulation to the inroads of the tubercle bacillus. *They are of no future interest, since artificial resolution can easily be brought about.*

Every practitioner of experience has watched the dilating nostrils of the pneumonic patient. In poorer class practices it is the pathognomonic differentiation in children between diseases of the chest and those of the abdomen.

To those who like myself have watched a child stuffed with adenoids, and with a large pulmonary consolidation, make persistent and untiring efforts to breathe through the nose, instead of breathing as usual through open mouth; not merely is the physiological capacity of the nose to form antibodies demonstrated, but it visualizes also our inherent instinct to resist disease.

Now I have by means of insufflations of tubercle bacillary emulsion artificially brought about the resolution of tuberculous consolidation both in its early stages, and after secondary changes have taken place. In other words consolidation of a few days duration, and again in cases unresolved even after fifteen years.

The length of time required is roughly proportionate to the duration of the consolidation. Thus in the early stages, tuberculous consolidation can be made to resolve as speedily as is usual in pneumococcic cases. In old cases it may take months to accomplish, but it is interesting to notice the similarity of physical signs with the return to normal.

The mysteries of physiology and pathology are unlimited. But how extraordinary and marvellous is the chain of events by which a few insufflations of one ten thousandth of a milligram of tubercle bacillary emulsion on the epithelial cells of the ethmoidal region can bring about the resolution of a pathological exudate in the alveoli of the lungs!

Is the process nervous or telepathic, psychic or humoral? And be it remembered this is originally a normal physiological circumstance, whereby the deposition of bacilli on the ethmoidal epithelium inhibits and prevents their growth in other parts of the body.

Its employment by the physician is required only when anatomical faultiness precludes a normal function.

Medicolegal Notes.

Revocation of License for Misconduct.—A petition for a writ of prohibition to restrain the Massachusetts Board of Registration in Medicine from holding a hearing on a charge against the petitioner of gross misconduct in the practice of his profession, with a view to the revocation of his certificate of registration, alleged that the statute, St. 1917, c. 218, under which the board intended to act, was unconstitutional. Affirming an order of the board dismissing the petition the Massachusetts Supreme Judicial Court says: "The right to follow a legitimate calling for any lawful purpose is sacred and is protected both by the Constitution of the United States and that of this commonwealth. The right of a physician to toil in his profession as well as that of all other citizens to labor in their chosen work is both liberty and property, partaking of the nature of each, and is guaranteed by constitutional mandate from unwarrantable interference. U. S. Constitution, art. 14 of Amendments, § 1; Declaration of Rights, arts. 1, 10; Coppage v. Kansas, 236 U. S. 1; Bogni v. Perotti, 224 Mass. 152. This right with all its sanctity and safeguards is not absolute. It must yield to the paramount right of government to protect the public health by any rational means. No argument is required to demonstrate that legislation reasonably designed to promote the general health of members of society is within the welfare clause of our Constitution, pt. 2, c. 1, § 1, art. 4. Laws requiring the examination, registration and certification of physicians and prohibiting all others, with exceptions not here material, from practising medicine, have been upheld as not violative of any constitutional provision. Commonwealth v. Porn, 196 Mass. 326; Commonwealth v. Jewelle, 199 Mass. 558; Commonwealth v. Houtenbrink, 235 Mass. 323. Their validity rests upon the proposition that those who undertake to cure the ills, to treat the ailments, to prevent the diseases, and to relieve the sufferings of the race may be required to show themselves possessed of technical skill to those ends. Soundness of moral fiber to insure the proper use of medical learning is as essential to the public health as medical learning itself. Mere intellectual power and scientific achievement without uprightness of character may be more harmful than ignorance. Highly trained intelligence combined with disregard of the fundamental virtues is a menace. A physician, however skillful, who is guilty of deceit, malpractice or gross misconduct in the practice of his profession, even though not amounting to an offence against the criminal laws, well may be thought to be pernicious in relation to the health of the community. It is for the Legislature to determine within reasonable limits in the exercise of the police power what the tests shall be for moral character sufficient to enable one to continue in the practice of medicine. The statute in this particular is not open to objection. The circumstance that the petitioner already had been registered and given a certificate to practise medicine gave him no immunity against future legislation of the nature embodied in said chapter 218. He had no vested right to prey upon society by the exercise of deceit, malpractice or gross misconduct in the practice of his profession. His license to practice constituted no contract of that nature. Burgess v. Mayor and Aldermen of Brockton, 235 Mass. 95, 100, 126 N. E. 456. The statute affords every reasonable safeguard to protect the rights of the petitioner by requiring a hearing at which he may be present with witnesses and counsel and providing also for hearing in court and revision and reversal of the finding of the board, if justice demands such action." The entering into an agreement to perform or attempt to perform an abortion would warrant, if it would not require, the revocation of a license to practise.—Lawrence v. Briry (Mass.) 132 N. E. 174.

ALCOHOL AND PSYCHOLOGY.

THE importance of psychology is beginning to be recognized as a branch of medical science which should be studied closely and the lessons learned therefrom applied in a practical way. At many of the chief medical schools, chairs of psychology have been established and treatment of certain mental states on psychological lines has met with a very considerable amount of success. No doubt, as the teaching and practice of psychology develop, such treatment will advance pari passu. Of all the works on psychology written recently none has had a greater vogue than McDougall's "National Welfare and National Decay," and in this book he deals at some length with the alcohol question from the psychological standpoint. In a paper read before the British Society for the Study of Inebriety in January 1922, an exhaustive abstract of which was published in the *Medical Press and Circular*, January 25, 1922, Dr. Charles F. Harford, discusses some of the views set forth in McDougall's widely recognized book. For example, McDougall accepts the new division of races of Western Europe into the Nordic races and the Mediterranean; the former he styles introverts, the latter extroverts, and in contradistinction to the well known views of Sir Archdall Reid, he advances the following hypothesis. He argues that the greater proneness to alcoholic intoxication of the Northern peoples, and the greater sobriety in this respect in the Mediterranean peoples is to be found in the introvert quality of the Nordic race. Alcohol acts on the nervous system in a way which renders it temporarily extrovert; and thus for the introvert it brings relief from the brooding melancholy to which he is constitutionally liable; it enables him to enjoy the freedom of emotional expression, which in his normal condition is denied him by his introvert tendency.

Harford finds it hard to reconcile the introvert type with the British peoples as such, but the argument as applied to introverts and extroverts is suggestive. It is not unlikely, however, that the climate of northern countries conduces as much to strong drink as the psychology of its individual members. Dull cold weather tends to melancholy, and those who have lived and whose forebears have lived under climatic conditions of this nature for generations are apt to become of a melancholic temperament. However, no doubt psychology plays a rôle in the production of a brooding state of mind.

That part of McDougall's book which discusses the alcohol problem as affecting the colored races is of the first interest. The menace of alcoholism is chiefly concerned with the negro races, and the author says, regarding this, that while it is impossible in any accurate way to describe a common negro psychology, yet there are certain characteristics, especially of the pagan races, which amount to some extent to what may be termed a group mind, which belongs to all. (1) They are essentially extroverts in that they are light hearted, irresponsible, and ready to take things as they are. This is indicated by their merry ways, their dances, and their songs. As instances of the latter, we may quote their boat songs, the songs accompanying their dances, their hymns, and the plantation songs of Kentucky. (2) They are suggestive and imitative. Phantasy rather than reality is that which largely influences them. (3) They have strong social instincts. The influence of tribe or chieftainship is an essential point in their lives. (4) They have strong religious instincts in which phantasy has a prominent place, as shown by images, totems, and witchcraft. As the writer is at pains to point out in the article above mentioned, all of these apparently innate characteristics of the race predispose its members in many ways to drug addiction, and particularly to the use of alcoholic liquors. The regions of phantasy are more easily reached through alcohol than in any other way. Dr. Harford attributes the prevalence of drinking among the native of Africa, as well as of the Pacific Islands, to the influence of Europeans and other white men who have introduced drinking and other vices of civilization, and in the natives have found virgin soil in which these habits have flourished exceedingly. He further holds that the only possible remedy is the banishment of drink from these areas without question of racial discrimination.

With McDougall's opinions as to the psychology of the northern races leading to their addiction to alcohol there are grounds for dissent, and in fact, the views of Sir Archdall Reid appear more reasonable. But no thinking person can disagree with his views with regard to the extremely injurious effects of alcohol on the negro races owing to their psychology, which renders them peculiarly susceptible to its influence. Indeed, the psychology of the negro resembles in many features that of a child. Irresponsibility and phantasy are predominant in the minds of children and negroes alike, and it is easy to understand that races or people possessing this stamp of mind are especially amenable to the effects of alcohol, and that consequently they should be debarred from using it. Harford suggests that a good deal of the unrest which is so widespread at the present time may be due to alcohol or, at least, aggravated by it.

BASTEDO'S SYMPTOM IN THE DIAGNOSIS OF APPENDICITIS.

THIS phenomenon was described by Bastedo of New York in 1911 and since that period several European surgeons have written papers on "Bastedo's symptom," which consists in induced pain following colonic insufflation, a negative result sufficing to exclude appendicitis in differential diagnosis. The most recent article on this symptom is by Jerlov of Karlstad, Sweden (*Acta Chirurgica Scandinavica*, November 16, 1921, liv., 2), who has analyzed 100 cases of abdominal troubles in making or excluding the diagnosis of appendicitis. The author's technique is somewhat elaborate and, as the reader is doubtless familiar with the original method of Bastedo, may be passed over. For control each patient was also tested for the Rovsing symptom. Sixty of the hundred patients and appendicitis verified by operation, one had peri-appendicitis and one a neoplasm of the appendix. The remaining 38 patients had no affection of the appendix. Among the 60 cases of appendicitis practically all forms were represented, as chronic catarrhal, chronic catarrhal with acute exacerbation, ulcerous and gangrenous forms, and appendicitis with peritonitis.

Analyzed in detail, Bastedo's symptom was positive in 13 out of 24 cases of chronic catarrhal appendicitis and negative in 11; positive in 17 out of 19 cases of chronic catarrhal appendicitis with acute exacerbation and negative in 2; positive in 13 out of 14 cases of ulcerous or gangrenous appendicitis and negative in one; and positive in each of 3 cases of appendicitis with peritonitis. It therefore is a sign of much value in active appendicitis but equivocal in the interval case. In the latter the pressure in the colon was run up to 50 mm. mercury, while in the other forms the symptom was induced with a pressure of 31-33 mm. Hg. The silence of so many interval cases was due in some at least to adhesion formation. In the 38 cases in which operation had revealed the appendix intact or, in a few cases, absent from previous extirpation, the sign of Bastedo was uniformly negative. These patients presented varied conditions, such as cystopyelitis, salpingitis, biliary affections, nephrolithiasis, gastric ulcer, thoracic affections simulating abdominal, etc. In this series several of the patients did not go under the knife, but appendicitis could be excluded to the author's satisfaction. The motivation of the pain is not so simple as at first sight appears. Its site is doubtless in the appendix purely for it never reappeared after extirpation. Probably a mobile appendix is necessary to evoke pain in the silent cases. The author is unable to confirm the finds of Rost to the effect that a positive Bastedo is sometimes obtainable in enterocolitis; due in all likelihood, however, to traction on an inflamed mesentery. He concludes that in hospital practice with proper selection and strictly carried out technique this symptom has considerable absolute value, although since the diagnosis can usually be made in its absence, its use must be restricted. In acute peritonitis of unknown cause there is no necessary contraindication to its employment.

THE PORT OF NEW YORK AND THE TRANSIT PROBLEMS.

AT a meeting of the New York Academy of Medicine on February 16, the replanning of New York City and its transit, transport, and sewage problems were discussed. These matters should be of personal and technical interest to physicians, for they involve questions of proper housing, of cheaper and better food supply, of over-crowding of passengers, and in general of the intensive progress of our city's congestion. Both Mr. Stein, who presented the plan of the Port Authority, and Gen. O'Ryan, who presented that of passenger transit, agreed that the "disease" of the City was this progressive congestion, for the help of which no previous planning has been made.

The New York Transit Commission presents a scheme for relieving passenger transit by condemning and getting possession of all the present 2,000 franchises that now control the situation, and of consolidating into three companies the transportation under these corporations. The Port Authority's plan for the City provides for direct delivery of freight through tunnels to Manhattan and to Long Island. But this plan would mean nothing for the betterment of the city unless accompanied by the development of the so-called "Garden-City" units, *i. e.* suburban centers of limited size arranged to provide for industrial activities and for residences of the workers near where they work. The land of each suburban unit would be owned by the people who lived there and each city unit is to be surrounded by fields and woods and to be limited in population. A city growing in this way could expand happily and almost indefinitely, if the sewage and water supply problem could also be satisfactorily solved.

The medical profession was eloquently appealed to by Gen. O'Ryan to take an interest in and give support to these efforts to have not a bigger but a better city. The details of the two plans are given in our report of the meeting published on page 348 in this issue of the MEDICAL RECORD.

MULTIPLE PRIMARY CARCINOMA.

ON account of the great infrequency of this coincidence, authentic cases are invested with considerable interest. In a cancerophile subject it is difficult to understand why multiple irritation does not more frequently cause multiple primary cancer, and this failure suggests something like an immunizing effect of a first cancer which prevents the development of other lesions. In 1894 Frankel, a French author, could find records of but fifteen cases, and several more were added during the nineties from French sources. In 1902 G. Muller published a series of twenty-nine cases and since then, including a number which were overlooked by collectors and some miscellaneous autopsy finds, the recorded num-

ber should have at least doubled. The coincidences are of the most bizarre character, including cancroid with true carcinoma. Perhaps the most nearly unique case was a triple cancer of the pharynx, stomach, and rectum, each of a different histological character. The pharyngeal cancer was a squamous cell, the stomach growth a medullary cancer, and the cancer of the rectum an adenocarcinoma. This case appeared in the *Zeitschrift für Krebsforschung* for 1909, and a close second is the case of Walter of a pavement-cell cancer of the cardia, a fibrocarcinoma of the uterus, and a cylindroid cancer of the uterine cavity. These cases, however, are really pathological curiosities and, moreover, each case reported of this type is usually challenged as founded on defective observation, since it is difficult to prove beyond doubt that one growth is not secondary to the other or others. The entire subject is covered by Renaud in the *Revue médicale de la Suisse romande* for December, 1921, xli., 12. His own contribution is not of great interest, as the subject presented a cancroid (squamous-cell) of the left frontoparietal region with a basal-cell cancer of the right temporal region. The difference in histological structure is of interest, although generally speaking multiple cancroid of the face is not usually reckoned among cases of multiple cancer, and is not in itself so very rare.

The Index of Robustness.

There is an alleged law that the weight of an individual in kilograms should be equal to the number of centimeters of height over and above one meter. When Meo sought to verify this law on the persons of certain West African negroes he found notable departures which could not be explained by the assumption of inferior specific gravity. These aborigines are of the natural athletic type, agreeing with the developed and more or less artificial white athlete. Heckel in the interest of the alleged relation between weight and height has availed himself of the known measurements of many pugilists although the only weights given are the socalled fighting weight (*La Presse Médicale*, December 31, 1921, xxix., 105). A tabulation shows that the excess of centimeters over a meter is invariably greater than the weight. The discrepancy is stated to be the same as in the natural negro athlete, indicating that the two classes of men have the same specific gravity. In such a case there should be the same amount of adipose tissue in each class, although one can hardly visualize the possibility that the African negro is as destitute of superfluous fat as the white man who has gone through intensive training for some weeks. The author, who is an athletic director at Rheims, estimates the average amount of weight lost by training as 5 to 6 kilos. A source of fallacy not mentioned is that intensive training is something more than taking off fat; it is a "drying-out" as well, especially in the final hours of training. Measurements of density of recent years have shown figures much lower than those once registered in textbooks and the entire subject of human specific gravity is unsettled. The author, who has measured many individuals of all degrees of robustness, points out that a relatively high density means muscular robustness because of the greater bulk of the muscles which have an individual specific gravity of 1.06. A man chiefly muscle and bone, deprived of fat and excess water, would necessarily have a high specific gravity.

News of the Week.

Influenza in Connecticut.—A survey made by the State Department of Health of Connecticut shows that 1043 cases of influenza have been reported in that State since January 1. There has been an increasing number of cases of pneumonia developing from it, 30 to 45 per cent. of which have proved fatal. The survey shows 142 cases of smallpox in nine towns.

Influenza in Uniontown, Pa.—A report to the New York *Herald* under date of February 10 states that approximately 10,000 persons, or 50 per cent. of the population of Uniontown, are ill with influenza, and unless drastic measures are taken the situation will become extremely serious.

New York State Death Rate in 1921 Lowest on Record.—The death rate of New York State for the year 1921 reached the new low level of 12.2 per thousand of the population, according to calculations completed by the State Health Department's Division of Vital Statistics. This rate may be compared with that of 13.8 for the year 1920, and that of 14.7 for 1914, the year in which the State Department of Health was reorganized and took on its present form. In terms of lives saved, the rate for 1921 means that approximately 16,000 more residents of the State are now living than would have been the case if the 1920 death rate had not been reduced as above indicated. Comparing 1921 with 1914, the difference in the death rate means that 26,000 more people are now alive than would have been if the 1914 death rate had prevailed up to the present time. New York City, with a death rate of 11.2, still retains its lead over the remainder of the State, for which the 1921 rate was 13.5 per 1000 of population. In the up-State area it is also of interest to note that the 1921 rate in cities was 12.6 as against 13.5 for the rural area.

More Hospitals for Ex-Soldiers.—According to a statement made by Chairman Langley of the House Public Buildings and Grounds Committee, President Harding has given his approval to the bill authorizing an appropriation of $16,000,000 for the construction of additional hospitals for war veterans. Passage of the bill also is advocated by the Federal Board of Hospitalization, with the recommendation that a clause providing that $500,000 be expended in enlarging Mount Alto Hospital, Washington, D. C., be eliminated. The bill will be taken up by the House at an early date.

Chicken Salad Poisons Girl Students.—More than three hundred students of the Mississippi State College for Women at Columbus suffered from food poisoning caused by eating chicken salad served at the evening meal on February 12. Although a large number were seriously ill, no deaths occurred.

To Provide Rural Doctors.—The State Grange, at its annual convention held in Binghamton, N. Y., on February 10, went on record in favor of the plan of M. E. Gregg of Mottville, N. Y., who proposes that each country community now without a

physician, erect a home and a small hospital for the use of any physician who will settle there. Dr. Gregg says that where a farming community erects a home, the Rockefeller Foundation will send a physician, thus providing medical service for those places in the State now without it. Dr. Gregg further states that the plan has received the approval of the State Association of Health Officers. The State Department of Health and the Rockefeller Foundation will be asked to join in the movement.

Hearing on Betts Bill.—A hearing on the Betts bill, which would forbid experiments on living dogs, was held in Albany on February 7. The same bill has been before the Legislature for ten successive years. Among the advocates of the bill were Dr. Joseph J. Harrigan, representing the New York Anti-Vivisection Society, and Dr. Willard Carver of New York. Opposition to the bill included Dr. Simon Flexner, director of the Rockefeller Institute; Dr. H. B. Williams of Columbia University, and Dr. Augustus B. Wadsworth of the State Department of Health.

Bill to Provide Scholarships in Medical Colleges.—A bill was introduced into the Virginia Legislature on February 2, authorizing the board of visitors of the Medical College of Virginia to offer twenty State scholarships in the department of medicine to students from Virginia, and making an appropriation of $5,000 each for the years 1923 and 1924 for this purpose. The bill carries this additional provision: "Every student receiving the benefits of the scholarship provided for in this act shall practise medicine for a peroid of not less than five years after graduation in a rural section of the congressional district from which he or she is appointed, or shall repay the value of the scholarship to the Medical College of Virginia within the same period of time." The scholarships are to be allocated, or apportioned, two to each of the ten congressional districts, the benficiaries to be selected following competitive examinations.

Dean Edsall Urges Correlation of Medical Study.—Dr. David L. Edsall, in his annual report as Dean of the Harvard Medical School, lays special emphasis on the need of correlation in medical study, and particularly in the correlation of teaching in medicine and public health, so that the practising physician and the public health officer may learn to work together for the public service. Dean Edsall says: "It is not so much the details of knowledge that are omitted; the knowledge needed for his public health relations is for the most part the same, as has been indicated, as that the physician needs and acquires when well prepared for the practice of medicine. Some things should be added to it, not in extensive detail, but in the form of the principles that guide public health. The chief thing needed, however, is to make the public health aspects of the physician's knowledge and of his activities more visible and living. For this reason, the establishment of the new School of Public Health at Harvard, which will probably open next autumn, and will be closely related to the Harvard Medical School, may prove to be the most important development for many years in its influence upon the medical school.

Columbia University Gathers Ideas for New Medical School.—A committee representing the Medical School of Columbia University, New York, inspected the general hospital and the medical college of the University of Cincinnati, Saturday, for the purpose of gathering ideas for the proposed new medical school at Columbia. The delegation included Edward Harkness and William Sloane, James Gamble Rogers, architect; Dr. William D. Darrach, dean of the Columbia Medical School, and Dr. C. C. Burlingame.

New Plan to Eliminate Tuberculous Cows.—The State Department of Agriculture has initiated a project whereby it hopes to eradicate tuberculosis among the dairy herds of the State. The method proposed is known as the free area plan and involves the creation of zones, and the examination of all cattle and the extermination of all affected animals within their boundaries, extending by degrees the territory of such complete supervision until the whole State is included. At present 30 veterinarians are examining herds in these ten counties under the free area plan. In 1919, figures available at the State Bureau of Animal Industry show that $132,-701 was expended in the effort to eliminate tuberculous cattle in this State; in 1920 the figure was $506,857, and last year $1,558,112. Out of a total of 130,584 cows examined by the State agents last year, 19,897 were found to be tuberculous and were slaughtered. Under the new plan the loss is distributed between the Federal Government, the State, and the counties.

Campaign to Save Eyes.—Plans to carry eye conservation into industry, schools and colleges, the professions, athletics and other forms of effort were announced recently following a series of meetings and conferences of industrialists, educators and eye experts from various parts of the country, held in New York under the auspices of the Eyesight Conservation Council of America. The campaign will be under the general direction of L. W. Wallace, executive secretary of the American Engineering Council of the Federated American Engineering, and is largely the outcome of the disclosures of huge waste in men and money through defective vision made by the Hoover Committee on Elimination of Waste in Industry. According to figures presented at the conference, the eye is found to be involved in 11 per cent. of all the permanent industrial accidents of the country, and approximately 25,000,000 workers in the United States have defective vision that requires correction.

Immunity of Jews Cuts Tuberculosis in New York.—At the annual meeting of the New York Tuberculosis Association, held on February 8, G. J. Drolet, statistician of the association, stated that the marked decline in tuberculosis during the last few years demanded explanation. He accounted for it on the ground that prohibition had reduced the amount of misery and increased the amount of money available for food, clothing, and shelter. The resistance of the people has been increased by the general rise in the standard of living. Mr. Drolet stated that in New York City this coming into the population of a large group of Jewish stock, noted for their immunity to all diseases that commonly characterize congested city life had been a factor in reducing the death rate from tuberculosis. A recent study of the tuberculosis death rate in each of the small sani-

tary areas of Manhattan has revealed that the lowest mortality prevails in districts like Mount Sinai, Gouverneur, Corlears, and Stuyvesant in the extreme lower East Side, which are largely Jewish, whereas in all the districts of the lower West Side, where live most of the longshoremen, stevedores, and the poorer immigrants of Irish and Italian stock, as well as the artist and bohemian colonies of Greenwich Village, the tuberculosis mortality was several times larger."

Plan Extensive Maternity Study.—At the annual meeting of the Maternity Center Association, New York, it was officially announced that the association had begun a scientific study of the essentials of complete maternity care and that it was opening a new chapter in the fight to cut down the mother and baby death rate in the United States. More than a million pamphlets are being prepared for nation wide distribution. The annual report of the association showed that during the year 8211 patients were reported for care, 48,729 visits were made to the homes of patients by nurses and 23,002 visits were made by the patients to the twenty-five nursing centers maintained by the association.

Undernourished Children of the Rich.—The annual report of the Board of Education of South Orange, N. J., made public on February 13, declared that at least one-third of the school children were undernourished and that "a mother's care cannot be replaced by a servant's judgment." The report states that there is more undernourishment in the homes of the well-to-do than in those of moderate circumstances. The report further declares that undernourishment is the greatest evil with which the school authorities have to contend.

Glandular Fever in New York State.—A number of cases of illness in children which are in all probability instances of so-called glandular fever have recently been reported to the State Department of Health. Small epidemics of this condition have been noted elsewhere within the last few years. The January issue of *Health News*, the bulletin of the New York State Health Department, calls attention to the outstanding points in the differential diagnosis of this condition.

Campaign in Breast Feeding.—The Children's Bureau of the United States Department of Labor has entered upon an intensive nation-wide campaign of education in the importance of breast feeding, in which work the departments of health of the States are asked to lend their active cooperation. Dr. Florence McKay, Director of the Division of Child Hygiene, New York State Department of Health, asks the assistance of all public health workers in promoting the spread of knowledge regarding this very important measure for child health. Dr. McKay is mailing a copy of Breast Feeding, published by the Children's Bureau, to every health officer and public health nurse in the State.

Newark Physicians to Have Office Buildings.—A six-story building to be devoted entirely to offices for physicians and dentists will be erected at 23 and 25 Hill Street, west of Broad Street, Newark. The estimated cost of the building is $150,000.

Medical Office Building for New Orleans.—An association of New Orleans physicians is making preparations for the erection of an eight-story office building for physicians at Prytania and Aline streets, near the Touro Infirmary.

The New York Academy of Medicine, at its stated meeting held February 16, adopted an amendment to its constitution increasing its resident fellowship from 1,350 to 1,400 and its nonresident fellowship to 300.

Flatbush Physicians Oppose Bills.—The Flatbush (Brooklyn) Medical Society, at a meeting held at the Union League Club on February 10, put itself on record as opposed to the Male bill, the State Maternity bill, the Chiropractic, Optometrist, and the Medical and Dental Inspection and Attendance bills now before the State Legislature.

Hospital Notes.—The name of the United States Public Health Service Hospital 61 at Fox Hills, Staten Island, N. Y., has been changed for the third time. Hereafter it will be known as United States Veterans' Hospital 61. The change is said to have been made because of confusion between this institution and the United States Marine Hospital, which is also a Public Health Service Hospital.

Plans are approaching completion for what will probably be known as the Charlotte Eye, Ear, Nose, and Throat Hospital to be located at Charlotte, N. C. The cost of the new hospital is estimated at $100,000.

Work will be started soon on the Nellie Johns Memorial Hospital, to be erected at a cost of $15,000 on the campus of the Kansas Industrial and Educational Institute, Topeka, Kan.

The citizens of Baltimore have authorized the expenditure of $750,000 to be raised by special loan for a new municipal hospital, which will be located in the Hillen Road Section.

Johns Hopkins Hospital has work under way on a new $380,000 pathological building and a $400,000 hospital for women.

The University of Maryland will build a nurses' home for about $300,000 as the first unit of new construction to involve finally an outlay of $1,250,000.

Bids are being received for a new building for the Union Memorial Hospital, Baltimore, which will cost something over $1,000,000. Its present building will be used as a colored hospital, to be known as the Victory Hospital.

Cleveland's new city hospital which, when completed, will cost $3,500,000, will not be opened until 1923, unless the additional $700,000 necessary for its operation can be secured from some source yet undiscovered. The hospital building will be ready for occupancy by May 1.

Plans have been completed for a 500-room hospital, which, it is estimated, will cost $1,000,000, to be erected on a six-acre tract bounded by Washington and Twentieth streets, Los Angeles. The hospital will be known as the University Hospital and Clinic. The College of Physicians and Surgeons is already located on the tract.

Hays County, Texas, is conducting an intensive campaign to raise $50,000 with which to build and equip a memorial hospital as a tribute to the

boys who went from this county to the World War.

The Physicians' and Surgeons' Hospital Association of Wilmington, Del., is planning to build a new hospital at Broome and Chestnut streets.

The State Hygiene Department has recently purchased a site at Warren, Ohio, for a $100,000 tuberculosis hospital.

Property has been acquired at Russellville, Ark., which is to be used by the United States Public Health Service as a trachoma hospital.

An article in the Los Angeles *Examiner* announces that the Mayo Brothers of Rochester, Minn., are negotiating for a site in Los Angeles for one of the largest hospitals in the world.

Dr. Ernest LaPlace of Philadelphia was the guest of honor at a dinner given by the Right Reverend Peter Masson, director of the Sacred Heart Hospital, Allentown, Pa., to eight physicians and friends. Dr. William J. Hausman, Jr., officiated as toastmaster.

Dr. James Clark of Endicott City, Md., was recently elected president of the Howard County Public Health Association.

Dr. Charles H. Crampton of Harrisburg, Vice-President of the Colored American Medical Association, has been appointed by State Health Commissioner Martin to lecture on venereal diseases to the colored people of Pennsylvania.

Dr. J. M. Davies of Utica, N. Y., has been elected president of the Board of Managers of the Oneida County Hospital.

Dr. Arch I. Carson has been appointed a member of the Board of Health of Cincinnati by Mayor Carrel to fill the vacancy created by the death of Dr. E. Gustav Zinke.

Charitable Gifts and Bequests.—By the will of the late Rachel E. Reimer of Haddon Heights, N. J., bequests are made as follows: The Philadelphia Home for Incurables, $1,000; the Children's Homeopathic Hospital of Philadelphia, $500.

Leverett Newcombe of Vineland, N. J., has agreed to donate to the Vineland Hospital Association between $150,000 and $200,000; this includes two city lots blocks, valued between $20,000 and $30,000, to be used as a site for the hospital.

By the will of the late Ann Ward Pearsall of Lower Merion, Pa., the sum of $10,000 is bequeathed to the Episcopal Hospital of Philadelphia.

By the will of the late Harry D. Schell of Philadelphia bequests are made as follows: Northwestern General Hospital, $25,000; American Oncologic Hospital, Methodist Hospital, Howard Hospital, Children's Homeopathic Hospital, each $10,000, one-half of the last for the endowment of a bed in memory of the testator's wife, Kate D. Schell; Philadelphia Home for Incurables, Frederick Douglass Memorial Hospital, Hahnemann Hospital and Medical College, Jewish Hospital, Devitt's Camp for Consumptives, Woman's Southern Homeopathic Hospital, Pennsylvania Hospital, each $5,000; Kensington Hospital for Women, $6,000; Woman's Medical College, Woman's Hospital, West Philadelphia Hospital for Women, Women's Homeopathic Association, each $2,500; Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, $2,000; Maternity Hospital, Frankford Hospital, Germantown Hospital and Dispensary, Gynecean Hospital, Philadelphia Polyclinic and College for Graduates in Medicine, Rush Hospital for Consumptives, each $1,000; Northern Dispensary, Southern Dispensary, each $500.

The will of Mrs. Minnie Croy Whitmore of Dayton, Ohio, provides for a bequest of $50,000 to the Miami Valley Hospital Society to be used for the construction of a building for the treatment of deformed and crippled children.

By the will of the late James M. Stokes of Philadelphia the sum of $1,000 is bequeathed to Hahnemann Hospital as a memorial to the wife of the testator, Anna D. Stokes.

Course in Infectious Diseases and Public Health.—The annual course in Infections Diseases and Public Health given by the Albany Medical College in co-operation with the State Department of Health will begin March second. A program of the course will be mailed to any physician upon request.

Harvey Lecture.—Dr. William M. Bayliss, Professor of General Physiology, University College, London, will deliver the seventh Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, March 4, 1922. His subject will be "Vasomotor Reactions and Wound Shock."

Medical Society Elections.—THE HARRISBURG (PA.) ACADEMY OF MEDICINE, at its annual meeting held Jan. 27, 1922, elected the following officers for the ensuing year: *President,* Dr. E. R. Whippel; *vice-president,* Dr. H. F. Gross; *second vice-president,* Dr. A. J. Ritzman; *secretary-treasurer,* Dr. Gilbert Dailey; *trustee,* Dr. Park A. Deckard.

THE NEW YORK TUBERCULOSIS ASSOCIATION, at its annual meeting held Feb. 8, elected the following officers for the ensuing year: *President,* Dr. James Alexander Miller (re-elected); *vice-president,* Homer Folks; *treasurer,* Thomas W. Lamont; secretary, Dr. Nathan E. Brill.

THE PORTSMOUTH (N. H.) MEDICAL SOCIETY, at its annual meeting held Feb. 7, 1922, elected the following officers for the ensuing year: *President,* Dr. George A. Tredick; *secretary,* Dr. L. R. Hazzard; *treasurer,* Dr. H. L. Taylor.

Obituary Notes.—Dr. MILTON B. BLOUKE of Chicago, a graduate of the Chicago Homeopathic Medical College in 1885, died in St. Petersburg, Fla., on Feb. 12, at the age of fifty-nine years. He served for fourteen years on the staff of the Cook County Hospital.

Dr. JOHN B. CARSON of Blairsville, Pa., a graduate of Jefferson Medical College in 1889, died suddenly on Jan. 30, at the age of fifty-five years. He was a Fellow of the American Medical Association and a member of the Medical Society of the State of Pennsylvania.

Dr. LUCIUS ELY FELTON, formerly of Potsdam, N. Y., died at his home in Hanford, Cal., about Jan. 20, at the age of seventy-three years. He was graduated from Bellevue Hospital Medical College in 1871, was an ex-president of the Northern New York Medical Society and an ex-president of the Hanford Board of Health. He was a member of the Federal Pension Board for forty-nine years.

Dr. HARRY C. BARTLESON of Lansdowne, Pa., died on Jan. 29, at the age of seventy-seven years. He served in the Eighth Maryland Volunteers during the Civil War, being mustered out as Captain. He

was graduated from Jefferson Medical College in 1870. He was a member of the Delaware County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. ARTHUR M. HEILMAN of Butler, Pa., died in a hospital at St. Petersburg, Fla., of cerebral hemorrhage on Jan. 30, at the age of forty-three years. He was graduated from the Medical Department of the University of Pennsylvania in 1902.

Dr. JOHN ADDISON JENKINS of Brooklyn, a graduate of Bellevue Hospital Medical College in 1865, died on Feb. 4, at the age of seventy-eight years.

Dr. SAMUEL RUSSELL died at his home in Brooklyn on Feb. 3, at the age of eighty-four years. He was graduated from the Long Island College Hospital.

Dr. GEORGE BLEY of Beardstown, Ill., died suddenly at Bunker Hill on Jan. 17, at the age of seventy-one years. He was graduated from Jefferson Medical College in 1881.

Dr. HUGO MALOR, a graduate of the University of Louisville Medical School in 1898, died at his home in Louisville, Ky., on Jan. 19, at the age of sixty years.

Dr. WALTER B. MILLER died of heart disease at his home in Millerton, N. Y., on Jan. 13, at the age of sixty-six years. He was graduated from Albany Medical College in 1882.

Dr. HYRUM SMITH WOOLLEY of Pocatello, Idaho, died suddenly on Jan. 10, at the age of forty-eight years. He was graduated from the Northwestern Medical School in 1909.

Dr. FLOYD J. GREGORY, JR., of Keysville, Va., died of pneumonia in Chase City, Va., on Jan. 20, at the age of forty-seven years. He was graduated from the Vanderbilt University Medical School, Nashville, Tenn., in 1901.

Dr. HENRY M. HOLZCLAW, a graduate of Bellevue Hospital Medical College in 1881, died on Jan. 22, at the age of sixty-one years.

Dr. ELIZA MARKWELL MITCHELL of Kansas City, Mo., died on Jan. 31. She was graduated from the University of Michigan Medical School, Ann Arbor, in 1877.

Dr. BELLE J. MACDONALD of New York, a graduate of the Willamette University Medical Department, Salem, Ore., in 1886, died in Palermo, Sicily, on Feb. 10, at the age of fifty-six years.

Dr. ELIZABETH REIFSNYDER died of heart disease at Liverpool, Pa., on Feb. 4, at the age of sixty-four years. She was graduated from the Woman's Medical College of Pennsylvania in 1881. She served for many years as physician to the Margaret Williamson Hospital at Shanghai, China.

Dr. HANNAH M. THOMPSON died at Wilmington, Del., on Feb. 5, at the age of seventy-five years. She was graduated from the Woman's Medical College of Pennsylvania in 1883.

Dr. ISAAC W. HEULINGS died at Moorestown, N. J., on Feb. 9, at the age of seventy-four years. He was graduated from Jefferson Medical College in 1867.

Dr. JAMES W. HOLLAND died in Jefferson Hospital, Philadelphia, on Feb. 10, at the age of seventy-three years. He was graduated from Jefferson Medical College in 1868. From 1872 to 1875 he was professor of chemistry in the Medical Department of the University of Louisville and editor of the *Louisville Medical News*. From 1885 to 1912 he was professor of medical chemistry and toxicology and dean in Jefferson Medical College. He was at one time president of the Kentucky State Medical Society and a member of the Kentucky State Board of Health. He was a member of the American Philosophical Society, the Philadelphia Medical Society, the Medical Society of the State of Pennsylvania, and a Fellow of the College of Physicians of Philadelphia and of the American Medical Association.

Dr. CHARLES ALEXANDER RHODES of New York died of heart disease at his home on Feb. 14, at the age of sixty-seven years. He was graduated from New York University Medical College in 1884, and was visiting physician to St. Joseph's and St. Luke's Home.

Dr. SARAH ELIZABETH SIMONET of Croghan, N. Y., a graduate of the University of Buffalo Department of Medicine in 1885, died of heart disease on February 3, at the age of sixty-eight years.

Dr. HARRY H. HUBBELL of Corning, N. Y., a graduate of the University of Buffalo Department of Medicine in 1901, died of encephalitis following pneumonia on January 4, at the age of forty-four years.

Dr. HARRY T. CARTER, retired, formerly of Oneida, N. Y., died on Feb. 1, at the home of a relative in North East, Pa. He was a graduate of New York University Medical College.

Dr. STEPHEN KELLY, retired, died from pneumonia at his home in New York City on Feb. 11, at the age of seventy-four years. He was graduated from Bellevue Hospital Medical College in 1871.

Dr. GUY L. MCCUTCHEON of Buffalo, N. Y., died in Phœnix, Ariz., after a long period of ill health, on February 2, at the age of forty-eight years. He was graduated from the Department of Medicine of the University of Buffalo in 1896. He was a Fellow of the American Medical Association, a member of the Erie County Medical Society, and the Buffalo Academy of Medicine. He was on the staffs of the Buffalo General and City Hospitals.

Dr. ADRIAN YOUNG REID of New York died at Pleasantville, N. Y., on February 18, at the age of seventy-three years. He was graduated from New York University Medical School in 1880.

Dr. JAMES MARTIN PEEBLES died at his home in Los Angeles, Cal., on February 15, lacking forty days of being one hundred years of age. He was graduated from the Philadelphia University of Medicine and Surgery in 1876. Dr. Peebles was born in Whitingham, Vt., March 23, 1822, and was graduated from Oxford Academy, in Chenango County, New York, in 1841. He owned and edited a number of papers and went around the world five times, lecturing in Oriental countries. He was a member of the Indian Peace Commission which, in 1868, settled some of the Indian troubles in the Middle West, and in 1869 was United States Consul at Trebizond, Turkey. Later he represented the United States Arbitration League at the International Peace Commission of Europe in Paris. For three years Dr. Peebles was Professor in the Eclectic Medical College of Cincinnati, he was President of the California College of Science for four years and president and founder in 1914 of the

Peebles College of Science and Philosophy in Los Angeles. He founded in the latter city the California Centenarian Club and served as president of the California Humanitarian League. He was the author of a number of books, religious, psychological and similar topics.

Dr. ERNEST GUSTAV ZINKE of Cincinnati, Ohio, died suddenly at Palm Beach, Fla., on January 30, at the age of seventy-six years. He was graduated from the Ohio Medical College, Cincinnati, in 1875, after which he studied in London, Edinburgh, and Vienna. Dr. Zinke was professor emeritus of obstetrics of the Medical College of the University of Cincinnati and a member of the Cincinnati Board of Health. He was a former president of the Cincinnati Academy of Medicine secretary of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, and a Fellow of the American Medical Association.

Dr. YOUNG HANCE BOND of St. Louis, Mo., died on February 5, at the age of seventy-five years. He was a graduate of University of Maryland School of Medicine, Baltimore. He was a former president of the St. Louis Medical Society, founded the Marion Sims Medical College and when that institution was absorbed by the St. Louis University he became dean of the Medical Department. He was a former member of the St. Louis Board of Health.

Obituary.

DANIEL MACMARTIN STIMSON, M.D., LL.D.

NEW YORK

ONE of the links binding the present generation of physicians of New York with the great ones of the middle of the last century was broken by the death on February 21 of Dr. Daniel M. Stimson at the age of 78 years. He was born in Edinburgh, N. Y., on Jan. 2, 1844, and was graduated from Union College in 1864 and from the College of Physicians and Surgeons in this city in 1868. After a period of post-graduate study in Berlin, Vienna and Paris, he began the practice of medicine in New York City, being associated with Dr. Willard Parker, whose daughter he married in 1871. He was a member of many of the local medical societies, and was for a number of years attending surgeon to St. Peter's, the Presbyterian, and Mt. Sinai Hospitals.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

THE COST OF THE QUESTIONNAIRE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The results of the "questionable questionnaire," as you once called it, have now been published in the *Journal of the American Medical Association*, and are, as you prophesied they would be, wholly inconclusive. The votes of a fraction of the medical practitioners in the country were nearly evenly balanced, with a slight majority in favor of the therapeutic value of whiskey. It has occurred to me to inquire who authorized this expensive straw vote; was it done on the editor's own initiative, or did he tell the trustees of the Association to tell him to start it? In any case, it was a wanton waste of the Association's funds. The dues of the fellows have recently been raised 20 per cent., and if this is the way the additional $40,000 is to be expended, we had better go back to the old price. I have recently got an estimate from a friend familiar with the cost of printing of about how much was expended in this farcical inquiry. His estimate for composition, time work, paper, presswork, binding, and extra postage on the *Journal* was in the neighborhood of $3,000, to which must be added $2,160 for postage on the letters of inquiry and replies, $300 for stationery and an indefinite sum for the tabulation of the replies, extra labor, overhead, etc., bringing the total up to nearly $6,000. Who is responsible for this waste of our money?

A FELLOW A. M. A.

[We regret that we cannot gratify our correspondent's not unnatural curiosity, for we are not familiar with the inner workings of the editorial office of the *Journal* of the Association. So, in the language of the Service, we will pass the buck, and let George do it.—ED.]

WHAT IS NEEDED IN THE PRESENT CRISIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The remedy for the apparent lack of understanding between the public and the medical profession, now occupying the attention of Commissioner of Health Copeland and other physicians, is simple if properly applied. It lies in this. Let the public turn its attention from matters medical to matters legislative. The medical profession, through self-abnegation and achievement, has earned the right to public confidence. The legislature has done just the reverse of this. Let the legislature stop authorizing deluded people, fools, and dishonest persons, to care for the sick professionally and the problem is solved.

WILLIAM J. CRUIKSHANK, M.D., F.A.C.P.
102 FORT GREENE PLACE,
BROOKLYN, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Jan. 31, 1922.

Industrial Medicine.—In the realm of preventive medicine, no phase of it is of greater importance than that of industrial medicine. It is obvious that unless the worker is in good health he cannot work properly and is in a continual state of dis-

satisfaction. Therefore it is of manifest advantage to the employer of labor and of the government of a country to put forth every effort to maintain the health of the worker at a high standard. As a matter of fact, the prosperity of a country and, of course, of the employer hinges upon this point. This aspect of the question is beginning to be realized in Great Britain, and large employers, or at least some of the more far seeing, are endeavoring to keep their employees in good health and in a contented frame of mind, by not only having their factories and workshops in a good sanitary and hygienic condition, but by providing mental pabulum and distraction to obviate, to some extent, the deadly monotony of many kinds of toil, which kill the spirit and deaden the mind and react injuriously upon the physical powers. But enough is not done in this direction in this country, which lags far behind America in this respect. The medical correspondent of the London *Times*, who is deeply interested in preventive medicine and particularly so from the industrial standpoint, frequently writes illuminating articles on the subject. For example, in the *Times*, January 25, last he compares the care taken in America to conserve and maintain at a high stage of efficiency the human machinery with the lethargy displayed in this country in grappling with the same problem. He points out that it is recognized on your side of the Atlantic that unless and until industry tackles and solves the human problem there can be no peace within its ranks. He further directs attention to the fact that there are hundreds of agencies, state, municipal, industrial and private, which are now laboring on this problem. Perhaps the most important of these agencies are those concerned with education and vocational selection. In order to succeed in any line of endeavor an individual must like the work or he will not possess that zest which is essential for success. Moreover, he or she must be physically fitted for the work. These points were insisted upon by Sir Kenneth Goadby in an article some few months ago, who suggested that certain tests should be applied ere a vocation was chosen. Those who perform work for which they are not adapted do not give profitable service, and are a source of discontent and unrest to themselves and others. The writer of "At the Periphery" in the *Medical Press and Circular*, January 25, 1922, remarks that "Failure in life naturally begets discontent, and this again leads the individual to suppose that there must be something seriously wrong, not with himself but with things in general, so he sets out to put them right." And thus the agitator is made and more workers are unsettled and more discontent reigns. The aim of vocational selection is to find out a boy's or girl's aptitude at the earliest hour, to develop it and use it. The *Times'* medical correspondent points out that the appearance in an industry of men and women having what amounts to a vocation for that industry is recognized as a tremendous step in the direction away from distrust, discontent, and unhappiness. It tends to make a trade a profession, and thus to imbue those carrying it on with the professional spirit. Another phase of the problem showing the tendency of the age is the relation of psychology to employment. Psychology is rapidly coming into its own and the connection of psychopathy with employment is more intimate by far than is generally supposed. Monotonous work breeds mental sickness which must be fought with the proper weapons. However, enough has been said on this fascinating question, and it only remains to reiterate the statement made by the medical correspondent of the *Times* that industry in America can teach British industry a useful lesson in this respect.

Post-Graduate Lectures.—A course of post-graduate lectures is being delivered at the hospital for sick children, Great Ormond Street, London, W.C., this session on Thursdays at 4 P. M. and are free to medical practitioners on February 2. Dr. R. S. Frew will take as his subject "Pain in Infancy." Subsequent lectures will be announced in succeeding letters.

Infants' Hospital, Vincent Square, London.—A course of six lectures on the physiology and pathology of ante-natal and early post-natal life will be given by Dr. W. M. Feldman in the lecture theatre of the infants' hospital in Vincent Square, London on Thursdays at 4 P. M., beginning on Feb. 2. The first lecture will deal with Fetal and Infantile Mortality and the Peculiarities of Child Life. On Feb. 9 the subject will be Embryonic Physiology and Pathology; on Feb. 16, Fetal Physiology and Fetal Nutrition; on Feb. 23, the Physiology and Pathology of the New-Born, Initial Loss of Weight and Icterus Neonatorum. The two lectures on March 2 and 9 will be devoted to the Physiology of the Infant. The lectures will be illustrated and the practical significance of the various points will be pointed out and discussed.

Post-Graduate Courses at the University of Birmingham.—A course of post-graduate clinical demonstrations has been arranged for Tuesday, Wednesday, and Friday afternoons during the next two months. In the report of the University Council to be presented at the annual meeting of the Court of Governors, the great need for additional accommodation for laboratories, lecture theatres, and classrooms for the faculty of medicine and arts is pointed out. The number of medical students for the session 1920-21 was 259, as compared with 227 for the previous session, 123 in 1918-19, and 89 in 1917-18.

St. Andrew's Institute for Clinical Research.—A post-graduate course for general practitioners under the direction of Sir James Mackenzie will begin on May 3 and will extend over three weeks. The course will consist of lecture demonstrations dealing with the symptomatology of disease in its early stages, and will be supplemented by demonstrations on matters of clinical interest in anatomy, physiology, chemistry, bacteriology, ophthalmology, and radiology. The fee for the course is £10 10s.

It will be gathered from the above announcements that arrangements for post-graduate medical instruction are being made in London and the provincial medical schools and hospitals of Great Britain. The Fellowship of Medicine and Post-Graduate Association of London will issue shortly a full syllabus of the arrangements made in the metropolis for the behoof of those who desire to study British methods and perhaps especially clinical methods in the largest city of the world.

Presentation to Sir Patrick Manson.—No name is better known throughout the medical world than that of Sir Patrick Manson, F.R.S., who was a pioneer and the moving spirit of tropical medical research and investigation. It may be recalled to the minds of those interested in this form of research that it was Manson who suggested to Sir Ronald Ross to look for the mosquito as the predominating factor in the spread of malaria. Manson's name will go down to posterity linked with that of Ross as the discoverer of the main means of the dissemination of, on the whole, the disease most injurious to the human race. But not only did Manson point the way to the eradication, at any rate, to the lessening of this most deadly and enervating disease, but he was instrumental in blazing the trail along the untrodden path leading to the unveiling of the mystery of many obscure diseases of the tropics. Manson is distinctly a, if not the, pioneer in the parasitic field of research of investigation. He may be aptly termed the grand old man of tropical medicine. On Jan. 20, last, at the London School of Tropical Medicine, Sir Patrick was present at the unveiling of the portrait by Sir James Michelli, C.M.G. The portrait had been subscribed for by a number of Sir Patrick Manson's friends both at home and abroad and by past and present members of the school. A fund has also been established, in the hands of a committee over which Sir William Leishman, F.R.S., presides, for the institution of a medal to be awarded annually for clinical research and to be known as the Manson Medal. The ceremony took place in the entrance hall of the school, Prof. A. Alcock, F.R.S., briefly indicating the objects of the memorial fund. Sir James Michelli, in unveiling the portrait, referred to the long and intimate association with Sir Patrick Manson, to the history of the foundation of the school and the struggles of its earlier days. Sir Patrick, who was received with the greatest enthusiasm, responded briefly. He said, in part, that he looked forward to the time when thousands of medical men would flock to the school; the success it had attained in its comparatively short career had been remarkable and he believed in the future it would be even greater.

Obituary.—Sir John Kirk, the friend of Livingstone, has just died at the age of ninety. Kirk was the eldest son of the Rev. John Kirk of Arbirlot, Forfarshire, studied medicine at Edinburgh University, where he was graduated M.D. in 1854. After serving in the Crimean War, he was appointed naturalist and medical officer to the expedition which Livingstone was organizing. The remainder of Sir John Kirk's services were mostly employed in discharging duties of a political nature at Zanzibar, where in 1875 he was appointed consul-general. He retired in 1887, but continued to be employed by the Government, chiefly in an advisory capacity, for some years afterward. He was made LL.D. of Edinburgh University, D.C.L. of Oxford University, D.Sc. of Cambridge University. He also received the Fellowship of the Royal Society. He was appointed in 1881 K.C.M.G., in 1886 G.C.M.G., and K.C.B. in 1890. He was awarded the Patron's Medal of the Royal Geographical Society in 1882.

3. Perforated Gastroduodenal Ulcers. Some Notes as to Their Treatment. James J. Hepburn.
4. Stiff Fingers. Fred J. Cotton and Edward J. Sawyer.
5. The Aid Which the State Offers in Control of Tuberculosis Through Sanatoria and Consultation Clinics. Eugene R. Kelley.

1. A Reconsideration of Dyspepsias.—Francis W. Palfrey finds in the usual symptoms of dyspepsia suggestions of abnormalities of function which enable him to recognize three groups of cases and which give hints as to their treatment. One such group is that characterized by epigastric pressure and difficult belching. This he attributes to a valvelike closure of the cardiac orifice and designates as "valvular cardia." Minor cases of this condition are fairly common and may be little inconvenienced unless other disease is present. As for treatment, if the valvular action of the cardiac orifice is due to organic relations of the liver, the left crus of the diaphragm, and the last portion of the esophagus, we have at present no way of correcting it. If, on the other hand, kinking by pressure of a distended fundus is to blame, there is some hope of improving matters by avoiding such distention. To this end it is reasonable to give a diet which obviates the need of belching, and this diet fortunately is the same diet which tends to least distention of the fundus. For a second group of cases that are apt to have a sense of weight or dragging in the epigastrium, anorexia, vomiting of undigested food, general debility, ptosis and poor muscular development the term "gastric asthenia" is suggested, since the term gastric neurosis has been so loosely used in the past as to have lost its proper meaning and to include all dyspepsias without organic disease. These cases are often difficult to improve. The diet should be a general one, such as would be allowed a healthy older child. Bitter tonics before meals and dilute hydrochloric acid after meals may be of service, but more is to be expected from improvement of environment, habits, mental attitude, diet and general physical condition. As a third group the writer classes together what he considers cases of gastric irritation, under three subheads: catarrhal, toxic, and hyperacid. By far the most important of these is the group complaining of sour stomach and heartburn where the condition seems to be one of irritation of the stomach by pepsin-hydrochloric acid developed within. Here the question is brought up as to why these acid contents remain in the stomach instead of passing on and whether the abnormally long contact of this digesting fluid with the mucous membrane may not be the cause of gastric ulcer, and, further, whether the failure of ulcers to heal may not be due to their being daily eroded by this fluid. Such considerations suggest an abnormal mechanism of the pylorus. One signal for opening of the pylorus is free hydrochloric acid on the gastric side. In these cases of hyperacidity this requirement is obviously met. But the second requisite is the neutralization of acid on the duodenal side. The fault probably lies here. Patients belonging to this group are frequently benefited by bile or bile salts when given in coating, which will not be dissolved in the stomach.

4. Stiff Fingers.—Fred J. Cotton and Edward J. Sawyer assert that concerning stiff fingers in their various sorts, which are much commoner than they should be, we have no very definite scheme of attack. After trauma as in Colles' fracture; after metacarpal or phalangeal injuries; after infections; after acute rheumatism, or a subacute attack in hand or wrist; after all these conditions and other odd calamities one meets with stiff fingers. Twenty-four hour traction, by miniature winches or by pull of elastic bands, traction exerted in the line of deformity to produce a distraction of joint surfaces, with very gradual change of the line of pull toward flexion or toward extension as the case demands, will so supplement ordinary physiotherapy methods, or so displace them, that stiff hands and fingers may possibly come to be rare.

2. Tuberculous Empyema.—Lewis H. McKinnie cites a number of case histories to emphasize the following facts: (1) Open drainage in tuberculous empyema is an unsatisfactory and often a disastrous procedure when the end results are considered. (2) The presence of other organisms in the pleural pus besides the tubercle bacillus—mixed infections——can be successfully treated by aspiration and replacement by air, which is contrary to the usual teaching. (3) The tuberculous base of empyema is often overlooked. The greatest care should always be used to exclude tuberculosis before instituting open drainage. During the last few years McKinnie has observed twenty-eight cases of tuberculous empyema with mixed infection. Eight of these were treated by aspiration and twenty by open drainage. He treated all the aspiration cases, but did not see the open drainage cases until operation had been performed. Only those cases in which there was persistent bronchial fistula were opened. Of the patients treated by open drainage, nine are dead, only one being considered at all well; all the other must be classed as chronic invalids. Of the eight patients treated by aspiration, one is dead; all the others are working and in good health.

3. Chemotherapeutic Considerations of Pentavalent and Trivalent Arsenic.—Jay Frank Schamberg, George W. Raiziss, and John A. Kolmer relate the detail of this study from which they draw the following conclusions: (1) Arsenic in inorganic compounds is highly organotropic and devoid of destructive effect on trypanosomes and spirochetes. (2) When linked to carbon in organic compounds it may acquire a destructive influence on the parasite. (3) Organic arsenicals are generally less toxic than inorganic. Those containing pentavalent arsenic are no more toxic than the trivalent. The least toxic of the trivalent compounds are those which contain the so-called arseno group. Compounds of the arsenoxid and arsin type are considerably more toxic than of the arseno type. (4) The effect on trypanosomes and spirochetes appears to depend in considarable measure on the valence of the arsenic. Trivalent carbon-linked arsenic is a much more powerful trypanocide than pentavalent. The arsin type is more trypanocidal than any other type or organic trivalent arsenical, although arsenoxid also exhibits a high value in this respect. (5) The nitrohydroxyphenolarsonic acid possesses no trypanocidal effect, but when the nitro group is converted into an amino radical a striking change is immediately observed. (6) The arseno compounds, arsphenamine and neoarsphenamine, give distinctly the best therapeutic indices of the entire series, and in this respect neoarsphenamine is superior to arsphenamine.

4. Individual Variations as Influencing Rehfuss Fractional Method of Gastric Analysis.—Nicholas Kopeloff, in a preliminary communication, reports observations made on a group of twenty patients belonging to the so-called functional psychoses, twelve having been diagnosed as dementia precox, eight manic depressive insanity, and one depression. Repeated analyses were made on one individual within a short period of time—while the physical and mental condition remained practically unchanged—yielded different curves. These curves from the same individual varied as much from one another as the differences between the curves of different individuals. Variation in the total amount of fasting contents from the same individual is often greater than between different individuals. There is an imperfect correlation between the measurement of gastric acidity by the titration method and hydrogen ion concentration determinations. The latter yields more important information regarding true acidity. This agrees with the work of Shohl. Similar results were obtained when repeated analyses were made on healthy normal individuals showing no gastric symptoms. In only half the instances was there any correlation between the high gastric acidity and low bacterial count. This indicates that another unknown factor is in operation. It is suggested that the bacterial content of the stomach depends on the swallowing of saliva. Bacterial counts, reaction of saliva, and observation of amounts swallowed substantiate this, as well as removal of saliva during the analysis. There was little difference in the gastric acidity in the patients diagnosed as having dementia precox and manic depressive insanity. This investigation indicates that single determinations of gastric acidity by the Rehfuss method are not sufficient on which to base conclusions, because they do not take into consideration individual variation.

8. Familial Bladder Atony.—F. F. Gundrum calls attention to a condition of bladder atony with retention, dribbling and varying amounts of residual urine in which no obstruction exists and no spinal cord disease can be found. Walker, in 1912, reported a series of twelve such cases and offered as explanation a lesion in the hypogastric or hemorrhoidal plexus, producing either detrusor weakness or sphincter hypertonicity. Other authors have reported individual instances of this condition, but so far as the writer can ascertain the occurrence of several individuals with bladder atony of this type in one family seems not to have been reported. He describes a family group in which bladder trouble is considered, by the male members at least, a common heritage. A patient with this condition volunteered the information that his two younger brothers were both using catheters under the advice of a urologist, and also that his father had a similar difficulty. Such family data as could be gathered showed that in three generations there were five who almost surely, and four more who probably, belonged in this group described by Walker.

3. Influenza: Treatment by Direct Stimulation of Leucopoiesis.—Graham Willmore and F. M. Gardner-Medwin describe a summer and a winter type of influenza seen in Egypt in 1918 and the early weeks of 1919, the former strongly resembling sandfly fever. Three considerations seemed to indicate a line of treatment. These were the possibility that such organisms as Pfeiffer's bacillus and the strepto-diplococcus were both secondary infections, grafted on a soil previously prepared for their advent by the same resistance-lowering virus which may be the cause of the disease; the marked leucopenia invariably found to correspond with the clinical severity of the early uncomplicated cases, and the clinical aspects of many of the severer cases suggesting a profound toxemia out of all proportion to the lesions found at autopsy in the lungs. Logical treatment was therefore twofold: (1) To stimulate the production of leucocytes directly by means of injections hypodermically or intramuscularly of sodium nucleinate; and (2) to neutralize the poison already circulating in the tissues (and presumably causing the leucopoietic paralysis among other toxic effects), by large doses of alkalies (sodium bicarbonate, 1 dram, four-

hourly), and by giving as much glucose in the food as the patients would take. In the worst cases glucose was given also per rectum, subcutaneously, or intravenously, in a 3 per cent. solution, combined with sodium bicarbonate 2 per cent. Free purgation with calomel and salines, cardiac stimulants hypodermically (such as camphor in oil and caffeine in solution of sodium benzoate as required), and a mixture containing potassium iodide and creosote in cases in which there was much mucopurulent expectoration, were concomitants in the treatment. The diet consisted of milk and glucose, and dilute albumin-lemon-glucose-barley water, of which the patients were encouraged to drink as freely as ever they could. In nearly all cases improvement of the patient's general condition followed the injection of the nuclein so rapidly and strikingly that the conclusion was forced upon one that the crisis was actually precipitated by it, and was independent of the day of the disease; it usually occurred forty-eight hours after the first injection.

5. Bilious Attacks and Epilepsy.—C. Wilfred Vining presents evidence with a view to emphasizing the possibility of the "bilious attack" and other morbid phenomena occurring in the child and adolescent being in some cases an expression of the potentially epileptic nervous system. The secret of the prevention of epilepsy probably lies in the patient's preceding generation or generations, and to attempt its prevention in the child is at least more satisfactory than to attempt to produce a cure when epilepsy has fully developed. The recognition, therefore, of the possible relationship of these phenomena to the epileptic state and their active and prolonged treatment, together with suitable control of the child's life, may go a long way in the prevention of the development of the convulsive habit.

6. Researches on the Cinchona Alkaloids.—Hugh W. Acton states that quinine is generally regarded as a methoxy derivative of cinchonine, but since quinine is levorotatory and cinchonine dextrorotatory in their optical activity, it seems probable that quinine is not derived from cinchonine. Of the fourteen alkaloids which have been isolated from the various species of cinchona, the two series of crystallizable cinchona alkaloids, namely, the natural and the hydro-alkaloids, responsible for the curative action of cinchona bark in malarial fevers, have been investigated by the writer. With reference to the toxicity of the cinchona alkaloids, he concludes as follows: (1) The toxicity of the cinchona alkaloids on paramecium varies with the concentration of the culture. They are much more toxic in alkaline than in acid cultures. (2) With the exception of cinchonine, the detrorotatory alkaloids in alkaline culture are more toxic than the "cinchonidine series." (3) The toxicity increases with the higher members of the series. (4) The hydro-alkaloids are slightly less toxic than their corresponding neutral alkaloids. The investigation of the cinchonine derivatives, *i. e.* from hydrocupreidine, offers great possibilities as regards their action on bacteria and protozoa, as they are distinctly more toxic to mice and paramecium than the cupreine series. The cinchonine series have a greater inhibitory action on the digestive enzymes than the cinchonidine series. The inhibition is most with trypsin, less with pepsin, and feeble with erepsin. If these alkaloids were given half an hour after a meal they would not interfere with ptyalin digestion. The stronger the concentration the greater the inhibition produced by these alkaloids. Therefore, unnecessarily large doses should be avoided, and the alkaloid should be given well diluted. The inhibition is less when the ferment is first allowed to attack the protein than when the protein is first impregnated with the alkaloids. Therefore, these alkaloids should always be given after a meal. The mono-salts—that is, the commercial sulphates—should always be given with acids, as they use up free hydrochloric acid in the stomach, and thus further inhibit peptic digestion. In pill form, the bihydrochloride or bisulphate should always be employed. Any inhibition occurring in peptic digestion leads to a deficiency in the formation of peptones. Therefore, the alkaloids should be given at the end of the peptic digestion, *i. e.* half an hour to two hours after a meal. These alkaloids increase the amplitude and slow the rhythm of intestinal muscle. The diarrhea observed is probably due to an interference with digestion, both in the stomach and intestines, and not to its action on intestinal muscle. When strong solutions of acid salts of quinine are injected deep into the tissues of the body, the following local effects are produced: (1) An escharotic mass at the site of the injection due to the necrosis caused by the strong acid solution and the quinine being precipitated a white flocculent precipitate of base. (2) A negative chemotaxis of leucocytes occurs as long as the alkaloids remain at the site of the inoculation and are not absorbed. (3) The cinchonine series, so far tested, are less anesthetic on rabbit's cornea than the cinchonidine series. The cinchonine series are more powerful in their effects on blood pressure and uterine muscle than the levorotatory alkaloids of the cinchonidine series.

1. The Position of the Thyroid Gland in the Endocrine System.—W. Langdon Brown characterizes endocrinology as the missing link between biology and psychology, which has profoundly modified our conception of disease. The position which he assigns to the thyroid gland in the endocrine system is that of a powerful activator of metabolism. In this respect it cooperates with the adrenals and pituitary, and antagonizes the pancreas and parathyroids. On the nervous side it cooperates with the sympathetic nervous system, being both stimulated to increased activity by it and lowering the threshold to it. In this way it plays an important part both in external and internal defense. Externally it leads to greater manifestations of energy in the direction of fight or flight; internally it quickens the reactions to bacterial invasion. An important way in which it accomplishes this is by mobilizing the blood sugar. This increased supply of sugar may either be used for muscular energy in external defense or for heat in the febrile reaction of internal defense. As a provision against waste of this sugar the kidney threshold is raised to prevent its escape into the urine, so that despite hyperglycemia there may be no glycosuria. Yet this blood sugar may exceed this raised threshold, so that some escapes. This is particularly likely to occur during emotional excitement, when the gland is apt to enlarge. It interacts also with the gonads, and the undoubted fact that it plays a more active part in female metabolism may be due to its origin from the uterus of a Palaeostracan ancestor. This interaction may account for the disturbances which are apt to occur in the gland after an artificial or natural climacteric. That in the former instance this is likely to take the form of intermittent hyperthyroidism may be due to the gland being still in full activity; in the latter instance hypothyroidism is more common, presumably because the gland is already undergoing retrogression. The combination of a distressing emotion of matrimonial origin with a toxemia of alimentary origin is the most fertile cause of hyperthyroidism. Certain biological considerations are presented to show why this is the case.

5. The Carelli Method of Perirenal Inflation.—F. Hernaman-Johnson states that injection of gas into the peritoneal cavity, while of great value in outlining the

organs within that cavity, does not fully define the outline of the kidney, as that is an extraperitoneal organ. Carelli has therefore resorted to the production of an artificial emphysema around the kidney itself, and has carried out the procedure several hundred times without accident of any kind. The essential points in the technique are: (1) Use of a fine needle; (2) accurate location of the transverse process of the second lumbar vertebra; (3) proper direction of the needle after it has struck the process; (4) use of needle open so long as it is being advanced; this permits observation of punctured blood vessels; (5) sound judgment as to depth of insertion; (6) determination of entrance of needle point into perirenal tissue by manometer readings; (7) slow injection of gas; (8) quantity not to exceed 500 c.c. As to indications for use, any case in which there are signs or symptoms suggestive of kidney trouble, and in which clinical and ordinary radiographic examination does not completely clear up the diagnosis, should be investigated by this method. Alterations in shape, size or density are at once made clear, also calculi too small or faint to show in the usual manner. The procedure makes possible the investigation of alteration in the adrenal body, so that it may be of use in elucidating certain disorders of the ductless glands. As to risks, there may be a theoretical possibility of setting up perirenal cellulitis, but no suggestion of any ill effect has occurred in Dr. Carelli's practice. Hernaman-Johnson says that he has no hesitation in recommending the procedure as one of very great value.

9. Blood Pressure Observations in Functional Bruits in Children and Young Adults.—A. F. Martin has observed that during convalescence from various mild infections children often go through a period in which they exhibit a sustained rise in blood pressure, the development of a systolic apical bruit presenting the usual functional signs, and accompanied by some cardiac dilatation. The child is far more unstable in its circulatory equilibrium than an adult, and the heart muscle just recovering from the damage of a pyrexia is in no case able to sustain the increased work that a slight hyperpiesis involves. Children are very susceptible to the action of the nitrites. The writer uses them in the following combination in reducing blood pressure in his cases: Sodium nitrite, liquor trinitrini, and spirits etheris nitrosi in suitable dosage. In adults these are of no use. Regular blood pressure observations should be taken in all cases of "impure" heart sounds after fever. The explanation of these cases is difficult. Three factors at least must be considered, namely, the patient's temperament (it is particularly the "nervy" children who suffer this disability), secondly, the action of the toxin upon the arteries, and finally some fault in the endocrine system.

10. A Clinical Test for the Presence of Cellular Elements in the Urine.—T. H. C. Benians describes a simprocedure which shows with a very small percentage of error whether abnormal bodies are or are not present, and whether or not further investigation is needed. The test, however, does not differentiate between one form of cellular element and another. The technique is as follows: If the urine is strongly acid or alkaline to litmus it should first be neutralized by the addition of a few drops of alkali or acid. Take a third of a test tube of urine and add a quarter of the amount of 20 volumes of fresh peroxide to it. Allow the tube to stand in the rack, but not in the sunlight. In a strongly positive reaction bubbles start to rise immediately and form a permanent layer of foam at the top of the fluid. If the reaction is only faintly positive bubbles will rise gradually and form a thin layer on the top; this may take from fifteen to twenty minutes or longer if the urine is acid.

1. Suppurative Ringworm.—Douglas W. Montgomery and George D. Culver point out that there are a number of fungi which give rise to the affections known under the common term of ringworm. Some ringworm infections cause very strong circumscribed reactions with a mimicry of much graver maladies than the ordinary types of ringworm. These are called the suppurative ringworms, or kerions, or kerion Clesi. Many of the trichophyta cause this type of ringworm. It is not due to any particular strain, of which there are many, but it occurs more frequently when the infection is caught from one of the lower animals. The infection spreads from a center so as to form a circular elevated tumor with a flattened, irregular surface and a rounded, cushion-like, fleshy border, constricted at the base. French dermatologists very aptly call the tumor a macaroon, from its resemblance to the familiar almond paste, after-dinner cake. A kerion may be mistaken for an ordinary pyodermia and may be incised to evacuate pus. Such an incision is valueless, as the pus is being evacuated through the follicular openings, and incision neither facilitates nor hastens this. On the contrary, it may do harm by allowing the accompanying pyogenic infection to spread to the deeper tissues. Another diagnostic danger lies in mistaking the tumor for a carbuncle. It lacks the deep burrowing and the large slough of a carbuncle. In this type of ringworm neither *x*-ray nor radium should be employed, as is so frequently done in ordinary ringworm of the scalp, because the increased intensity of the follicular inflammation increases the danger of consequent permanent baldness. The treatment that has been found most effective is a thorough poulticing for at least an hour each day with boric acid starch poultice, and the application of a salicylic acid and sulphur ointment (2 per cent. of salicylic acid and 10 per cent. of precipitated sulphur). The usual situations for these suppurative trichophytic tumors, Motgomery and Culver point out, are the scalp, the wrists, the hands, and the bearded face.

5. The Pulse of the Nervous System.—J. Henry Dowd holds that the phosphatic index of the urine offers a ready means of determining the nutritional condition of the nerve cell. When nerve cell nutrition phosphorus, nuclein, and lecithin have performed their function, the waste is eliminated in their urine as phosphates, or end products. An estimation of the alkaline phosphates is a far more simple procedure than is a blood count in an examination for anemia. In making the test the second urine in the morning should be used. When the precipitate falls to NP (not easily disturbed on agitation) on the phosphatometer, no matter what may be the condition under treatment, the nervous system, *per se*, is not a factor in the case. A precipitate that remains above NP at the end of ten minutes indicates irritation, or hypersensibilty of the neurones; the reserve is being drawn upon. Such a condition may be found as a beginning of practically every case that ends in what is termed neurasthenia; it is practically always found plus in high blood pressure. Where the precipitate will not sink and is light and fluffy, or goes below NP, nerve cell nutrition is deficient, and no matter what the case may be, medical or surgical, resolution will be delayed and symptoms continue until the deficiency is supplied, either naturally or by artificial administration. In the functional conditions, one's first thought should be the condition of the nerve cell nutrition in every case which does not quickly respond to old and well tried methods of treatment. The phosphatic index is not a panacea but it often gives more information than any other test we have.

Book Reviews.

DIABETES MELLITUS. A System of Diets. By HERMAN O. MOSENTHAL, M.D. Assistant Professor of Medicine and Attending Physician, N. Y. Post Graduate Hospital and Medical School. Price $1.50, with set of pads, $6.50. New York: Paul B. Hoeber, 1921.

THIS work is designed to remove many doubts and perplexities in the mind of the person responsible for the preparation of the food of a diabetic member of the family. The restrictions in the diet are so many that the result is often a tiresome monotony that revolts and sickens the patient. A study of Dr. Mosenthal's system and a glance over the diet lists will, however, show that, even with strict carbohydrate exclusion, there is a variety of other foods, by a judicious playing upon which dietary monotony may be easily avoided. The following are the diet tables for the carrying out of which the printed sheets of directions are available: Starch-free diet, qualitative list; Minimal fat, starch-free, measured diet; Minimal fat, starch-free, weighed diet; Low fat, starch-free, measured diet; Low fat, starch-free, weighed diet; Accessory diet, rich in carbohydrates. The sheets containing directions for these several diets are bound in pads of fifty each.

MOUTH HYGIENE. A Text-Book for Dental Hygienists. Compiled and Edited by ALFRED C. FONES, D.D.S., Bridgeport, Conn. Second Edition. Thoroughly Revised. With 218 Illustrations and 8 Plates. Price $5. Philadelphia and New York: Lea & Febiger, 1921.

THE dental hygienist is a modern product created to meet a very real need in the prophylaxis of mouth diseases and their frequent sequelæ, constitutional diseases, sometimes even fatal. The teaching of mouth hygiene being thus a new profession, there are comparatively few text-books available for its study. Such being the case, it is fortunate that such books as these are, the one before us being one of the best, are so practical and so good. This book, though not of large size, is of the nature of a "system," the various chapters being the work of nine contributors. These chapters are entitled, Anatomy of the Head; Histology of the Teeth and Associated Structures; The Teeth as a Masticating Machine; Malocclusion of the Teeth; Inflammation; Deposits and Accretions Upon the Teeth; Pyorrhea Alveolaris; Dental Caries; Odontalgia and Neuralgia; The Relation of Oral Infections to General Health; Dental Prophylaxis. An Appendix deals with the field of service of the dental hygienist in institutional and private practice and the public schools, and a proposed curriculum for the training of the student. The dental hygienist, whether student or graduate, should read and study this work from cover to cover, and doing so, she will find her time has not been wasted.

THE SCIENCE OF OURSELVES (A Sequel to the "Descent of Man"). By SIR BAMPFYLDE FULLER, K.C.S.I., C.I.E. Author of "Studies of Indian Life and Sentiment," "The Empire of India," "Life and Human Nature," and other works. New York: Oxford University Press, American Branch, 1921.

FOR those who have a deep interest in speculative introspection and minds well trained to understand thoroughly such study, this volume will hold much that will aid in further speculation. The race and individual onpush motivate the book. Fortunately the writer has given a definite synopsis of his material at the end of each chapter, so that it is not necessary to reread an entire chapter for a wanted point or argument.

The book opens with the discussion of the planes of nervous activity, then takes up the physical plane; evolution of concepts; perception and thought; expectative and explorative thought; appreciative and imaginative thought; thought and muscular movement; the appetites, emotions, and will; fear, courage, and anger; the affections; evolutions of pleasures and displeasures. Various types of behavior are gone into as well as speech and writing, and character and education.

In the epilogue the author says: "The views to which these inquiries have led us are disillusioning—lamentably disillusioning, many will say—and, were it clear that mankind lived happily in the shadow of self-ignorance, one might shrink from piercing the canopy, and leading in the sunlight. . . . All said then, it cannot be claimed that illusion is successful; and there is a case for bringing the mainsprings of our behavior under the light."

PROSTHETIC DENTISTRY. A Text-Book on the Chair-side Work for Producing Plate Dentures. By DOUGLAS GABELL, L.R.C.P., M.R.C.S., L.D.S., Dental Surgeon to the Royal Dental and Charing Cross Hospital, Lecturer on Dental Mechanics to the University of London at the Royal Dental Hospital. New York: Oxford University Press. American Branch, 1921.

THIS is an excellent guide to what may be called the lighter mechanics of dental prosthetics, that is to say, with the fitting of ordinary dentures—the chair-side work as distinguished from the laboratory work. The subjects treated of are: Indication for and against plates and bridges; preparation of the mouth; impression and casts; taking the bite; selection of teeth, movements of jaw, setting up of teeth; strength and rigidity of dentures; retention of dentures; trying in the dentures; putting in the dentures; complaints of patients; refits, additions, and repairs. The book is elementary in character as regards the explicit details and directions in respect of every part of the work to be done, and as such will be of great service to the advanced student or young graduate; but it is not at all elementary in regard to the subjects treated, for every problem that may confront one at chair-side is met and solved. The chapter on Complaints is especially valuable and one should master it for no matter how good a mechanic he may be every maker and fitter of dentures will now or again make a mistake, or if he does not he will have patients who will think he has.

LEHRBUCH DER LUNGENKRANKHEITEN. By Dr. ADOLF BACMEISTER, Professor für innere Medizin, Freiburg University, Phys. in Chief Sanatorium St. Blasien; Second Edition. Price 126 Marks. Leipzig: Georg Thieme, 1921.

THIS is the second edition of what seems to be a rather popular book in Germany. The first one appeared five years ago in the midst of war times and never reached these shores. The first chapter is devoted to the anatomy and physiology of the lungs and of course does not bring out anything new. The second chapter, however, devoted to the examination of the normal lung in the living subject is of interest. Besides the physical examination, the percussion of the normal lung, the auscultation of normal breathing and of the voice, pectoral fremitus, and spirometry, are accurately described. Added to this is the Roentgen picture of the normal lung, anteriorly, posteriorly, and laterally. The study of this chapter is particularly important in order to enable one to understand the abnormal condition which the physical examination of the Roentgen pictures reveal. He entitles the chapter treating with the diseased lung "Typical Changes Resulting from Pathological Invasions." He very carefully describes the physical signs and particularly the adventitious signs perceived in the affected lung. In subsequent chapters where he speaks of symptoms, dyspnea, and changes in the respiratory movements, he distinguishes between various forms of dyspnea but seems to have overlooked the fact that dyspnea may also be due to idiosyncrasies for certain foods. The subsequent chapters deal with tracheitis, bronchitis, and bronchopneumonia, bronchiectasis, and emphysema. There is nothing new in these chapters, but the chapter on stenosis of the trachea and bronchi, and foreign bodies in the bronchial tree deserves careful perusal because of the admirable description of the conditions which arise from trauma or pathological processes. In the description of the various types of pneumonia the studies of Cole and his pupils of the Rockefeller Institute and the antipneumococcic serum receive no mention whatsoever. The final chapters deal with syphilis of the lungs and the parasites which may be found in the lungs. Under the chapter of clinical tuberculosis he describes the various types, and under treatment he advises the modern hygienic, dietetic, and institutional methods so well known. The last chapter treats of diseases of the pleura. As a whole the book is worth the perusal of the student of tuberculosis.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

Thirty-fourth Annual Session, Held at Pinehurst, N. C., December 13, 14 *and* 15, 1921.

THE PRESIDENT, DR. RANDOLPH WINSLOW OF BALTIMORE, IN THE CHAIR.

Traumatic Intracranial Hemorrhage.—Dr. WILLIAM PERRIN NICOLSON of Atlanta said that in all cases of traumatism to the head with or without fracture where a patient recovered consciousness and subsequently became unconscious the cause was practically always hemorrhage. Hemorrhage in these cases might be extradural or subdural, the former being more immediate than the latter, occurring sometimes days or weeks after the beginning. Such cases always deserved an exploratory operation and hemorrhages were usually easily found. Such hemorrhages when not relieved resulted in more or less extensive cysts which disabled the patient, and destroyed his usefulness. Exploratory operations upon the brain were no more dangerous than that upon any other part of the body.

Operation for Diaphragmatic Hernia.—Dr. HARVEY B. STONE of Baltimore said that abdominal exploration was essential in the great majority of cases of diaphragmatic hernia. Thoracic approach greatly facilitated the necessary operative steps. The method of choice, therefore, for the routine handling of these cases should be by combined abdominal and thoracic incisions. These incisions were best made separately instead of by the French method of a continuous incision.

Conservative Surgery in Nonmalignant Diseases of the Pelvic Organs.—Dr. E. P. HOGAN of Birmingham, Ala., stated that conservative surgery included a correct diagnosis and such preoperative treatment, Fowler-Ochsner-Murphy treatment, operation, and postoperative treatment as would save life primarily and would restore the patient to health and a normal or as nearly normal existence as possible. Diseases of the female pelvic organs rarely killed immediately. Coincident acute diseases of other origin not infrequently occurred, complicating or overshadowing the pelvic disease. Such cases should be treated primarily for the acute illness. Conservative treatment of acute pelvic infections aided nature to successfully resist the primary infection. Repeated acute or subacute attacks might require an operation for its relief. Such patients should be again conservatively treated before undergoing the operation. Cases requiring drainage were reduced to a minimum. Young women under 35 or 36 years of age operated for a nonmalignant disease of the pelvic organs should have the menstrual and if possible the reproductive function preserved. Radical operation—removal of tubes, ovaries and uterus—might be indicated in older women. Conservative surgery of the female pelvic organs reduced mortality and morbidity and increased the possibility of the preservation of these organs and their function.

The Surgical Treatment of Extensive Basal Cell Carcinoma.—Dr. J. SHELTON HORSLEY of Richmond, Va., said that in extensive basal cell cancers, in addition to cauterization and excision with a cautery, an important principle was to apply as soon as possible to the raw surface from which the cancer was excised, the raw surface of a pedunculated flap transplanted from a distance. It had formerly been thought that plastic operations for defects caused by extirpation of cancer should not be done until it had been determined, after the elapse of months or of years, that there would probably be no recurrence. The idea seemed to have prevailed that it would be useless to transplant a flap when cancer might recur beneath it. With basal cell cancer, however, this practice appeared to be erroneous, and a flap from a distance should be applied as soon as possible after the excision of the cancer, for the flap seemed to add an additional obstacle to the growth of the cancer by interposing its own natural resistance to the cancer cells.

Duodenal Diverticula.—Dr. WILLIAM A. DOWNES of New York stated that the majority of duodenal diverticula did not give rise to symptoms. Retention might occur in those with a narrow neck, and then the condition might become of great clinical importance. These diverticula were formed by the mucosa becoming herniated through the muscular coat of the gut wall and probably resulted from congenital defects. The diagnosis could be made only by the roentgen ray. Invagination or excision of the sac, whenever possible, was indicated in the cases giving symptoms.

Aneurysm of the Internal Carotid Artery.—Dr. NATHAN WINSLOW of Baltimore said the object of his paper was to insure a prompt recognition of this obscure lesion; to assemble all facts pertinent thereto; to render in abstract the cases reported in the literature, and to place on record a case. The first case was reported by Sir Astley Cooper, since then including the case herein reported, the number had risen to 70, 37 during the nineteenth century. Since 1900, 33. Though so seldom seen its chief interest centered in its being mistaken for a tonsillar abscess and lanced with disastrous results. Lee and Duke had reported this accident, the patients dying. Chassaignac fell into the same error, but saved his patient. The diagnosis was mainly between abscess, rarely malignancy. In aneurysm the symptoms were generally quite distinctive. There would be a tumor pushing the lateral pharyngeal wall into and obstructing the food channel. Unless the jaws were fixed the lump was accessible to sight and touch. It might be circumscribed or diffuse and was bulging and pulsatile. To touch it was soft and elastic and pulsated throughout. Externally there might be no evidence of the disease or there might be a puffiness in the neck, occasionally a visible tumor. Upon stethoscoping the lump a bruit was heard. Murmur and pulsation disappeared when the common carotid was compressed to recur immediately the pressure was removed. Dysphagia and dyspnea were not uncommon, likewise buzzing in the ear, persistent hemicrania, vertigo and paralysis of the muscles supplied by the ninth, tenth and twelfth cranial nerves. Diagnosis had been made by needling of the sac, but should only be practiced when the patient was so situated that a prompt operation could be done if rupture occurred through the path of the needle. The operation of choice was ligation of the internal carotid artery between the sac and the bifurcation of the primitive carotid; if this was impossible the ligaturing of both the common and the external carotids in close proximity to the point of division.

A negress, married, aged 48, cook by occupation, had a lump in her throat of nine months duration. It had progressively gotten larger and at the time of operation nearly obliterated her food passage. It was soft and elastic to the touch and pulsatile throughout. With a stethoscope behind the angle of the jaw a bruit was plainly audible. Its size was materially diminished by pressure on the common carotid, which resulted also in disappearance of bruit and pulsation. On February 1, 1921, the primitive carotid artery was tied in the triangle of election and the external carotid in close proximity to the bifurcation. She made an uneventful postoperative recovery, developing no evidence of intracranial mischief. For some months the swelling in the throat persisted, but never pulsated after the ligation. It had now entirely disappeared and, symptomatically at least, the patient was entirely cured.

Of the 70 cases recorded in the literature, 36 were spontaneous, 10 erosive, 13 traumatic and 1 unclassified; 37 were males, 31 females, 2 not stated. Of the spontaneous 26 were females as against 9 males; 1 the sex was not given. Cure was attempted by operation 48 times, with 32 recoveries and 16 deaths; 21 were not operated on, 16 perished, 4 were in the same or worse condition when the report was made, and 1 made a spontaneous recovery. Vander Veer thought he had effected a cure by compression, but the patient suddenly fell dead three months later. McMullen and Stanton attempted restorative endoaneurysmorrhaphy unsuccessfully. LeFort in an arteriovenous aneurysm did a transvenous suturing of the hole in the artery and capped the suture line with a piece of the vein. Bruns, Perthes, Morestin, and Moser practiced extirpation of the sac, and Agnew because of recurrence

of pulsation in the swelling ligated the opposite carotid, but the patient died about a week later of a secondary rupture of the sac. The common carotid alone was ligated 22 times with satisfactory results in 13 instances, the internal alone 4 times with 3 recoveries and 1 death.

Primary Carcinoma of the Female Bladder.—Dr. I. S. STONE of Washington, D. C., reported a case in which early excision of a supposedly malignant bladder tumor, by combined vaginal and abdominal operation, had resulted in an apparent cure.

Dr. G. PAUL LAROQUE of Richmond, Va., reported another case of bullet wound of the femoral artery and vein successfully treated by ligation of the artery and vein and extirpation of the injured segment.

Choice of Operation for Duodenal Ulcer.—Dr. LEGRAND GUERRY of Columbia, S. C., said that operation would hold first place ultimately which, when it had been completed, obeyed most closely the following points: Mechanical rest, physiological rest, altered chemistry which was dependent on the first two points, and a stomach whose position and motility were the least interfered with. We were after increasing the number of complete symptomatic cures from 75 per cent. to 95 per cent., or even more, if possible. To successfully carry out the above principle there was room, and lots of it, for the exercise of the very highest degree of surgical judgment and discrimination in the proper selection of the method to suit the particular case in hand. It was not primarily a question of the mechanical performance of an operation, but a proper understanding of general principles and the surgical philosophy which rested thereon.

A Consideration of Some Nontuberculous Kidney Infections.—Dr. RAYMOND P. SULLIVAN of New York stated that the kidney was the eliminating organ for circulating microbes, and in the course of this elimination might itself be damaged in a variety of ways. Hematogenous infection might be restricted not only to a single kidney, but even to a circumscribed portion of the organ. The source of the infection might not only be a general disease, but a distant and apparently insignificant focus might be responsible. Metastatic hematogenous infection of the kidney, perinephritic or paranephritic abscess was not always easily recognized, and might be confused with intraabdominal infections. A sudden attack of pain in kidney region associated with fever in a patient known to have a suppurative process elsewhere in the body should excite suspicion of metastatic kidney infection. Cystoscopy and pyelography were valuable aids, especially when urinary changes were incomplete, or the symptoms were referred to the healthy side. The treatment of perinephritic or paranephritic abscess was early drainage. Where the suppuration involved the kidney parenchyma, or where the process was an acute fulminating one, nephrectomy was indicated.

Total Transposition of Viscera.—Dr. HENRY H. SHERK of Pasadena, Cal., stated that total transposition of viscera was not so very infrequent. Its standing had changed from that of an anatomical curiosity to a matter of clinical interest and importance. It had no effect on the health of the individual. Its recognition was extremely important in certain surgical emergencies.

Reconstruction of the Female Urethra and Vesical Sphincter.—Dr. EDWARD H. RICHARDSON of Baltimore stated that congenital or acquired defects of the female urethra and bladder sphincter associated with urinary incontinence while relatively uncommon were, nevertheless, prevalent enough to be occasionally encountered in every active surgical clinic. The successful correction of such defects might challenge the skill and ingenuity of even the most experienced plastic operators. The plan of operative therapy should be dominated by the necessity of reconstructing an efficient bladder sphincter. To this end it was of fundamental importance to release from inhibiting scar tissue, jealously preserve, reunite and reinforce by either intra or extravesical plication sutures any existing sphincter rudiments or remnants. If there was complete absence of the sphincter, the construction of a compressor of the vesical neck through transplantation of the partially detached pyramidalis muscle, together with its anterior fascia, or of the pubic portion of the levator ani muscle, was the operation of choice. Reconstruction of the urethra was best accomplished by the simple submucous tunnel operation followed by the use of a retention catheter until epithelialization occurred from the bladder. Where an excess of scar tissue, or other disadvantageous local conditions, imperiled the success of this procedure, the value of the various plastic flap operations alone or in conjunction with transplanted epithelial tubes had been repeatedly demonstrated. The use of the Fallopian tube for this purpose, as attempted in his case, was, he believed, original and possessed distinct advantages. As in all reconstructive surgery, the frequent superiority of a several stage procedure must be borne in mind.

Periosteal Sarcoma in Association with Osteomyelitis.—Dr. R. L. RHODES of Augusta, Ga., reported three cases of large round cell sarcoma, of periosteal origin, which were associated with infection and necrosis of bone. They were all females, two whites and one negro. The ages were 14, 12, and 20 years, respectively. The left tibia was involved in each case. There was no history of trauma or serious illness. There was local pain in two, and none in the other. Staphylococcus aureus infection was found in each of the cases. There was rapid pulse and rather high fever in two, and none in the other. The treatment consisted of mid-thigh amputations. As to results, one patient died, and the other two were living free from signs of recurrence, local or elsewhere, at the present time.

Hernia of the Bladder.—Dr. J. N. BAKER of Montgomery, Ala., said the possibility of bladder involvement should always be suspected and due caution observed in all cases of large inguinal hernia, more especially those of advanced life and in those manifesting prostatic hypertrophy, or other signs of crippled bladder function. In all direct inguinal herniæ regardless of size or age, in all operations for recurrence of hernia for two reasons, namely, recurrences were notoriously of the direct type, and adhesions and distortions of the neck of the sac from the former operation, resulting in a possible pull on, and displacement of the bladder; in all herniae, presenting an undue amount of fatty tissue closely associated with the sac at or near the fovea inguinalis medialis, the possibility of injury to the bladder was increased and this danger signal should never go unheeded.

Jejunal Ulcer Without Previous Gastroenterostomy.—Dr. EDWARD P. RICHARDSON of Boston, Mass., said the literature gave evidence of the rare occurrence of jejunal ulcer apparently of simple type, and resembling somewhat peptic ulcer of the stomach or duodenum, and having a similar tendency to perforation and occasionally to cicatricial stenosis. No sharp line could be drawn between these simple ulcers of the jejunum, and similar ulcers occurring lower in the lower small intestine. While he had only considered jejunal ulcers, it would seem more rational to discuss as one inclusive group, simple ulcers of the jejuno-ileum. Whether these represented a clinical entity or were merely the odds and ends of various pathological processes, could not be asserted. The two cases which he reported appeared to be instances of simple ulcers affecting the jejunum. Such ulcers occurred chiefly in males beyond middle life. No definite etiology might be assigned to them. It was possible that in so rare a condition there might be almost as many causes as cases. In the cases where jejunal ulceration occurred close to the end of the duodenum, it was possible that disturbance of pyloric control might lead to gastric contents reaching the jejunum without neutralization, and so to the formation of true peptic ulcer. For ulcers situated lower in the intestinal tract, this cause seemed improbable. Since syphilis produced a form of intestinal ulceration which affected the jejunum, more readily than the ileum, and also had a tendency to cicatricial contraction and perforation, it must be considered as a possible cause of ulceration in some of these cases, although definite confirmatory evidence was lacking. Two points were of particular importance in future cases, a careful microscopic study of the lesions, including, if possible, the mesenteric lymph nodes, and the determination of the presence or absence of syphilis. Whatever the cause, the occurrence of perforation gave these ulcers a definite surgical importance, the more so since the perforation did not take place in one of the regions in which we were accustomed to search for it. He merely

offered this summary to call attention to this type of ulcer and the possible relation of some of these cases to syphilis of the small intestine.

Contracture of the Psoas Parvus as an Explanation of Obscure Abdominal Pain.—Dr. LLOYD NOLAND of Birmingham, Ala., said this contracture was not common, but he thought that its occasional occurrence might explain certain cases of obscure abdominal pain. The cases reported were the only ones of this condition discovered in over a thousand laparotomies, but even with this occasional recurrence, he thought that the condition was worth the attention of all surgeons. Each one of these cases was very carefully worked up, with medical, orthopedic, and urologic consultation, and in no instance was exploratory operation undertaken until every other practical means of diagnosis had been used with negative results.

A Skin Suture Without a Fault.—Dr. EDWARD H. OCHSNER of Chicago said that a perfect skin suture material must possess the following qualities: It must be relatively fine in proportion to its strength. It must be of uniform strength throughout and have no weak spots. It must be sufficiently strong for the purpose in hand. It must be of uniform thickness. It must be smooth and pliable. It must be impervious to the body fluids physically, *i.e.* have no seaton action. It must be unattackable by the body fluids chemically, impenetrable to leucocytes, nonirritating to the tissues and sterilizable by boiling in plain water. It must be easily stored. It must be of determinable length, not deteriorate with age, must not snarl and must not be too expensive. The skin suture material which he presented fulfilled all of these requirements and he believed was a skin suture without a fault. The No. 1 was suitable for superficial coaptation stitches. Nos. 2 and 3 were suitable for deep tension and subcuticular stitches.

Pelvic Tumors with Sacral Attachments.—Dr. ARTHUR A. LAW of Minneapolis believed that owing to the demonstrated tendency to malignant degeneration, these tumors should be removed when recognized, and he was convinced that they should always be attacked from behind through the sacrococcygeal route. The modified Kraske approach was ideal for the larger tumors and permitted them to be shelled out with little difficulty, usually without invading the peritoneum, and facilitated the control of hemorrhage. The interesting feature of this tumor was that there was only one tissue in it which could be definitely differentiated, and this tissue was prostatic tissue. This tissue suggested the interesting possibility that this tumor might represent an embryoma bearing the same relation to the prostate as did some of these tumors of the testicle to that organ, and that it might possibly be classed as a teratoma of the prostate in which development was one-sided. He was, however, unable to find any references in the literature which substantiated such an assumption. Inasmuch as it had been impossible to definitely differentiate this tumor, it was not important by what name it was designated, so long as we recognized that we were dealing with an embryoma of malignant tendency. Therefore he had stressed the importance of the removal of these embryonic tumors ventral to the sacrum, as he believed that most of them tended to malignant degeneration.

The Remaining Breast After Radical Removal of the Opposite Side for Carcinoma.—Dr. HUGH H. TROUT of Roanoke, Va., said that in a series of 27 patients under forty years of age who did not become pregnant, there was not a case of recurrence of the cancer in the remaining breast, although the recurrences elsewhere in the body were much higher in this group than in the rest of the series, all of whom were over forty years of age. Of this group over forty years of age he obtained definite information from 106, ten of whom, or over 10 per cent., developed cancer in the remaining breast, and this in spite of the fact of recurrences elsewhere in the body being as high as most of the recently published reports. In the reply received from James F. Mitchell he reported a case having a 13-year interval, and then developing carcinoma in the other breast, but not associated with a pregnancy. In a review of 218 cases of carcinoma of the breast from Rochester, Minn., 10 per cent. more of those over fifty years were alive from five to eight years after operation than of those under fifty years, suggesting there might be some ground for the rather prevalent opinion "the younger the patient the more active the malignancy." If these observations and deductions were correct, he believed surgeons should warn their patients, who were in the child-bearing period, and from whom a carcinoma of the breast had been removed, not to become pregnant for fear of serious trouble in the remaining breast.

Recurrence of the Benign Prostate.—Dr. W. A. BRYAN of Nashville stated that the patient who had had his prostate removed by a surgeon and had been relieved of his symptoms and later found those same symptoms returning had a question raised in his mind as to the genuineness of the removal of the gland. He finally was compelled to consult his physician, who examined him and told him that his prostate had never been removed, because it was still there, palpable and producing symptoms. This physician might be entirely honest, only a small per cent. of the profession probably knew of the fact of recurrence. The patient naturally felt unkindly toward the surgeon who claimed to have removed a gland which was still present at its original site. When compulsion drove him, this patient was likely to seek relief at other hands. The second surgeon probably was human and felt perhaps that he was about the only man in the world capable of doing a prostatectomy. In other words, he was conceited. He also might prove uncharitable and think that the first operator removed only a portion of the gland, and concluded that the recurrence was simply the continued growth of gross portions left in situ through ignorance or neglect. The treatment of such cases by two men consecutively robbed both of them of the possibility of arriving at the truth, because neither was in a position to compare the facts in his possesion with the facts in the possession of the other. It was only when the primary condition and the recurrence were treated by the same man that the truth could be reached. He had seen three cases of recurrence.

Meckel's Diverticulum.—Dr. ALEXIUS MCGLANNAN of Baltimore said Meckel's diverticulum had often been found as the contents of a hernia either alone or with other structures, including the cecum and appendix. In about three-fourths of the reported cases the diverticulum was the sole occupant of the hernial sac, as it was in the case reported by Littre, who gave his name to this type of hernia. Among congenital causes of intestinal obstruction, Meckel's diverticulum was generally accepted as the one most frequently present. In the series of 276 cases which he studied in 1915 there were nine instances where the diverticulum was recognized as the cause of the obstruction. Six of the patients died and three recovered after operation. In one case the diverticulum was attached to the inner surface of the umbilicus by a cord; in the others it was free or had become adherent by its tip, or a cord, to the bowel or mesentery. The obstruction was caused by entanglement of a loop of intestine around the diverticulum, except in one case, where an adherent diverticulum kinked the bowel by traction. In none of the cases was there any umbilical deformity or discharge.

Bleeding Ulcer of the Duodenum Associated with Cholecystitis.—Dr. EDWARD S. JUDD of Rochester, Minn., said that within the past year he had operated on four patients with bleeding duodenal ulcers in whom the pathologic condition was more extensive in the gall-bladder than in the duodenum. In each case the duodenal ulcer could be demonstrated easily, and in one case it was of long standing, as evidenced by the amount of scar aissue. A very severe grade of cholecystitis was also present in all of these cases. The gall-bladders of the four patients were very much alike, being rather larger than normal, with thick, edematous walls. They were not compressible, because of the inflammatory deposits in the tissues. They contained stones and infected bile in each instance. He believed that their mucous membranes were completely destroyed and that they were functionless. The findings of these four patients impressed him with the importance of infections in the gall-bladder as a possible etiologic factor in cases of gastrointestinal bleeding. A definite lesion in the duodenum was found in every instance and undoubtedly was the point from which bleeding

occurred. The hemorrhages were of the massive type, such as usually occurred from the pancreaticoduodenal artery, and yet in each case it was quite definitely shown that none of the larger vessels could be involved in the ulcerations. There was sufficient evidence to show that gastrointestinal bleeding might occur as a result of infection in the gall-bladder and liver. Balfour mentioned a case in which bleeding ceased after the removal of a chronically inflamed gall-bladder. Deaver reported profuse bleeding in hemorrhagic infections of the biliary tract. In one of his cases blood reached the duodenum through the common duct and then regurgitated to the stomach. The primary cause was streptococcic cholecystitis. He had an abundance of evidence to show that cholecystitis and hepatitis might be the source of the infection which resulted in bleeding, and he thought he also had evidence which suggested that cholecystitis might be the source of the infection causing this symptom even in the presence of ulcer of the stomach or of the duodenum.

1. Ligation of the Internal Iliac for Enormous Gluteal Aneurysm. 2. Cirsoid Aneurysm of the Scalp.—Dr. WILLIAM D. HAGGARD of Nashville said of the first patient that she complained of intolerable pain in the right leg and throbbing tumor of the right buttock. For a number of years she had been having trouble with pains in the calf of her right leg. During the six weeks prior to her entrance into the hospital she had three or four spells of excruciating pain in the calf of her right leg, referred up the posterior thigh to the right hip and had to have morphine for the relief of the pain during each of these spells. For the past three years she had noticed a swelling and throbbing in the right buttock, like a heart-beat. It was now as large as an inverted salad-bowl, diffuse, pulsating, and expansile, occupying the entire right buttock. It was soft, compressible, and thrill and bruit were made out over its entirety. An *x*-ray examination showed a large, round, soft tissue shadow, 20 cm. in diameter, enveloping the entire right buttock. Wassermann reaction (acetone insoluble antigen), 2 plus; cholesterin antigen, negative. The pain was so severe that she had to have morphine every four to six hours. Her mental condition did not seem to be at all good. She talked at random. At operation the right internal iliac artery was exposed. It was found to be as large as one's little finger. Two heavy silk ligatures were tied around the internal iliac one-half inch from its origin. To facilitate the agglutination of the wall of the aneurysmal sac it was emptied by firm pressure, and a large pad was very tightly strapped over it and firmly held in place by adhesive plaster. Convalescence was uneventful. The pulsation of the tumor which previously lifted the body perceptibly from the bed became quiet and the bruit and thrill disappeared entirely. It had been planned to do an obliterative endoaneurysmorrhapy as a second-stage following the ligation of the internal iliac, but when the aneurysmal tumor was so completely stilled by the former procedure it did not seem necessary to do anything additional.

The second case showed itself as a subcutaneous swelling made up of a pulsating network of arterial sinuses, from which radiated pulsating vessels that could be distinguished as individual trunks whether originally containing arterial or venous blood was not clear. A systolic blow and thrill might be transmitted to the palpating hand and a systolic murmur might be present and pressure on no one point obliterated the bruit. The patient was a female, aged 25, who presented with a pulsating tumor of the left scalp, which began ten years ago. Now it was about the size of a flattened goose egg, with tortuous branches spreading out to the left zygomatic arch on the left and across the median line to the opposite parietal region and posteriorly toward the occipital region. The left anterior half of the scalp was covered with a large tumor, like an aggregation of dilated, tortuous, pulsating, bluish tinted, elevated blood vessels. Just to the left of the median line was a larger mass, the size of a child's hand, with tortuous pulsating branches radiating out to the left zygomatic arch on the left. It felt like a bunch of worms or a varicocele except it was pulsatile, expansile and a thrill was felt and a bruit heard. Pressure on the external carotid artery was lessened, but it did not stop pulsation. Operation was performed by transverse incision, inch by inch, from the left middle temporal region to the right parietal well in the hair line, making a slight U-shaped flap with the base anterior. The entire tumor of blood vessels was excised en masse from beneath. The temporal artery was ligated; the posterior right occipital and anterior right temporal arteries were greatly enlarged, but not ligated. The patient was dismissed on the sixteenth day. Eight months afterward there was no return of the trouble.

The Present Status of Epiplopexy.—Drs. JOHN H. GIBBON and JOHN B. FLICK of Philadelphia stated that since the early publications of Morison and Talma, many contributions to this subject had been made from many countries and various modifications of the original technic had been suggested. Among the early notable papers in this country was one by Packward and LeConte, who presented this subject and reported two cases; another by Greenough, who presented a summary of 105 cases collected from the literature. The mortality within thirty days in these cases was 29.5 per cent., and there was improvement in 42 per cent. M. L. Harris analyzed the reported cases and several of his own and took a rather pessimistic view of the results obtained. He did not agree with the reasoning of Talma, but believed that chronic inflammatory changes in the peritoneum were influential in the production of ascites. White and other Englishmen held the same opinion. Many valuable papers had been presented during the past twenty years and showed very different views as to the benefit to be derived from epiplopexy. Their operative mortality was two out of the ten cases; one died of pneumonia forty-eight hours after operation, and the second four days after operation from peritonitis. These deaths occurred when they were following the more elaborate procedure. In the last six cases there had been but one death, with which the operation might be associated. This patient died two months after operation. She was a syphilitic.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 16, 1922.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE subject of the evening was "The Port of New York—Its Health and Sanitary Problems."

Congestion of Population; Housing and Community Planning.—Mr. CLARENCE S. STEIN, chairman of the Committee on Community Planning of the American Institute of Architects, chairman of the Committee on Port Development of the City Club, and formerly secretary of the Housing Committee of the New York State Reconstruction Commission, delivered this address. At the present time the Legislature was considering the plan brought in by the Port of New York Authority. This plan had been endorsed by the Merchants' Association and real estate interests because they saw in it the probability of increased business and increased real estate values; but the interest of the medical profession was not in business values or land values, but in human values. The question with them was, how was the development of the Port of New York going to affect human beings in New York? The plan was one of many schemes to cure the ills of a big city. The trouble with these schemes was that they sought the cure first and then looked at the disease afterward. The first question was, "What was the matter with New York?" The disease was concentration and centralization. The city under present conditions was not a fit place in which to live. We wanted a place where we could live happily and fully, a place to work, to play, to grow. In New York, with its crowded subways and streets, the congestion of trucks incident to the distribution of supplies, the conditions, even on Fifth Avenue, where with its lights and policemen one could walk faster than he could move in a cab, were intolerable. Congestion in the tenements was appalling. A survey of a typical downtown block showed that not one-half the rooms had light. Many of the tenements built twenty years ago fell below the standard required by

law both in respect to the size of the rooms and the question of light and sanitation. At the present time there was no up-keep. There was an insufficiency of houses, and the figures of vacant apartments showed that there was an insufficiency of housing accommodations. In 1916 there were 54,000 vacant apartments in the city, while last year there were less than 1,000 and at the end of the year only 700. But that was not the whole story, for very many of these apartments were occupied by two families where formerly one family had lived. This congestion was growing in the tenements of New York and in the apartments of the Bronx and Queens, and there was an ever-growing crowding in the subways. The plans to relieve congestion by more subways and other transit facilities simply tended to heighten congestion. Congestion could not be relieved by simply bringing people to Central Manhattan in the morning and taking them back again in the evening. The Reconstruction Commission had considered a plan to take old tenements and revamp them and bring them into line with present tenement-house laws, but it was found that it could not be done at a cost that would yield a reasonable income on the investment. Plans for new tenements were then considered. Architects had made great progress in recent years in the development of apartments with garden spaces in the center. Instead of covering 70 per cent. of the ground, they covered only 50 per cent., and were so arranged that the financial return where the price of land was not too high, was greater than in the old congested type of tenement; but this better type of apartment was not possible in Manhattan where land values were so high. To meet conditions in Manhattan a type of apartment had been worked out which covered 70 per cent. of the ground, and in which, where ordinarily there would be 36 rooms to 50 foot plot of ground, there were 46 rooms. These rooms were very small, making it apparent that the solution offered by the new apartments meant still more congestion. Then there was the problem of transportation and distribution of food and supplies of various kinds. Under present conditions business was concentrated and workers were distributed over large areas or else concentrated in very limited space. It was through a solution of the transit problem that the Port of New York authorities planned to solve the question of congestion. Under their plan, instead of bringing all food, building, and other supplies to the Island of Manhattan for distribution, the railroads terminating in New Jersey would be linked up and distribution made from the mainland to the different boroughs and suburban centers of population. New York had never been planned; its growth had been the growth of accident, and the railroads had never caught up with the growth of the city. The question now was whether the proposed plan would lead to decentralization and do away with the congestion of population and business. It would not unless we acted intelligently. As an example of the kind of mistakes that are made Mr. Stein cited that of the clothing industries. When the clothing industry was forced off of Fifth Avenue, it went over to the Pennsylvania Station section and built on a large scale. The workers live in the Bronx or the Lower East Side. Property in the Chelsea section was so valuable that this class of workers could not afford to live near their work, and transit facilities were inadequate to carry them to and from work. If the new plan simply meant a series of centers of concentration it was not better than the old way. The scheme that seemed worth while would be to develop the regions about Manhattan. There would be a triple series of railways connecting the railroads coming to the port; each circle of the series would connect a different type of city. Instead of large congested centers the towns would be limited in size as, for example, in that type of town developed in England and known as garden city plan, which provided for both industry and living. The garden city would be limited in size by being encircled by green farm land or forest land. Congestion would be prevented by ownership of the land not being in the hands of the individual who would speculate with it and force congestion, but would be held by the community as a whole and increased value would go to the benefit of the community. It was evident that if living conditions were to be bettered we must plan ahead by knowing what kind of a city we want.

Passenger Traffic—The Transit Problem.—Major General JOHN F. O'RYAN, member of the New York Transit Commission, outlined a plan for better transit facilities which the commission had formulated after their investigation which had been going on for more than a year. He first described the conditions under which people moved about in this city and declared that they were indecent and degrading and were actually lowering the moral standards of the people of the city. The conditions were something more than mere discomfort and inconvenience but involved the question of plain decency and morality. An analysis of the traction situation had revealed things known in a general way. They had found more than 200 corporations engaged in transit in the city of New York. This did not add to system. A parallel could be traced in the conditions during the war, when there were engaged not 200 allies but seven or eight principal powers. Disunited, they waged war for four years without success. They then united and systematized their campaign under one leadership and in less than six months achieved victory. Taking a lesson from this it was evident that the first essential to the evolution of an adequate transit system was unified leadership. In the second place the investigating had uncovered more than 1,000 franchises. Many of these franchises had been sold or given away dishonestly and many had been given in perpetuity. Some were unusually harsh and contained numerous conditions, while others contained no conditions whatever. The idea of a public body giving away to an individual or a corporation rights, not for a time but forever, was absurd and he did not think a court of law would uphold a franchise of that kind. The commission had gone into all these details in regard to franchises. As a result of competition some parts of the city were "overtransitized" while other parts were entirely lacking in transportation facilities. No solution of the transit problem could be looked for until the lines were operated as one, the franchises called in and profit-making subordinated to service. That brought up a third point, namely, that every company operating a transit line was operating for one primary purpose, to make money. Legally there was nothing wrong about that. A secondary reason for operating a transit line was a desire to serve the public, but only to the extent necessary to make profits. The mass of the people, however, were not interested in the money side of transit, but the thing of vital concern to them was service. To the operating company the problem was to carry the greatest number of passengers with the least number of cars; that was the obligation of the company to its employers, the stock and bondholders. These were the outstanding features that entered into the transit problem. There was no solution that was compatible with these conditions. A plan had to be devised to do away with these conditions. The commission began its work by laying down the proposition that each and every franchise must be turned in and surrendered, and the stockholder and speculator in transit securities must be eliminated. Whatever interest was provided must be limited to a fixed return. The logical place for the title and ownership of the transit system was the city of New York, the municipality. The plan by which this might be brought about was to make a careful valuation of each company's holdings and to offer the company 100 cents for every dollar of honest valuation. If a company refused the price—how could they enforce it? Well, if the commission wanted to be rough they could force the company to give the maximum of service compatible with a 5-cent fare and then the company would not make any money. Speaking generally, it would take from six to seven hundred million to a billion dollars to purchase the transit holdings of the various companies. Of course the city of New York did not have the money to make any such payment, nor has it sufficient borrowing power to raise such a sum. To meet this situation they had taken advantage of certain conditions that were brought about during the war which led to the development of a new type of corporation as exemplified in the Emergency Fleet Corporation and the War Finance Corporation. There would be a board

of control composed of three members appointed outright by the mayor and three by the interests holding equities in the transit properties, and a seventh member chosen by the six. These should function as a corporation. When a fair valuation was agreed upon by the Board of Control and the transit company, the latter would deed to the city all its holdings in return for which it would receive bonds of the operating company bearing 5 per cent. interest. There would also be an agreement by which the Board of Control would undertake to amortize the principal by setting aside 1 per cent. a year. To guarantee still further the transit companies the Board of Control would make a contract to so manage the system that the fare would always be enough to give the people adequate service, and second, it would always be enough to insure the 5 per cent. per annum and the 1 per cent. amortization. At the end of thirty-eight years the purchase price would be amortised and the city would own the property free and clear. This plan seemed radical but it would go to the root of the transit difficulties. This plan would afford better service with less equipment because all the cars of all the companies would be available and could be shifted to where they were most needed at a given time. Owing to jealousies between existing companies the plan further provided for three operating agencies, one for the subways and elevated, one for the surface cars of Manhattan and the Bronx and one covering the Brooklyn Rapid Transit and the Richmond and Queens systems would be operated by one system or the other. This plan would do away with many of the evils of private ownership and as the three operating companies would control the personnel it would be under the Board of Control. After the 5 per cent. interest and the 1 per cent. amortization found was provided for, the balance would constitute what they had termed a barometer fund which would serve as a graduated scale for the regulation of fares. If this fund fell below a certain minimum it would call for an increase of 1 cent in the fare. If the fund exceeded a certain maximum the surplus would be used as bonus for the personnel, and additional royalties to the bondholders or some other purpose. They were confident that there would be no need for an increase of the fare over 5 cents, but the plans were made so that unusual conditions, such as had arisen during the war, might be met. General O'Ryan said he had made his explanation of the plan as simple as possible so that it could be readily understood because it was unreasonable to ask the support of the public unless the scheme was understood by the people.

Harbor Pollution.—Dr. GEORGE A. SOPER, president of the former Metropolitan Sewage Commission, discussed this subject. He stated that he had received a note before the meeting asking him to speak of the more elementary facts in relation to water pollution, things that people were supposed to know, but that most of them did not know. First, it was scarcely within the knowledge of most people how bad water overpolluted with sewage could be. One of the most classic examples was afforded by the experience of London. At one time London had many cesspools built to receive waste, and in the course of time became honeycombed with them. There was a great deal of disease which was attributable to these cesspools and the use of a water supply from the same source. In the course of a few years 30,000 of these cesspools were connected with sewers and which were discharged in the easiest way, which, of course, was into the Thames. Samuel Budd, well known to physicians, had described the condition, telling us that the air was so foul that it was necessary to close the blinds of the House of Parliament and to use chloride of lime. The stench from the river was so offensive that the river steamers lost their traffic. There was no experience at that time to guide municipalities in the disposal of sewage, and it seemed that one city did not learn from another until it was visited by an epidemic, the necessity for making its waterways clean. London had put in a system by which all sewers were discharged into a main drain. About $60,000,000 had been invested in the undertaking of sanitating the Thames. All the sewage was taken to two points, where it passed through settling tanks. The first tank removed the solids and the effluvium passed to another tank, where finer sediment was collected, and was then discharged into the water, where the movement of the tides caused its diffusion. This method was not believed to be permanently satisfactory, inasmuch as the city was growing and sanitary standards were becoming more exacting. Other methods of sewage disposal were being considered, as, for instance, its intensive purification and placing it on the land. In considering some of the elementary questions in regard to sewage, we might ask first "What is sewage?" Sewage, Dr. Soper said, did not contain a great deal of excrement or solid matter, but was the refuse from sinks, bathrooms, etc. It was merely dirty looking water. If one filled a bottle with it, stoppered the bottle, and left it at room temperature the sewage would putrify and there would be first a slight flocculent precipitate. In a few days the odor would increase and the mass would become black and turbid. This indicated that the action of bacteria was taking place. If one kept the bottle long enough the unpleasant odor would disappear and we would have a subpurification of the specimen. The solids became liquified and the liquids were oxidized. All manner of waste passes through those stages. The sewer trunks in New York were comparatively short, so that the sewage was fresh and that was of some advantage. Then, too, was the additional advantage that they were combined sewers, taking both house drainage and storm water, though the latter was much less than one would suppose. It had been estimated that about a thousand million gallons of sewage was discharged daily into the water about New York. The problem that this presented had been set forth in the three volume Report of the Metropolitan Sewerage Commission, with its five volumes of testimony. There was being discharged into the waters of New York Harbor not only the sewage of New York City, but of other cities bordering on its waters, and also of inland cities, Paterson, Summit, Newark, etc. These cities had unified great sewer systems and ran trunk sewers to the harbor. In 1903 the Governor appointed a commission to inquire into sewerage conditions in the Passaic Valley. It was found that the Passaic Valley project was harmful and threatened health. The proper course of action seemed to be a suit in the Supreme Court. That suit lasted twelve years and was one of the most famous sanitary cases ever tried in this country. At that time the Bay Pollution Commission sounded a warning as to the harm that was being done to the port of New York by the large amount of sewage discharged therein. The commission recommended that a thorough study be made of all the conditions concerning sewage disposal in the metropolitan territory, some 700 square miles, and to outline a policy whereby the harbor for all time should be kept reasonably clean. New Jersey was to cooperate with the proposed new commission. This commission was appointed under the name of the Metropolitan Sewerage Commission, which carried on its work for eight years. During this time it went into the fundamentals of the subject and a great deal of careful study was given to the problem. The commissioners were selected for their qualifications for the work, there being no politics involved. Experts were brought from all parts of the world; wherever there was a man who had knowledge that could be turned to good account he was called, thus some twenty-seven experts were employed. Their reports had all been published. Of the facts brought out by this study, one was contrary to the general impression that the flushing action of the tides was insufficient to carry away all impurities to sea. Again it was shown that there was no peculiar disinfecting property in salt water. It was true that sewage was carried away from the point of its discharge, but it was not carried very far nor was it carried away permanently. Dr. Soper described investigations made to determine just what happened to an object beneath the surface of the water. The experiments were carried on in the East River, and material discharged at Hell Gate was followed. It traveled back and forth a distance of 108 miles between Hell Gate and Governor's Island, and came back to within one mile from the starting point. That observation was checked up carefully. There was absolutely no flushing action of the ocean that we could depend upon to clean out the harbor. There was a mixing action which was helpful, but it did not remove

the refuse far enough. The accumulation disappeared through the action of microbes or chemical action. In New York we had not only present conditions to consider, but worse ones threatened in the future. The plans which had been made for the protection of the harbor were engineering plans based on the experience of other cities. In short, a system of main drainage was recommended. The sewers, instead of emptying into the waters, would empty into mains and the number of outlets be reduced. These large mains should discharge into disposal plants, where the refuse would be collected and the effluvium discharged into a main tidal system which should empty at the bottom of the water at a suitable distance from the city. It was evident that in the course of time the present system would be totally inadequate to deal with the increasing amount of sewage. By 1940 we would have 12,000,000 people in Greater New York, and by that time we must have some new plan for taking the sewage out to the ocean. The problem was within the range of engineering, but it would cost $140,000,000 The question had been raised why not put the sewage on farm lands. That could not be done because it would take more land than was available. It would take the whole of Long Island and would destroy the value of the Great South Bay, and this, too, would cost $140,000,000. Other plans for intensive purification were discussed, which Dr. Soper said would be objectionable to those living in the vicinity. The longer the solution of the problem was deferred the more expensive it was going to be in the long run. The Metropolitan Sewerage Commission had gone out of office of its own accord. It had recommended that there be appointed an interstate supervising and directing body. At the present time there was no regulation or supervision whatever exercised over the discharge in the metropolitan district, and yet there were some eighty municipalities discharging their waste into New York Harbor, and each one might act without reference to the welfare of the great population in this territory. When the Metropolitan Sewerage Commission had completed their work the Board of Estimate and Apportionment took over the plans and submitted them to the city engineers for criticism and suggestions. There was a great deal of criticism and dissatisfaction and nothing had been done. Recently the Chamber of Commerce of the State of New York has taken an interest in the sewerage problem, as in the transportation questions and other things, and it was possible that there might be a renewed interest taken in the question. Any plan for dealing with the problem of harbor pollution should be a comprehensive plan and should apply not only to the metropolitan district of New York, but to New Jersey as well. Any plan adopted must be flexible and capable of expansion. It must apply to all localities wishing to discharge waste into the harbor. The work need not all be done at once; it should be done progressively, but it should conform to a general plan and be in charge of a central authority. The question of sewage disposal for New York was not a single problem, but a number of problems, each one necessarily related to the other.

Port Development Plans and Public Health.—Dr. ROYAL S. COPELAND, Commissioner of Health, spoke briefly on this phase of the subject. He first explained that the reports in the newspapers which had accredited him with saying that doctors should advertise and that he was glad he was not a member of the New York Academy of Medicine had misquoted him; that was the first statement misquoted him, the latter remark he had never made at all. What he had said was that the medical profession as a profession should make known what it could do so that the public might be informed and not fall into the hands of chiropractors and all kinds of quacks and charlatans. That was quite a different statement from the one attributed to him that physicians individually should advertise. Coming to his subject, Commissioner Copeland said he had observed a note of regret in Dr. Soper's remarks because of the fact that the city had not gone on with the project of sewage disposal. The reason this and other plans had not been carried out was because of the financial inability of the city to handle them. We would never solve these great problems of transit, sewage disposal and water supply until the metropolitan district was divorced from the State and other suburban places naturally linked up with the city were taken in. There was never united support of any project by the legislature and there never would be while New York City paid 70 per cent. of the taxes, contributed 60 per cent. of the population, and had only 40 per cent. of the representation in the legislature. We could never forge ahead with these much needed projects until we were independent from up-state, and he believed we would not prosper until we had that independence. It had recently been estimated that all the available fresh water that could be brought to New York would be exhausted by 1931. If that was true it would become necessary to have some filtration process by which we could take water from the Hudson River above Poughkeepsie. That would cost another $140,000,000. The city did not have the money. We were now paying interest on bonds of the city of New York issued in 1865 to pay for the paving of streets that had been paved three times since the original bond issue. These were matters of interest to the medical profession because they had a very direct bearing on public health, yet when there were hearings on such questions as had been discussed this evening the doctors were not represented. The time was here when the medical profession ought to be alert in these matters having to do with public health. At the present time we had a great problem in the housing situation. There were 100,000 families tucked two families to two or three rooms. He had seen instances where twelve persons were living in two or three rooms. There were hundreds of socalled homes without light and ventilation. It was time that the medical profession said something about that. If we were living in normal times he would put the seal of the Health Department on those places, but as there was no other place for those people to go, he could not turn them out. The improvement of the harbor was a matter of vast importance. We had in this city only one day's supply of milk, perhaps three or four days' supply of other essential foods, and a supply of meat for one month. If we were cut off from the centers of supply we would starve in sixty days. These were matters of importance and demanded solution from the standpoint of public health. Commissioner Copeland congratulated Dr. Cofer on the fine piece of work he had done for the port on Hoffman Island and described the difficulties under which that work had been done. He said he hoped the New York Academy of Medicine would go forward and would use its influence in solving the questions relative to the harbor. He was not there to discuss the relative merits of the two port plans but he did believe the whole question of port development was one which involved public health to such an extent that it might well engage the serious attention of the Academy of Medicine in order that this influential body might direct public officials to solve these problems in the right way.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ARTERIAL SCLEROSIS. By LOUIS F. BISHOP. 383 pages, with illustrations. Published by Henry Frowde and Hodder & Stoughton. Price, $4.25.

HYGIENE OF WOMEN AND CHILDREN. By JANET E. CLAYPON. 354 pages, with illustrations. Published by Henry Frowde and Hodder & Stoughton. Price, $5.00.

EARLY SYMPTOMS AND TREATMENT OF CIRCULATORY DISEASE. By R. M. WILSON. 245 pages, with illustrations. Published by Henry Frowde and Hodder & Stoughton. Price, $4.75.

LE BACTERIOPHAGE, Son Role dans L'Immunité. By F. D'HERELLE. 227 pages, with illustration. Price, 12 fr. Published by Masson et Cie., Paris.

NOUVEAU TRAITÉ DE MÉDECINE. By Professors G. H. ROGERS, FERNAND WIDAL, and P. J. TEISSIER. 718 pages, with illustrations. Vol. IV. Price, 40 fr. Published by Masson et Cie., Paris.

Miscellany.

Dessessartz and His Croup Remedy.—It often happens that the man whose memory is handed down largely through some modest invention was not an obscure citizen but one of the prominent men of his day. However it happens, this is probably the rule. The subject of our sketch was born in 1729 and was a brilliant student who at first chose theology as a career. He decided in favor of medicine, however, and, being too poor to go to Paris, took his degree at Rheims. He was a small town practitioner for 15 years, but made himself so well and favorably known that the Paris faculty invited him to join it. In 1770 he took the chair of surgery, and in 1775 that of pharmacy, becoming dean in 1776. He opposed the formation of a new medical society, because he feared that the profession would be split up instead of benefiting from a healthy rivalry, but after the Recolution he took the opposite view and helped organize the medical and surgical societies which culminated in the Academy of Medicine. When he died in 1811 no less a man than Cuvier delivered the eulogy. His first book, published in 1760, was on the physical education of children, and one of the last of his writings, in 1807, was a monograph on croup which was responsible for handing down a French equivalent of hive syrup. His first book created such an interest that Rousseau, then writing his celebrated "Emile," made extensive modifications therein, but neglected to give Dessessartz credit. The latter felt no resentment against Rousseau for his "swiping" and remained one of his greatest admirers, although he had contributed as much to the book as many an acknowledged collaborator. Despite his extensive practice, he could not save anything, but he had made a religion of treating the poor without fee, so that his poverty redounds to his credit. His cough mixture contained ipecac, senna, and wild poppy, and was probably of use in false croup. It was reputed to be an expectorant and sedative, and was apparently not intended to produce vomiting.—*La Presse Médicale.*

Alexander Trallianus as a French Practitioner.—It is not generally known that this ancient Asiatic physician, who lived in the first half of the VI Century, practised for a time in France. His biographers mention Spain as the extreme of his occidental travels. He took his surname from a little town in Lydia and his father before him was a physician. He went to Rome, where he succeeded in establishing himself successfully. But before this period he traveled extensively, his writings bearing evidence of his knowledge of various countries. The object of travel was clearly that of a post-graduate course. It is known that he had studied under at least one celebrated master, concerning whom hardly anything is known. Alexander merely mentions the name of this professor's son. In France, called then Gallia, he learned some organotherapy—the treatment of epilepsy with the testicles of a cock. In Italy he studied the medicinal properties of Italian wines. When he had finally located in Rome, patients came to seek him from the entire Empire. His reputation was so exceptional that he was spoken of simply as "The Doctor," without any qualification. This recalls the custom of our own day of terming the most eminent practitioner of a limited community "the doctor." Like Galen he wrote his own system of medicine, which comprised 12 volumes and which gained him the repute in some quarters of being second only to Hippocrates. In therapeutics he was an eclectic of eclectics and did not shrink from incantations and other expressions of psychotherapy. He was against purgation and used opium sparingly, combining it with other remedies. His celebrated "cynoglossus pills" contained a number of substances, including opium, and are still to be found with some modification in the French Codex.—*La Presse Médicale.*

Geography of Scrofula.—Steiner approaches this subject from the viewpoint of the ophthalmologist. Having practised in Java he announces that the so-called scrofulous lesions of the eye and appendages were practically absent in the Javanese. But it is equally true that the pure white inhabitant of the island is immune. The factors believed to favor the development of the disease in Europe are represented here as well—uncleanliness, vermin, and a history of measles, whooping cough, etc. Bone scrofula and lupus are infrequent, so that in general it may be asserted that clinical scrofula has a very low incidence. The frequency of pulmonary tuberculosis is, on the other hand, conspicuous, and the two basic conditions, tuberculosis and scrofula, are clinically dissociated. The absence of the latter in Java may be attributable to the fresh air and light. In other words, the natural conditions agree quite well with those utilized in temperate zones in the treatment of scrofula—abundant fresh air, sunshine, life in the open. In some parts of Europe the scrofulous child is made to go lightly clad and largely nude, the better to profit by the light and air. From this angle scrofula is a creature of cold climates, in which man is forced to clothe himself heavily and pen himself up in dark and unventilated rooms. It has a genetic relationship with rachitis, with which it is often associated, with the addition that in rachitis the young child is also immobilized or deprived by circumstances from taking exercise of any kind. The author does not touch on the subject of dietetics in this paper and has but little to say of the probable relationship between tubercle and scrofula. But if the former is almost universal, the so-called scrofulous child has no more latent tubercle than any other child.—*Schweizerische medizinische Wochenschrift.*

More Bubonic Plague in Paris.—In 1921 Paris escaped with less than a dozen cases of this malady, occurring only in small foci without any secondary cases. Joltrain, who has been in charge of plague cases in earlier visitations, relates that the diagnosis was not made at first, for the patients were badly septic when first seen. Puncture of enlarged lymphnodes, however, revealed the *Bacillus pestis.* A drop of blood from the finger pulp swarmed with the latter. Intensive intravenous serotherapy was unable to stem the condition. Two victims were shown to have been bitten by rat fleas, or at least by fleas in rat-infested neighborhoods. The rat is now known to suffer from a chronic form of the plague, a fact which makes the authorities apprehensive for next summer.—*Le Bulletin Médical.*

THE EFFICIENT TREATMENT OF COMPOUND FRACTURES*.

By CLARENCE A. McWILLIAMS, A.M., M.D., F.A.C.S.,

NEW YORK.

THE ordinary results of the old routine treatment of compound fractures are so bad that I have taken it upon myself to bring this hackneyed subject to your attention, hoping that a definite, systematic procedure may be generally adopted which will give results as excellent as those obtained in simple fractures. Better teaching of this important subject is required in our Medical Schools. The old bugbear of the threatening presence of infection has led men to consider most important of all the treatment of the soft parts, allowing the fractures to take care of themselves, hoping by some legerdemain to remedy the resulting deformities at some future date. I particularly wish to bring out the fact that the proper, early position of the bony fragments is just as important to care for as the wound in the soft parts, and both should be treated, at the primary operation, by methods which have proved themselves efficacious, times without number, during the war.

The following case gives the text for my presentation of the subject:

A lad of 21 years of age was injured by getting his arm in a rotary machine in a manufacturing suburb of New York City, on November 22, 1920, producing two fractures of each of the bones of the left forearm, badly compounded in the lower third. Both the lower fragments were exposed in the lower wound. The upper fractures were simple.

The lad was taken to a hospital operating room, given ether, and the treatment adopted was that along the old, orthodox lines. The wound was cleaned and sewn up. The surgeon's attention was entirely given over to the care of the soft parts, though there was no débridement of them, *i.e.* removal of the contaminated areas, nor were the bones placed in such apposition and held there that they would remain in proper position. No Carrel tubes for subsequent Dakin's solution were inserted.

X-ray pictures were taken soon after the operation. Following the operation, as was to be expected, there was infection and the wound had to be opened throughout. The old treatment with packing of the wound was instituted. No Carrel tubes were employed nor Dakin's solution. The splint used was a fracture box and then a wire splint. Weights were applied to the hand, with the elbow in extension. There was a long convalescence, due to the infection, and the final result is seen in the *x*-ray (Fig. 1). The elbow was stiff and out straight (the pictures here shown were taken six months after the accident), and there was no pronation nor supination. There were fractures of the left

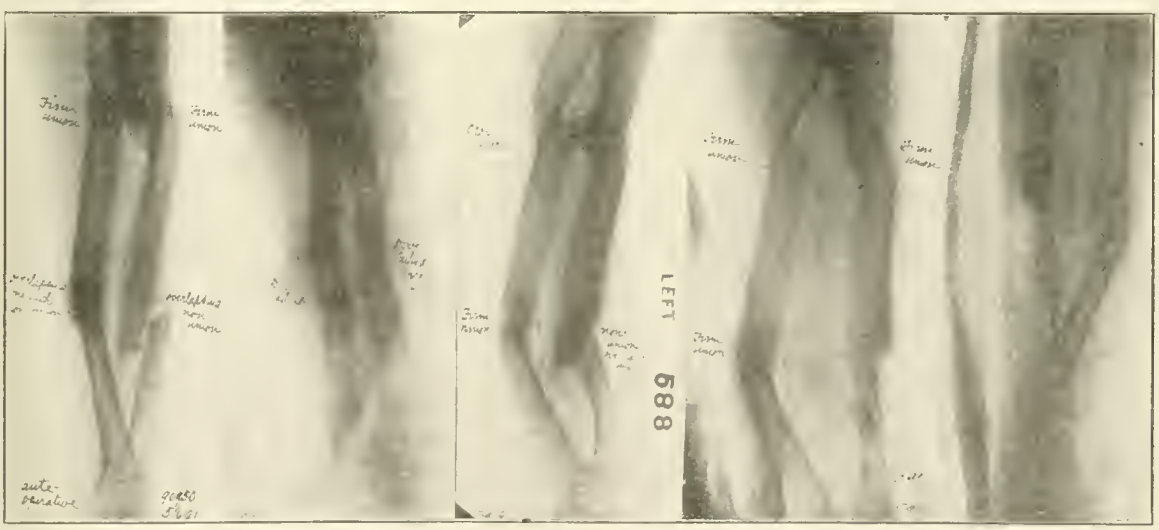

FIG. 1.—Result of old method of treating compound fractures. Soft part infection only considered without reference to the position of the fragments. No Carrel-Dakin treatment. Result after six months, when wound was healed. Upper fractures united with angulation. Lower fractures overlap and are ununited.

FIG. 2.—Lower united fractures dovetailed into each other. Held by chromic sutures.

FIG. 3.—Result four months after operation of Fig. 2. Upper fractures united but with a rare complication of forearm fractures, cross-union. Below the radial fracture has healed, but the lower ulna fragment has become displaced and is ununited.

FIG. 4.—Immediate result of third operation in which the upper cross bridge of bone was chiseled away and the lower ulna fragments were sawn off with Gigli saw and placed end to end where they were held by chromic sutures.

FIG. 5.—Taken five weeks after the second operation. The ulna fragments have remained in perfect apposition and from the disappearance of the drill holes and the haziness of the fracture line one judges that new bone is being formed.

*Read before the Westchester County Medical Society, White Plains, November 15, 1921, and before the Surgical Section of the New York Academy of Medicine, January 6, 1922.

radius and the ulna, each in two places at the corresponding levels. The upper fractures became united with some angulation and with cross union. The lower fractures were ununited and each fragment of the radius and ulna overlapped its corresponding fragment an inch.

Operation was undertaken by me in the Presbyterian Hospital, June 9, 1921, seven months after the accident. The lower fractures, at the first operation, only were operated upon (Fig. 2). A tourniquet was placed about the arm, the fragments were exposed, and no interposed soft parts were found between the fragments. The upper ends of the lower fragments were sawn so as to make points of their extremities, while the lower ends of the upper fragments were slotted. With the ends thus dovetailed into each other, drill holes were made through each and chromic gut sutures were passed through and tied. The soft parts were sewn together without drainage, and copious sterile dressings were applied, anterior and posterior plaster of Paris stirrups were made, and bandaged on the extremity with the hand in mid-pronation, and the elbow held in less than a right angle. The wound healed by first intention. There was nonunion at the end of six weeks, but union began at the eighth week and was complete by the twelfth week. The picture, taken four months after the operation, was somewhat disappointing (Fig. 3). There was firm union of the radial lower fragments, but the lower ulna fragment had slipped. It overlapped the upper fragment one inch, and was ununited. At the site of the upper, firmly united fractures, there was a firm, cross bridge of bone, three-quarters of an inch wide, which looked as though it were a fragment of bone which had become interposed rather than a bridge formed of new bone from periosteum. Cross union is a rare complication in forearm fractures, for of 100 forearm fractures treated in the Presbyterian Hospital there was not a single instance of cross union. There was no pronation nor supination. A second operation was undertaken on October 6, 1921, four months after the primary operation (Fig. 4). Both upper and lower fractures were exposed by one long, posterior, ulnar incision along the outer edge of the ulna. The bridge of bone between the upper healed fractures was chiseled away cleanly without difficulty. The lower ulna fragments were exposed and a Gigli saw passed about them both. The bones were sawn off flush and brought end-to-end, where they were held by four chromic sutures passed through drill holes (Fig. 4). Union was by primary intention. At the present time, five weeks after the operation (Fig. 5), the ulna fragments are in perfect apposition. There is, however, as was to be expected, no definite union as yet. I should not look for union to occur before eight or ten weeks at the least. There is, however, a haziness about the ulnar fracture and the drill holes have become filled in as though new bone were beginning to be formed. The periosteum about the radial fracture (Figs. 4 and 5) has proliferated much new bone.

War surgical experiences have much advanced the correct treatment of compound fractures, and I will outline my idea of how civil compound fractures should best be treated. The first variety is one which we can easily pass over. It is the case where skin is punctured by a sharp fragment of bone. This fragment should not be reduced until the skin all about it and the protruding fragment have been cleaned, then the bone extremity should be cut off flush with the skin and the fracture reduced. Then the edges of the skin puncture should be cut away and sewn, possibly with a rubber tissue drain inserted into the depths.

The second most important variety, in which we are more particularly interested, is that in which there is a large wound in the soft parts, all of which are contused and dirty. How shall we proceed? The first thing to be done is, always to give an injection of tetanus antitoxin. Then administer ether to the patient and carefully proceed with disinfection. The wash of the skin should not be allowed to get into the wound. Pack this first and then shave the skin. Then wash the skin *away* from the wound with gasoline, benzine, kerosene, or ether. Apply alcohol, allow this to dry, then paint the skin with iodine solution 3½ per cent. Then remove the pack and pick out all foreign particles from the depths. Flood the wound with ether and then with 3½ per cent. iodine and trim away the contused skin edges and fascia. Expose the depths with retractors and cut away all frayed-out edges of tendons and pulpified muscle, which latter is black, which does not bleed, and which does not contract on pinching it. Expose the bone ends and bring them out of the wound. Remove only entirely loose bone fragments. Leave all fragments which are attached to periosteum, never mind how slightly, since they may act as grafts later. Do not cut away any periosteum except frayed-out fringes. The ends of the bones should be cleaned by sawing off a thin slice or biting off small sections with a rongeur. If it is seen that the fragments will not stay in proper apposition, one should make the point of one fragment dovetail into a depression made in the end of the opposite fragment, and through these two fragments drill holes should be made and chromic sutures passed and tied. I would not advocate metal plates nor metal screws nor metal wires, since they predispose to infection. They are seldom necessary. If the fragments cannot be held by any other means, one might, in exceptional cases, use a screw or a metal plate but only when subsequent treatment with Dakin's solution is used. Subsequently these foreign substances should be removed as early as possible.

Divided nerves should be anastomosed with silk. If these do not unite, the sutures will hold the ends together, which can then be easily identified at a subsequent operation.

We are now ready for the final steps. *Never close a large compound fracture.* I cannot say this too strongly. I think it not too emphatic to say that most compound fractures, if sewn up, become infected. This was so strongly shown in the war, even after careful débridement, that an order went forth from Headquarters that no war wound should be completely sewn up at the primary operation. Prevention of infection should be our endeavor rather than to await its appearance, and I know no means so efficacious as to insert Carrel's tubes at the operation, and to instil thereafter through these tubes, every two hours, night and day, Dakin's solution, held in a reservoir and never instilled through the tubes by means of a syringe. This latter is a very common error. When a syringe is used, the infection, always present in the open ends of the tubes, is washed into the wound. The rubber tube leading from the reservoir should always be left attached to the Carrel tubes. After this thorough Dakinization, if infection of the wound occurs, it will be mild and will soon yield to the Dakin's solution. The sterile Carrel tubes should be removed every day and replaced by fresh ones and copious dressings applied. At the finish of the operation an appropriate splint, which will make the dressings easy, should be applied. A picture of the best splint for a compound forearm fracture, that I know, is shown in Keen's surgery, Vol.

VII, Blake, page 477. It is a Thomas splint, bent at the elbow, and any degree of traction can be made by twisting the Spanish windlass attached to the fingers. In this way we have absolute control of all infection as well as the position of the fragments. I do not understand why Carrel tubes and Dakin's solution are not more generally used in all infections. They are our sovereign remedy for this condition. A surgeon is not well up in treatment who is not familiar with the Carrel-Dakin method of treatment of wounds. Dakin's solution robs infection of all its terrors so one should never omit at the primary operation to place the fractured bones in proper position and to see to it that they stay thus. After the temperature has been normal for a few days, we may then consider sewing up the soft parts. This, however, should not be done until we have made smears from the depths of the wound and have them examined for bacteria. We may sew up the wound if we do not get more than one bacterium in two or three fields on two successive days, provided that that bacterium is not the hemolytic streptococcus. If the time since the original injury is not more than from 6 to 10 days, and we get such negative smears, nothing need be done save insert sutures through the edges with a rubber tissue drain. If the sewing up is done *after* 10 days, it may be necessary to excise the granulating skin edges, but deeper granulations should not be touched. By this secondary suture no time is lost in the final outcome and one feels very confident of his control of the infection. One can then focus attention upon the fracture as though it were a simple fracture.

I can hear objections to examining the smears because many suburban hospitals are not supposed to be equipped to do this. I am sorry for any hospital which cannot have this done, since most house surgeons are competent to do this. As for Dakin's solution, tablets are now made from which can be made very acceptable Dakin's solution. If infection occurs, a thick, yellow pus means staphylococcus infection; thin, colorless pus, streptococcus; green pus, pyocyaneus, which is of low virulency. Foul, odorous discharge usually means colon infection. If there is any crepitation, bubbling, or gaseous formation in the wound, the infection is of the dangerous type of malignant edema (gas gangrene), caused by the *Bacillus aerogenes capsulatus*, which requires free incisions of the soft parts, with the cutting away of any edematous, blackish, gaseous muscle, and the insertion of numerous Carrel tubes and abundant, frequent Dakin's solution irrigations. No bandage had better be used under the splints because of the danger of producing ischemic paralysis from too tight bandaging, thus cutting off the proper blood supply of the limb upon which bony union depends.

Dakinization is particularly advisable in compound fractures in a situation such as the forearm, where complete débridement might destroy very important structures, such as tendons, etc. Infection should be anticipated and minimized by Dakinization, since infection produces such dire results in the loss of tendons. Objections to Dakinization are raised, firstly, in the difficulty of getting house officers to attend properly to the dressings, and, secondly, to the difficulty in making standard Dakin's solution. The first objection is met by insisting upon the operating surgeon doing the dressings himself for the first week as long as infection threatens, and the second, by the fact that ready-made tablets, to make Dakin's solution, are good substitutes for made-to-order Dakin's. The constant irrigations will keep the wound clean as no packing can do, and the antiseptic action will diminish the virulency of the infection. After smears are practically negative, the wound can be secondarily closed and no time lost in the eventual outcome. With the fragments put in the proper apposition at the original operation, and held in this position, and with the infection controlled, the fracture can be treated as any simple fracture.

The treatment of compound point fractures has been much simplified by the principles enunciated by Willems, of Ghent, whose results the treatment of joint war injuries has fully substantiated. His method has supplanted in actual experience all the old surgical traditions. I can fully agree with all that he has said, and, from being a sceptic, have become a great enthusiast, having seen marvelous results from his method of treating joint injuries, fractures, and infections by *active* (never passive) mobilizations. In such an injury, excise all the devitalized, dirty tissues in the soft parts and the skin edges. Remove all free particles of bone, then completely close the synovial membrane, and Dakinize the superficial soft parts through Carrel tubes. Then immediately follow this up by active motions (never passive), every two hours. One is surprised how little disturbance is caused in ordinary fractured bone, about joints, by these motions. By using only *active* motions, the patient will not go so far as to allow any motion between the fragments, which would cause pain, while damage to their proper position might be caused were *passive* motions to be instituted, since these might be carried too far. To be certain no movement takes place between the fragments, it is well to have the active motions, made by the patient, performed once under the fluoroscope. Should pus appear in the joint, open it freely immediately. Do not insert any drainage tubes nor Carrel tubes. Do not flush the joint but insist on the patient's moving the joint every two hours, day and night. The muscular contractions, causing the active motions, provide the very best possible drainage for the joint. By these contractions the joint is kept emptied of pus and ankylosis is prevented. All voluntary motions can safely be allowed and should be vigorously encouraged. The patient will not himself go beyond the safe limit of motions as pain would thereby be caused. The patient is, at first, very timid, but as he finds no pain is caused by the motions, confidence will be acquired and the motions will become more and more free and extended. Every hospital should have ready for immediate use Balkan frames and Thomas' splints. The old expectant treatment of compound fractures is no longer held by the courts to be sufficient; one must go further and apply prophylaxis against infection as well as set the fractures properly *at once*. Only by such adequate treatment can the surgeon avoid having damages awarded against him.

After treatment is all important. Union of bones depends on a good blood supply and everything

should be done to keep this as free and unimpeded as possible. Bandages should not be tight. Bakings are most helpful in producing hyperemia in the extremity. Splints should be removed every day, if possible, and the joints above and below the fracture should be moved passively and gentle massage given to the muscles of the extremity. By these means stagnation of the blood stream is prevented and muscular tone is preserved. Retain splints on the extremity the minimum duration of time. Using all these means of treatment, non-union will be a rarity and the final results as to function will be much better than under the old, expectant treatment, and the period of disability will be cut in half.

Dr. Samuel Stern last summer visited the clinic of Prof. Lexer and Dr. Kohler where for the past year and a half they have been treating fresh fractures with so-called irritating doses with most satisfactory results. They have succeeded in reducing the healing time to about one half. Usually only one treatment is given as soon after the fracture has been set as possible. The voltage is around 180,000. The dose given is about one-tenth of an erythema dose, thus:

Distance	Filter	Spark Gap	Ma	Time
35 cm.	½ mm. Cu.	180 KM.	2	10 mm.

In small bones only one field is treated; larger bones are treated anteriorly and posteriorly but with reduced time.

Conclusions.—1. Débride the injured and septic soft parts thoroughly. 2. Never completely close a compound fracture except the small punctured ones; before doing this, however, the projecting point of bone should be sawed off flush with the skin. Most compound fractures become infected. 3. As the best prophylaxis against infection, insert Carrel tubes at the time of the first operation and Dakinize the wound every two hours by means of a reservoir and *never* through the syringe. 4. Place the bones in accurate apposition at the time of the original operation, enlarging the wound if necessary. Hold them there by chromic sutures. Rarely will metal appliances be necessary. 5. Apply a splint which will be comfortable, hold the fragments in good position and which will render the daily dressings easiest. 6. When the purulent discharge becomes slight, smears should be taken from the depths of the wound and examined for bacteria. When there is not more than one bacterium in two or three fields found on examinations on two or three successive days, the wound should be sewn together, after which the subsequent treatment will be that of a simple fracture. 7. Every hospital should have Balkan frames and Thomas' splints ready for any emergency.

19 East Sixty-fifth Street.

One Paranoiac Exploits Another.—Heuyer and Santenoise described what is probably not an infrequent form of behavior. The stronger character was a man who had a sort of hypnotic control over a woman paranoiac. It became necessary to interne the latter. An active and intelligent paranoiac who cannot be committed for insanity can do much harm. Attempts to interne such men are usually responsible for an entire propaganda directed against the authorities who are accused of false commitments and the idea is conveyed that many alleged insane ought to be liberated. The man in the case fought against the commitment of the woman and sought to utilize her case as an example of unwarranted internment.—*La Presse Médicale.*

PERICECAL TUMOR, *X*-RAY DIAGNOSIS; BENEFIT FROM *X*-RAY AND RADIUM THERAPY FOR POST-OPERATION RECURRENCE.*

By SINCLAIR TOUSEY, M.D.,

NEW YORK.

Mrs. D., aged 66 years, was referred to me by Dr. Parke for *x*-ray diagnosis. The symptoms had been trouble with digestion and spasmodic vomiting of solid food, then she would feel well for about three weeks. This had been going on for about three years. She complained of "a dull weight in the stomach which was relieved by taking hot water," also a pain under the right shoulder. Seven years before coming under observation she had undergone an operation for the removal of a tumor thought to be malignant, and of one ovary. On ex-

Fig. 1.—Pericecal tumor with stasis in small intestine; six hours after barium meal.

amination a tumor was readily palpable in the right iliac fossa. The first radiograph was of the abdomen prone upon the plate with the stomach and intestine empty. Others showed the stomach after the barium meal, the patient being erect (A) or prone (B). Another (Fig. 1) was made 6 hours later and others were made after a barium enema. Of these, Fig. 2 was made with patient erect and for Fig. 3 the patient was prone with the thorax 45 degrees lower than the pelvis. This (Tousey's) position is devised in case of ptosis of the transverse colon to show whether that part of the intestine is free to gravitate toward the thorax. If so, a supporting belt and pad might relieve the symptoms due to ptosis but not if the transverse colon remains bound in the pelvis by adhesions.

The radiographs showed in A that the stomach was at high level; the *pars pylorica* of irregular

*Case reported before the Surgical Section of the New York Academy of Medicine, January 6, 1922.

shape, and the duodenal cap incompletely filled and somewhat deformed. The B picture showed the *pars pylorica* and duodenal cap deformed; no distention of the distal portions of the duodenum; normal appearance of the body of the stomach. Fig. 1, six hours after the barium meal, shows that the stomach was empty but there was a remarkable accumulation throughout the small intestine. The meal was arrested in the region of the cecum. The small intestine did not gravitate into the pelvis at all. In Fig. 2 the enema reached all parts of the large intestine; no ptosis; cecum and ascending colon of irregular shape and at a high level. In picture F, the cecum appeared of irregular shape and at a high level. My deduction from these *x*-ray findings was that the tumor did not involve the intestine and that it could be removed without operating upon the intestine.

At operation Dr. Parke found a mass of a gelatinous character which was removed (I never received a microscopical report). The wall of the intestine was not involved. Four months later the patient was brought to me for treatment with radium and *x*-ray. There was again a palpable tumor in the right iliac region, almost complete intestinal obstruction, with inability to take anything but liquid nourishment, and a great deal of pain.

Treatment was by radium and *x*-ray. The *x*-ray was applied from a Coolidge Tube actuated by my own generator which produces a constant high tension current. The cathode particles all have approximately the same velocity and there is an approximation to homogeneous *x*-radiation. A deep dose is secured in a shorter time and with less sur-

Fig. 2—Pericecal tumor with stasis in the small intestine, but an enema fills all parts of the large intestine

face effect than with any of the generators giving current made up of a series of impulses. The radium was applied with the patient supine and with a heavy bowling ball compressing the right iliac region so that the radium tube was in very close contact with the deep-seated tumor. As a result the tumor disappeared, the action of the bowels became natural and the patient was able to take all kinds of nourishment. She gained in weight and strength and was free from pain. Once or

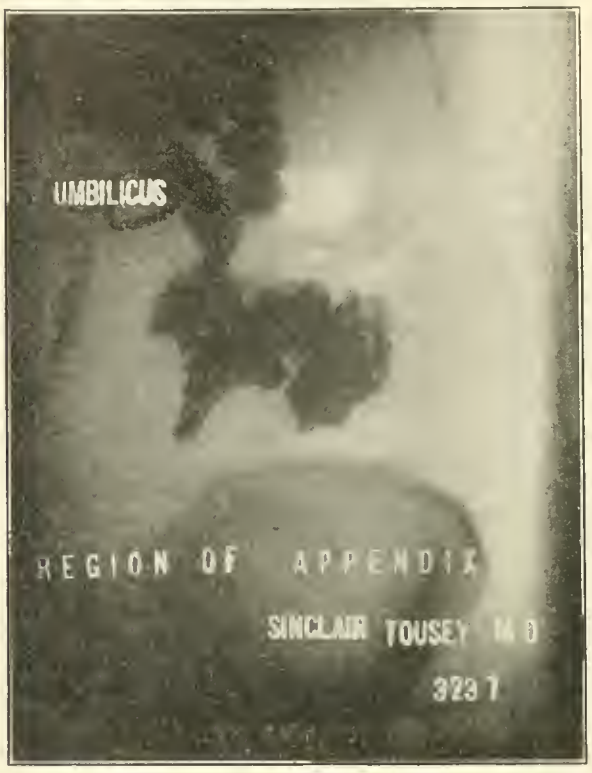

Fig. 3.—Pericecal tumor without involvement of the wall of the intestine.

twice in the history of the case the peritoneal cavity became distended with the same gelatinous substance and this was evacuated through a median incision. Four years after the first *x*-ray examination and three years after the last *x*-ray and radium treatment and eleven years after the first operation the patient died following a period of pain and vomiting. We felt that the treatment by radiation had had a very beneficial effect even though it did not prevent ultimate death.

Treatments, 1917, pericecal tumor.

X-ray, October 11, 90 Kv, 3 ma, 10 inch 3 mm. aluminum, area exposed, 6 inch diameter 10 minutes, left hypochondriac region.

Radium, October 25, 3 hours, 20 mg. glass, lead and rubber, divided in three spots 1½ inches apart.

X-ray, October 27, 83 K, 3 ma, right upper quadrant, 10 minutes.

X-ray, October 31, left lower quadrant, 10 minutes.

X-ray, November 7, 83 K, 3 ma, 10 min. + 10 min., right lower front, right side of back, prone, with compression ball at cecum.

X-ray, November 10, 83 K, 3 ma, 10 min. + 10 min., left upper front and left back.

Radium, November 14, 3 hours, 20 mg. glass, lead, thin rubber.

X-ray, November 17, 7 min., right upper front, abdomen.

X-ray, November 21, 7 min., left lower front, abdomen.
She had burning sensation November 20 and 23; just a faint suggestion of redness in the right iliac region. November 30, slight swelling could be noted in the right iliac region.

X-ray, November 30, 7 min. + 7 min., right and left sides of back.

Radium, December 5, 20 mg. 3 hours, glass, lead and thin rubber.

These reatments were followed by disappearance of the tumor and natural movements of the bowels.

550 Seventh Avenue.

PURPURA WITH GASTROINTESTINAL SYMPTOMS.

By W. HOWARD BARBER, M.D.,

NEW YORK.

FROM THE DEPARTMENT OF SURGERY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Purpura is generally recognized as a circulatory manifestation of a severe toxemia. It is characterized by hemorrhages into the skin, mucous, or serous membranes.[1] The extent of the extravasations of blood is supposed to correspond with the intensity of the intoxication. The purpuras are unsatisfactorily classified as symptomatic and essential or arthritic. The symptomatic purpuras depend upon or are associated with some recognized acute or chronic infection or toxemia (the acute exanthemata, typhus, typhoid, tuberculosis, ptomaines, snake venom, and certain drugs), constitutional disease (cancer, Hodgkin's, Bright's, scurvy) nervous diseases (tabes, myelitis), or trauma (varices, fractures). The essential purpuras include those in which both the causative agent and the mode of entry remain unknown and for purposes of description are spoken of as (1) the simple, affecting the skin, (2) the rheumatic or Schoenlein's disease, involving the skin and joints, (3) Henoch's purpura, in which the skin, joints, and gastrointestinal mucosæ are involved, (4) the hemorrhagic purpura or morbus maculosis of Werlhof, which is characterized by hemorrhages from all of the mucous membranes,[2] and (5) the fulminating type described by Calmels[3] as occurring in children of five years with fatal results after from ten hours to four days. Little is actually known of the pathology of this obscure condition although Fraser[4] has described purpura, on the basis of microscopical study of the bloodvessels taken at autopsies, as an inflammatory disease of the bloodvessel walls in which the blood is allowed to pass through into the surrounding tissues. Mouson[5] emphasizes the importance of the blood platelets as the cause of the large group of true hemorrhagic purpuras but holds there are as many varieties of these hemorrhagic syndromes as there are factors in the mechanism of hemorrhage. In one, the wall of the vessel is at fault, as in slow endocarditis; in another, the coagulating ferments are lacking, as in sporadic hemophilia; in others nothing can be found to explain the hemorrhagic tendency, as in scurvy.

Henoch[6] published his first report in 1874. He presented four cases, two boys and two girls, ranging in age from 4 to 15 years, with skin hemorrhages about the joints and blood in the stools. In these cases the "spots" appeared first and in one dysentery together with "spots" on the elbows. All showed remissions of the disease extending over a period of four to seven weeks. In 1876, two additional cases were reported by him. Osler contributed several cases in three separate reports on the subject. (*American Journal of the Medical Sciences*, Jan., 1904). This form of purpura with colic has been described and illustrated by many others and unreported cases occur in the records of most large hospital services. The four cases herein presented are of special interest from the standpoint of diagnosis and treatment.

Case I.—A. F., referred by Dr. E. Payne, Riverhead, N. Y., Oct. 25, 1919. Girl, aged 5 years, born in U. S. of Polish parents. Family history negative. Past history represents patient as a delicate eater and has having had "stomach trouble" She developed petechiæ on arms and legs; this was followed by nausea and vomiting, pains in elbow, knee, and fingers, pain about the umbilicus, hemorrhages into skin of all parts of the body, epistaxis, hematemesis and melena.

Temperature, 98.8; pulse, 90; respirations, 18.

Physical examination at this time revealed a fairly well nourished child, anemic, with her hands clasping the umbilical region as in an effort to express intra-abdominal pain. There were scabs at the mucocutaneous junctions of her nose marking recent hemorrhages, and a suspicious spot on one tonsil; the submaxillary gland on one side was slightly enlarged; chest negative; tenderness and increased muscular resistance above and to left of umbilicus but no definite rigidity or localized tenderness; the stomach was distended with gas to the interspinous line; the liver palpable one finger below the costal border; the spleen was not palpated. No Kernig or meningeal signs were elicited.

November 10: Temperature, 102°; pulse, 90-100. Blood count: W. B. C., 10,000; polys., 70 per cent.; R. B. C., 1,700,000; Hgb., 72 per cent. Wasserman negative. Blood cultures negative. Urine: Albumin, 3 plus; blood in considerable amount; casts, hyaline and granular.

Dr. R. E. Stetson was called in consultation and the case placed under his care (Bellevue Hospital) for repeated transfusions, while repeated efforts were made to determine the possible existence of a focal infection. The child improved symptomatically for a short time after each transfusion, but after each of the five transfusions she inevitably relapsed until her exitus on Dec. 9, 1919.

Note in this case (1) the possibility of tonsillar infection; (2) the persistent tendency to bleed and the prolongation of life by repeated transfusions; (3) the sequence of "spots," vomiting, joint pain, central abdominal cramp, and profuse hemorrhages from the skin and mucous membranes; (4) the absence at any time of a definite indication for surgical intervention.

Case II.—C. S. Born in U. S. A. Aged 22 years. Female Admitted to Bellevue Hospital, May 26, 1920, with a history of having been treated for purpura hemorrhagica. In September, 1918, she was operated upon for acute suppurative appendicitis. The appendix was removed at that time and no untoward experience with bleeding was encountered. Symptoms on entry (1920) were nausea, vomiting, pain and mass in right lower quadrant. Examination confirmed hard, fluctuating mass in right iliac region, localized rigidity and tenderness. Blood count: W. B. C., 18,000, and 88 per cent. polynuclears.

At operation (May 27) hemorrhagic fluid was found in peritoneal cavity. Inflamed omentum and right parietes. Abscess to outer side of cecocolon. Acute phlegmon of cecocolon and enlarged mesenteric nodes from ileocecal region to root of mesentery. Technic: Amputation of cecocolon with distal end of ileum and proximal end of colon left in the lower and upper ends of wound, respectively.

Pathology: Thickened edematous cecocolon, termination of ileum, and appendix stump of 1.5 cm. Enterolith in stump (which may have ulcerated through giving rise to enterocolitis and abscess). Acute suppurative colitis.

May 29: Ileostomy.

June 10: Local condition satisfactory. Purpuric eruption over body and hemorrhages from nose and ileal stoma. Leucocytes, 75,000; differential count polys., 90; transitionals, 2; lymphocytes, 5, and myelocytes, 3.

Blood culture negative. Wasserman negative. Transfusion (Dr. Stetson).

June 28: 3,200,000 red cells and 40 per cent. Hgb. Petechiæ over lower extremities. Prolonged profuse menstrual bleeding. Weight 102 pounds; 98 on admission. Transfusion (Dr. Stetson). Convalescence. Burke's Convalescent Home.

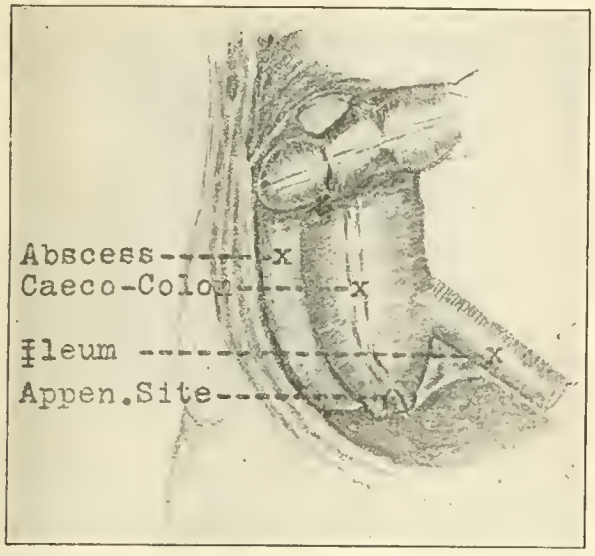

Fig. 1.—Case II. Illustrating the phlegmonous ileocolon and perforated appendix site, following an appendectomy 20 months before.

Sept. 17: Operation of enterocolostomy and removal of terminal ileal loop. Lateral anastomosis carried out as expeditiously as possible. The ileum was divided distal to the site of anastomosis and everted by attaching a rubber catheter within it and drawing on the outside of the abdomen. The bleeding was profuse and uncontrollable, excepting by pressure and heat within the abdominal wall. Within the abdomen no difficulty with bleeding was encountered.

Sept. 20: Ileal loop ligated and on the following day excised.

Oct. 4: General condition satisfactory. Bowels moved from fourth day post-operative. Patient healed primarily.

May 2, 1921: Patient had been seen in interim and found in good condition; weight reached 120, and bowels moved spontaneously 1-3 times daily. She was admitted on the tuberculosis division of the hospital and succumbed on June 1 in the third stage of pulmonary tuberculosis.

Note: (1) bleeding history; (2) association of purpura with enterocolitis; (3) absence of purpura 3¼ months later but persistence of the "bleeder" tendency as manifested in operation for closure of ileostomy. Rapid convalescence within normal period; (4) final development of virulent pulmonary tuberculosis and exitus 2 years 9 months after first coming under observation.

Case III.—M. R., U. S. A. Aged 30. Female. Admitted to Bellevue Hospital M,ay 20, 1921. Illness began with acute onset of persistent vomiting and pain in upper abdomen Abdomen generally rigid and tender. Urine negative. Blood: Leucocytes, 20,400 and 90 polys. The pronounced rigidity and continuous vomiting led to provisional diagnosis by the house staff of perforated gastric ulcer. Temperature normal. The acute abdominal signs responded so well to the usual preoperative morphine that the feeling arose that the patient might be suffering from mesenteric thrombosis or that the condition might not be surgical at all. At operation a recent hemorrhage of the subserous tissue of the mid-transverse colon was disclosed with purpuric spots on an adjacent loop of small intestine. This hemorrhagic tissue was dissected away and the abdomen was closed. The convalescence was normal, excepting for the nausea which was prolonged four or five days after operation. The microscopical examination of the tissue removed showed "fatty omentum infiltrated with blood."

Note: (1) absence of history of purpura; (2) sudden occurrence of serous hemorrhage without associated hemorrhages from the mucous membranes or skin; (3) the pronounced vomiting and abdominal pain out of all proportion to the discoverable hemorrhage; (4) the abrupt disappearance of the symptoms and the untoward convalescence following the administration of morphine and laparotomy.

Case IV.—A. L. Male. Age 46 years. Machinist. Born in Germany. Family history negative. For the past 10 years he has suffered from recurring attacks of dyspepsia One month ago he tripped over a steam pipe 4 feet from the floor and passed bloody urine in the afternoon of the same day. The next day he vomited blood and the following three days passed bright blood from the bowels. He has had no other evidence of hemorrhage from the gastrointestinal or urinary tracts; no signs of bleeding into the skin or joints. This patient was not seen by me until four weeks after these acute symptoms. His medical advisers at the time of injury suspected gastric ulcer and proposed operation. No positive physical or laboratory findings persist at

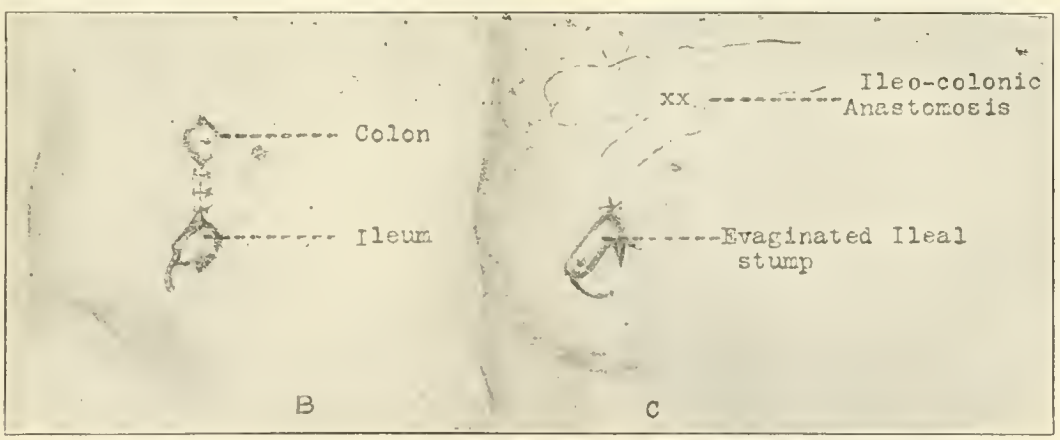

Fig. 2.—Case II. Showing colopexy and ileostomy following excision of cecocolon for what appeared to be malignancy (*B*); and final enterocolostomy and evagination of ileal stump (*C*). Although the transverse and descending colon were left unused and closed at proximal end for four months, this loop of colon promptly regained motor function after ileocolostomy. Hemorrhages decreased with improvement in the general condition of the patient.

the present time, except an acute suppurative gingivitis. For the treatment of this condition and for the removal of this possible focus of infection the patient has been referred to a dental surgeon.

Note in Mr. L.'s case a similarity with Case II in that active suppurative foci exist in both in association with hemorrhage from the digestive tract. From experience with the above cases, and the purpuras occurring from time to time in routine practice, it appears that one has to be on his guard for surgical indications. In the cases above enumerated there may have been an indication for enucleation of chronically diseased tonsils before the first patient came under observation. A thorough clean-up of the pyorrheal condition was certainly called for in the fourth individual. The eradication of the infected material was obviously necessary in Case II, and investigation appeared to be indicated in the third case. The relationship existing between the infectious process and its hemorrhagic manifestations is believed to be very suggestively shown in the second patient.

SARCOMA OF THE STOMACH.*

By WILLIAM J. GILLETTE, M.D.,
TOLEDO, OHIO.
SURGEON TO ROBINWOOD HOSPITAL.

While carcinoma of the stomach is of rather frequent occurrence, sarcoma is seldom met with in this organ, few cases having been reported. It is for this reason the case here reported is of interest. Basch[1] thinks sarcoma of the stomach to be of more frequent occurrence than we have been led to believe, but does not undertake to make an estimate of its frequency. Apparently his contention is borne out by a report from the Mayo Clinic[4] for twelve cases occurring there from Jan. 1, 1913, to December 1, 1920, or during a period of approximately seven years, sarcoma appeared in the proportion of one to sixty-eight of carcinomata, approximately 1½ per cent., which is a much greater frequency than is reported from other clinics and sources. In 1919 Smithies and Ochsner in an analysis of 928 cases of cancer of the stomach found only 4 of sarcoma or less than ½ of 1 per cent. The German clinics estimate the frequency at 1 per cent. Douglas[2] gathered together 227 cases of sarcoma of the stomach from the literature, and added to them 3 from his own experience, making a total of 230 reported at the time of the writing of his paper. In a discussion of his paper before the New York Surgical Society, Dr. Erdman reported, in addition, two cases from his own experience and Dr. Fischer, during the same discussion, one more case found at autopsy. Dr. Haggard[3] of Nashville, Tenn., has reported a case and Dr. Basch[1] another, making altogether, with my own, 236 cases of sarcoma of the stomach. One hundred and fifteen of these were operated upon and the diagnosis made then, and the rest were found at autopsy.

Three distinct groups of sarcoma of the stomach have been observed: (1) Spindle-celled myosarcoma; (2) lymphosarcoma, and (3) round-celled sarcoma. Sarcoma may involve the whole stomach or form large masses growing from it. Cantwell removed one of these growths weighing 12 pounds. Lymphosarcoma originates in the submucus layer, and the spindle cell type in the muscular layer, while carcinoma originates only in the epithelial layer and this fact is of diagnostic significance, for it makes ulceration when present in sarcoma a manifestation of much later date than in carcinoma. Inasmuch as all the various forms of sarcoma metastasize more slowly than carcinoma, prognosis following operation should be better, but the experience of the Mayo Clinic[4] would indicate otherwise. Of the 12 cases found there, "Resection was performed in six; in the other six the condition was found inoperable on exploration. Two of the six patients who had resections died of peritonitis following operation. One died four months after operation of recurrence in the lower bowel, liver, and remainder of stomach. One returned five months after operation in poor condition; he had lost 20 pounds and had a mass in the left epigastrium which probably was a recurrence. Another returned seven months after operation apparently with recurrence. The remaining patient was operated on too recently to be considered in the results. Four of the six patients who had explorations are dead. They lived from six weeks to four months after exploration. Information has not been received from the other two patients." These cases would indicate that prognosis following operation is exceedingly unfavorable. However, a number of patients have been known to recover following operation and to live for a number of years. Three patients in a list reported by Gossett were living one, four and six years respectively. Haggard[5] reports a case which he found in the literature in which the patient was living seven and one half years after operation, while in a case operated by Moschowitz in 1909 the patient lived until 1919, and then she died with some other disease. In a case reported by Rupert and operated upon by Schopf the patient was well fourteen years after. Metastases seems to occur earliest and most frequently in the lymph nodes in relation to the stomach and later to the liver following the same line of progress as carcinoma. Sarcoma is located most frequently just above, but not at the pylorus, and the location next in frequency is at the greater curvature, then the wall of the lesser curvature and occasionally the entire stomach is involved.

Symptomatology—At first there seems to be but little gastric disturbance in sarcoma of the stomach. Pain is usually the first symptom noted and becomes more pronounced at the advent of ulceration. Vomiting and hæmatemesis are not as constantly present as in carcinoma, nor is pyloric obstruction so frequent. Cachexia develops slowly but in anæmia is usually present. An inflammatory leucocytosis has also been reported. Schlesinghe

*Read before the Academy of Medicine, Toledo, Ohio, October 1, 1920.

states that in 10 per cent. of the cases of sarcoma there is present enlargement of the spleen. Hydrochloric acid is more frequently present in sarcoma of the stomach than in cancer, but in a small proportion of cases is absent. Blood may be present

Fig. 1.—Gross appearance of the growth.

in stool and in vomit, but its absence does not rule out sarcoma, as it does in cancer. It would seem to be absent in a majority of cases until late in the progress of the disease. While the *x*-ray can only tell us that a deformity of the stomach wall is present, nevertheless it constitutes our most reliable diagnostic help, taken together with an accurate history of the case.

This patient, C. W., a carpenter by trade, forty-five years of age, was referred to Robinwood Hospital, Toledo, by Dr. F. A. Cobb of this city on July 7th last. He gave the following history: Father died of pneumonia and mother of "nervous breakdown." One brother living at forty-seven and one sister at thirty years of age. No brothers or sisters dead. Has always been well until the past two or three months. About June 20 last, after an attack of severe pain in the epigastrium, which radiated across to the left side, he vomited about a pint of dark-colored fluid which he thought at the time to be coffee. Following this he had diarrhea; the stools were black. He vomited the same kind of dark-colored fluid from time to time until July 4; since then has not vomited at all; his bowels soon became regular again, the stools appearing normal. During this time he belched much gas and complained of a dull ache, most of the time in the epigastrium, that food did not relieve. He gained seven pounds during two weeks prior to his entrance to the hospital.

Physical examination: Weight 137 pounds, pulse 78, temperature 97, respirations 18; blood pressure, systolic 114, diastolic 64. Nutrition seemed good and he was well developed. Teeth good; tongue slightly coated; pupils reacted normally; heart and lungs negative. There was no distention of the abdomen, some gas in colon, and slight tenderness in epigastrium to the right of the median line. Neither the edge of the liver nor the spleen could be felt. Reflexes normal. No enlarged glands. So far there was little upon which to base a diagnosis, except the history of the case, the vomited blood, the bloody stool, and the epigastric pain. The man would have felt comparatively well had it not been for the persistent and oftentimes severe pain. He was referred to Dr. A. J. Hartman for an *x*-ray examination of his stomach and intestinal tract. Dr. Hartman reported that the stomach tone was orthotonic. Size and position normal, though the form was of fish-hook type, moderately mobile. Peristalsis was interrupted for about two inches along the lesser curvature and at this point, and for the same distance, a filling defect was observed. Motility was somewhat delayed and a tender point over the stomach to the right of the median line was observed. One-third of the meal was retained after six hours. Duodenal bulb normal. Diagnosis: Probably carcinoma at lesser curvature or possibly an ulcer. Unquestionably a surgical case.

Examination of the blood gave a hemoglobin reading of 85; red cell count of 4,170,000, and white cell count of 15,300. Wasserman negative. Uranalysis negative. Following his examination at Robinwood, the patient went to Battle Creek, Mich., and Dr. Eggleston wrote to me that the *x*-ray there showed the fundus of the gallbladder distinctly. Dr. Hartman did not observe it in his plates, but otherwise the *x*-ray findings and diagnosis were exactly the same. Unfortunately, the chemistry of the stomach content was not determined, except that of a vomited portion largely made up of blood.

Operation.—On August 8 the patient was readmitted to Robinwood and was operated upon the following day. At this time his respirations were accelerated to 30 and pulse 100, otherwise he had not changed materially since examination in July. Operation, under gas anesthesia, consisted of opening the abdomen in median line above the umbilicus, eviscerating the stomach and as much as possible of the duodenum, when a subtotal gastrectomy was done. Clamps were applied above and below, and well outside the diseased area, and this area removed with a cautery. The duodenal opening was closed with linen and the stomach with catgut and silk anastomosis. Bleeding points were carefully ligated with catgut and the abdomen closed without drainage. The patient was placed in bed in good condition; in fact, he did not suffer shock at all, and very soon after his pulse and respiration dropped to normal, and remained so throughout convalescence. His recovery was as uncomplicated and uneventful as recovery from a simple appendectomy.

Pathological Report.—The specimen removed was turned over to the laboratory for examination and Dr. A. H. Schade reported as follows: Gross description: Specimen consists of about two-thirds of the stomach. On the lesser curvature at near the middle is a large ulcerated mass 80-50 mm. On cross section it has the appearance of fish flesh. The mucous membrane of the stomach outside the ulcerated area appears normal. The ulcer has an irregular outline and seems to be made up from the fusion of several smaller ulcers. Sections of the mass show it to be made up of solid masses of lymph cells with a small amount of fibrous infiltration and a small area of inflammatory cells. Eosinophiles very numerous. There is noted, too, a decided increase in the reticulum.

Diagnosis.—Lymphsarcoma which may be entirely

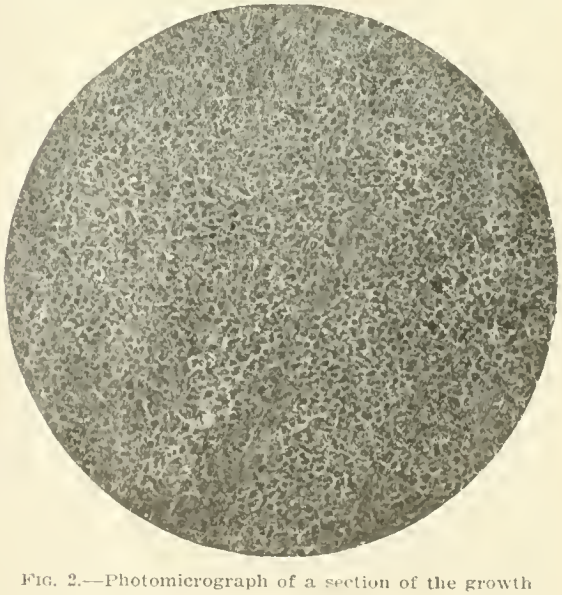

Fig. 2.—Photomicrograph of a section of the growth

localized, or which is more likely to be a part of a general lymphsarcomatosis of the gastrointestinal tract. In the former case the prognosis is good; in the latter it is of course very bad. The very abundant eosinophilic infiltration may be taken as one indication that it is a generalized process. Such a condition sometimes be-

comes leucemic and hence the man's blood should be examined from time to time. At this date, November 21, the patient has gained many pounds in weight, is working at his trade, and expresses himself as feeling as well as he ever did. He is a bit careful of his diet, but eats plenty of food and is not distressed in the least by it.

It is no doubt quite true that in many cases it is impossible to differentiate before operation between ulcer of the stomach and cancer, and it is equally difficult to differentiate between these diseases and sarcoma. In fact, so far as recorded, a correct diagnosis of sarcoma of the stomach prior to operation has not been made, though the disease has some distinctive signs which should lead one to suspect its presence in at least a small proportion of cases. With evidence of tumor of the stomach in a patient who has not yet reached the age when it is usual for cancer to appear, a short history of gastric disturbances, absence of blood in either gastric contents or stools, with the presence of free hydrochloric acid, and an anemia with an unusual amount of pain in a majority of instances, should lead us to suspect the presence of sarcoma.

DIPHTHERITIC AND POSTDIPHTHERITIC PARALYSIS.

By HERMAN B. SHEFFIELD, M.D.,
NEW YORK.

DIPHTHERITIC, or more correctly speaking, postdiphtheritic, paralysis is observed comparatively more frequently nowadays than prior to the use of diphtheria antitoxin. This is readily explained by the fact that as a result of antitoxin treatment so many more children survive an attack of diphtheria and hence are more liable to its after effects. There is no positive evidence on hand to prove that diphtheria antitoxin acts as a preventive of paralysis. Postdiphtheritic paralysis seems to be more common in apparently mild cases of diphtheria, and we frequently meet with children suffering from postdiphtheritic paralysis whose parents are not at all aware of the preexistence of diphtheria and only on thorough questioning recall that several weeks before the onset of the paralysis their children had been ill with a mild sore throat which was diagnosed as tonsillitis. This, by the way, is one of the main reasons why some cases of polyneuritis are occasionally attributed to other infectious diseases—which might have set in some time between the overlooked attack of diphtheria and the development of the paralysis. Only very recently I saw a six-year-old boy, afflicted with postdiphtheritic paralysis of the muscles of the neck and extremities, who about four weeks before had suffered from a sore throat and two weeks later from an attack of the grip and was treated for torticollis and muscular rheumatism of grippal origin.

The apparent lack of correlation between the degree of severity of the attack of diphtheria and the frequency of concurrence of paralysis has led to a great deal of uncertainty as to the actual cause of postdiphtheritic paralysis. Is it the toxin engendered by the diphtheritic microorganism at the seat of the local lesion that primarily involves the peripheral nerves and secondarily the nerve roots, etc., or are we dealing with some form of general sepsis which finally settles in the peripheral nerves? Careful study of this subject leads me to the conclusion that we are actually confronted by both of these processes, *i.e. general sepsis*, giving rise to sudden paralysis during the acute course of the diphtheria (*e.g.* heart death), and *local toxic action*, leading to the more gradually developing postdiphtheritic polyneuritis. Indeed, postmortem findings tend to confirm this assumption. Thus, on the one hand we find a parenchymatous and granular degeneration of the heart muscle, a toxic myocarditis, in connection with similar degenerative lesions in the liver, spleen, kidneys, and brain; in short, lesions that are commonly found in very grave forms of septic processes; and, on the other hand, pathological processes that are limited essentially to the peripheral nerves and contiguous structures. In other words, in the latter case we are dealing with a selective toxic action similar to that observed in poliomyelitis and akin diseases, or in polyneuritis, due to chemical poisons, as for example, lead or alcohol. This view explains why sudden heart death is so rare during the *convalescence* from diphtheria, and, when it does occur, it is the result of involvement of the vagus nerve and respiratory muscles. As to the exact pathology of this, postdiphtheritic, variety of paralysis, our knowledge is still incomplete. Different lesions have been recorded by different clinicians, ranging between simple inflammation in the peripheral nerves and the anterior cornua of the spinal cord and severe lesions in the medulla and brain. Experimentally it has been shown that the inflammation spreads by way of the nerves rather than of the blood vessels.

Involvement of the palate usually precedes that of any other portion of the body, and is attributable to the fact that the nerves of the palate are most exposed to the diphtheritic poison. In the same manner, for instance, the abdominal muscles suffer first when the diphtheria is localized in the umbilicus. Paralysis of the palate is manifested by a nasal tone of the voice (rhinolalia aperta) and often regurgitation of liquids through the nose in swallowing. "P" is pronounced like "M." It is due to failure of the soft palate to close the nasal cavity during phonation (closure of the anterior nares removes the disability). The patients are usually unable to distend the cheeks in blowing, to blow out a candle, or to gargle. On inspection of the pharynx it is found that in pronouncing "ah" the soft palate fails to rise as in health, and that sensation is lost when the palate is touched. Less frequently the larynx is affected. Laryngoscopic examination then discloses failure of the epiglottis to shut during the act of swallowing, and immobility of the vocal cords during phonation (aphonia). In bad cases there is also difficult deglutition, and, exceptionally, paralysis of the tongue and concomitant difficulty of speech. The paralysis of the throat, by the way, may be limited to only one side, ordinarily the side which presented the primary diphtheritic lesions. Furthermore, the nose and throat may escape the paralysis entirely, while the extremities may suffer.

In close connection with the paralysis of the throat and most probably as an immediate extension of the peripheral degenerative process along the cervical plexus, the neck is the next most frequent seat of predilection for the effects of the diphtheritic poison. The paralysis may be so very slight as to escape observation or, owing to the accompanying neuritic pain, may be mistaken for "stiff neck." Where the paralysis is pronounced, the child is unable to support the head, so that the latter drops either forward or sideways.

With the involvement of the cervical portion of the cord the diphtheritic degenerative process usually spreads to other portions of the cord. Hence the loss of the patellar and often the Achilles tendon reflexes, and the gradual appearance of pain and weakness or paralysis of several groups of muscles of the extremities. The pain is either spontaneous or on pressure upon the nerve trunks or muscles and consists of pricking, tingling or cutting sensations. Occasionally numbness prevails. The paralysis, like the pain, is symmetrical on both sides of the body, but usually more pronounced in the lower extremities. Here it is ordinarily manifested by an unsteady, irregular, ataxic or dragging gait; "the legs are moved as if they were at once heavy and limp" (Gowers). In the arms the muscular disorder is characterized by an irregular tremor and incoordination. After some time, especially in severe cases, the muscles lose their response to the faradic current and show marked evidence of atrophy. The irritability of the nerve trunks is feeble to both the faradic and galvanic currents. Less frequently the paresis extends to the muscles of the trunk, abdomen and thorax.

Diphtheritic polyneuritis in a boy four years old, affecting several groups of muscles of the neck, trunk and extremities. Note his total inability to rise from the floor.

In the case here illustrated almost the entire body musculature was affected. The four-year-old boy had a "sore throat" about four weeks prior to the onset of the paralysis. As the epidemic of poliomyelitis, though passed, was still vivid in the minds of the profession, the case was diagnosed in several clinics as infantile paralysis. When the patient came under my observation two weeks later his paralysis did indeed resemble that of poliomyelitis. Thus, he was unable to walk without support, and even then his gait was unsteady and waddling. When in recumbent posture he was unable to turn around and when on the floor he was unable to rise (see the illustration). He could use his arms freely but could not grasp firmly. The muscles of the neck were badly involved, the head dropped forward and sideways beyond control of the patient, and there were also distinct signs of implication of the intercostal muscles and possibly also the diaphragm—judging by the sighing, irregular respiration. On superficial examination the symptoms greatly resembled those of poliomyelitis, but, in addition, we found marked paralysis of the palate, with regurgitation of fluids through the nose on swallowing, moderate aphonia, difficult accommodation of the eyes for near objects (without involvement of the oculomotor or abducens) and, although the paralysis was already of long standing, the muscles showed no signs of genuine atrophy, real wasting, as is always met with in infantile paralysis. Moreover, the history of a preceding "sore throat," the symmetrical involvement of the muscles during the onset without recession of the paralysis at a later stage were very helpful in the diagnosis. The patient regained the power in the muscles of the trunk and extremities in the course of six weeks. The paralysis of the muscles of the neck, however, persisted for several months thereafter.

Occasionally the affection of the respiratory muscles is very grave in character, and exceptionally may even lead to a fatal issue. Whether or not in such cases there is simultaneous degeneration of the heart muscles or vagus nerve is not fully established. In both cases there is more or less marked dyspnea and arrhythmia.

As previously stated, the eyes quite frequently present signs of diphtheritic paralysis, chiefly by loss of the power of accommodation. The patient cannot read from a near point, but is able to see objects at a distance. This symptom, of course, cannot be elicited in the very young or in the myotic patient. The ciliary paralysis is usually bilateral, more pronounced on one side than on the other. The light reflex remains normal or is slightly sluggish. Occasionally the external eye muscles are affected, giving rise to strabismus when the recti are attacked or ptosis when the levator palpebri is implicated—in consequence of paralysis of the oculomotor or abducens respectively. In connection with paralysis of these cranial nerves it may here be noted that several cases are on record in which other cranial nerves were affected and that organic lesions (thrombosis, embolism, and hemorrhage) were found in other portions of the brain which led to permanent paralyses. I am inclined to believe that these gross lesions were septic in character, symptoms of *general sepsis* already spoken of.

In very severe cases we may also find retention or incontinence of urine, and trophic disturbances.

With the aforementioned typical symptoms in view, and more especially with a history of antecedent diphtheria, the diagnosis of postdiphtheritic polyneuritis ought to be made without much difficulty. However, the history may be obscured by complicating diseases and the symptomatology may be either very slight or exceptionally severe, so that the diagnosis may tax the skill even of the expert. Diphtheritic polyneuritis is most apt to be mistaken for poliomyelitis, especially of the so-called polyneuritic type. In both of these affections pain and paralysis form the paramount symptoms, and unless there be a history of diphtheria and paralysis of the palate in the one, or a history of exposure to poliomyelitis and marked paralysis and atrophy in the other, I hardly believe that a differential diagnosis can be made clinically with any degree of certainty in the early course of the disease. Considerable difficulty is experienced also in differentiating poliomyelitis from postdiphtheritic

paralysis in which the muscles of the neck and trunk are involved, as in the case already referred to (see the illustration). In all such cases the eyes should be particularly scrutinized for loss of accommodation or strabismus, which, as already stated, is a rather common occurrence in postdiphtheritic paralysis. The author had the opportunity to observe an eight-year-old girl suffering from progressive bulbar paralysis which was mistaken for postdiphtheritic paralysis. In the former affection we usually find early involvement of the tongue (tremor, difficulty of speech and atrophy), dribbling of saliva from the mouth, mask-like appearance of the face, in addition to the paralysis of the velum palati and the muscles of the pharynx and larynx. Furthermore, the disease is progressive in character, whereas postdiphtheritic paralysis shows an early tendency toward recovery. Finally, polyneuritis from lead, alcohol and arsenic poisoning, as well as endemic polyneuritis (*beriberi*) have several symptoms in common with postdiphtheritic polyneuritis and the two can in the early stages be differentiated only by careful attention to their etiologic factors. In their later stages the pathognomic symptoms of their own are decisive in the diagnosis. Thus, in lead palsy, recurrent epigastric pain, blue line along the gums, and marked radial paralysis (wrist-drop); in arsenical neuritis, paralysis and severe pain, especially in the distal portions of the extremities, early muscular atrophy, and often reaction of degeneration and trophic disturbances of the skin (hyperidrosis, glossy skin, etc.); in alcoholic neuritis, a history of severe cerebral symptoms at the onset, pronounced ataxic gait or paresis, symptoms of alcoholic intoxication in other organs of the body, such as the heart and liver; beriberi develops insidiously with epigastric pain, precordial oppression and general debility and wasting and edema of the lower extremities; sensory disturbances are absent. Moreover, in none of these forms of neuritis we obtain a history of diphtheria or definite signs of paralysis of the palate.

As we have repeatedly emphasized, postdiphtheritic paralysis is the result of a degenerative process, be it chemical or bacterial, of the peripheral nerves, primarily originating at the seat of the diphtheritic lesion. Hence, in order to prevent the paralysis we have to endeavor to destroy the toxic products at their primary source, which is generally the nasopharynx. I may possibly venture the opinion that perhaps one of the reasons why postdiphtheritic paralysis is more common in mild cases of diphtheria, and more particularly since the antitoxin era, is the fact that in both cases but little attention is given to the local lesions. And I therefore urgently recommend that the throat be actively treated locally, irrespective of what other measures are being employed for their constitutional effect. The following combination will be found particularly useful for that purpose:

Acidi phenolis, 3i.
Resorcini, 3ss.
Pulv. camphoræ, Gr. xv.
Alcoholis, 3iv.
Glycerini, q.s. ad f, 3iii.
M. S. Swab throat every three to six hours.

Simultaneously with the throat treatment, the nose is thoroughly cleansed with warm boric acid or Dobell's solution. It is generally recognized that strychnine is a useful remedy in both the acute and the chronic peripheral neuritis, and I firmly believe that if administered early in the course of diphtheria, strychnine is a very efficient preventive of the diphtheritic paralysis. In severe cases it should be given hypodermatically (gr. 1/60, t.i.d.), otherwise by mouth and its use should be continued for several weeks.

The feeding should receive especial attention, more particularly in infants. As a rule, only part of the food is regurgitated during the swallowing and when food in small quantities is administered at frequent intervals, nutrition will rarely suffer. However, where the palatal paralysis is complete, the infant must be fed by gavage, with a small catheter introduced into the stomach by way of the nose. Older children usually succeed in swallowing semi-solid foods, even if liquids are regurgitated. In these cases custards, soft boiled egg, milk toast, well-cooked fruits and cereals and vegetables will answer the purpose admirably. The pain is rarely so severe as to call for anodynes, but if need be, the salicylates, with or without pyramidon, will give prompt relief. A well-padded felt collar will be found very useful to support the child's neck and also to relieve pain in paralysis of the muscles of the neck; and a warm tub-bath, followed by gentle general massage should be given daily, for the soothing effect upon the peripheral and central nerve systems as well as to stimulate the body musculature. Rest in bed is essential during the early course of the polyneuritis, and more especially when the heart or respiratory muscles are involved. When cardiac arrhythmia persists I have derived considerable success from the administration of small doses of digitalis, and do not hesitate to recommend its use, the views of some clinicians to the contrary notwithstanding.

RECTAL STRICTURE AND RECTAL CANCER TREATED WITH CARBON DIOXIDE SNOW.

(PRELIMINARY REPORT.)

By E. JAY CLEMONS, M.D.,
LOS ANGELES, CAL.

Conceiving the idea that cold applied to organized rectal stricture would cause relaxation, while freezing rectal cancerous tissue would cause necrosis, the author improvised the following means of application.

Carbon dioxide snow is obtained by the usual procedure of allowing the gas to escape from a tank into a pocket of chamois. A rubber finger-cot is filled with snow thus obtained. A thread is tied around the free end of the finger-cot placed over the projection of a retaining catheter, in such a manner as to allow the escape of gas from the melting snow through the catheter. The catheter is inserted into a piece of rubber tubing, the diameter of which is such as can be inserted into a proctoscope, with the filled finger-cot projecting.

The application is made by inserting the proctoscope, withdrawing the obturator, and plunging the filled finger-cot into the strictured area. The proctoscope can then be removed, leaving the rub-

ber tube with the catheter in place, thus providing a means for the gas to escape without causing damage, as rubber is a non-conductor of cold.

Thus we have an agency, 109° F. below freezing, that can be applied to the exact location desired in any portion of the rectum, and moreover the extent of freezing can be exactly regulated, as after the primary application the zone is that of five minutes duration, the next eight, the next eleven, and the next fifteen. Apparently the fifteen minute zone is the limitation of the effects of one ounce applications of the snow. These zones are definitely recognized owing to the fact that the applied finger-cot adheres till the snow melts.

A proctoscope with obturator replaced by a piece of rubber hose. Projecting from the hose is a finger-cot filled with carbon dioxide snow. Passing through the hose is a catheter attached to the finger-cot.

The remarkable and pleasing part is that the procedure is not only painless during application, but the after effects are without pain or discomfort. A serous exudate oozes during the twenty hours following freezing. There is no sloughing of tissue where applications have been made intermittently at fifteen minute intervals. The tissues simply relax and change from hard fibrous to soft elastic consistency. Where freezing occurs the tissues begin sloughing within a week or ten days. Granulations begin in two weeks.

Later a detailed report of specific cases thus treated will be forthcoming. However, one can state that in carbon dioxide we have an agency which will relax organized rectal stricture quickly, pleasantly, and safely; and which will destroy rectal cancerous tissue painlessly, and the destruction will be followed by absence of pain and discomfort.

A PLEA FOR THE STANDARDIZATION OF OBSTETRICAL PROCEDURES IN OPEN HOSPITALS.*

By JULIUS WEISS, B.S., M.D.,

NEW YORK.

VISITING SURGEON, BRONX MATERNITY HOSPITAL.

It is the object of this paper to present tested obstetrical procedures as a basis for discussion, with the hope of reaching an agreement as to the best methods to be adopted in the treatment and care of parturients in hospitals extending the privileges of the use of their wards to the medical profession.

Physicians vary in their ideas as to the preparation, the conduct of labor, and the after-care of the parturients, resulting in a variety of procedures, a complexity of maneuvers, and loss of efficiency in the professional management of patients.

*Read at a meeting of the Clinical Society of the Bronx Maternity Hospital, October 25, 1921.

Is it possible in open hospitals to adopt plans of procedure which will safeguard the mothers and their babies and at the same time standardize and simplify the professional care of the patients?

The subject will be considered under the following divisions: (a) Antepartum history; (b) preparation of the patient; (c) the management of labor; (d) care during the puerperium.

The management of the more common complications and emergencies as they may occur during any of the above periods will be briefly considered. I will refer especially to such emergencies and complications where the attending obstetrician cannot wait until the arrival of a consultant, but must work speedily to guard the interests of the mother and child.

(*a*) *Antepartum History.*—I take it for granted that no physician in these times fails to realize the importance of knowing the history of his obstetrical patient, including a knowledge of the age, para, results of previous pregnancies, measurements and deformities of the pelvis, the presence or absence of toxemias and specific infections, and whether there are any pathological conditions of the vital organs. Such a history ought also to convey the information whether there were any uterine hemorrhages during pregnancy, whether the existence of a placenta previa is suspected, the position of the child in utero, and the probable date of full term.

In the majority of cases the patients arrive at the hospital long before their attending obstetricians. It is of vital importance to the patients as well as to the reputation of the hospital, that the resident surgeon, who is the first to come in contact with these patients, should be armed with a complete knowledge of the condition of each case, that he may intelligently guard the patient until the arrival of her obstetrician. I therefore maintain that it is of the greatest importance for an open hospital to have deposited with it a history of each case, and to be furnished with important additional information at definite intervals, until the arrival of the woman at the hospital.

It is an established rule at the Bronx Maternity Hospital to notify the physician immediately upon the arrival of his patient. Occasionally the physician is not in his office to receive the message, and quite an interval may elapse before he learns that he is wanted. Under such circumstances not only is it important that the hospital possesses a history of the case, but it is at times vital for the patient that the resident surgeon shall have the authority to make an examination. In this last procedure the resident surgeon will be guided by the history of the patient and her condition while waiting for the arrival of her physician.

(*b*) *Preparation of the Parturient.*—The preparation of the parturient is the first important step in the management of labor. Fortunately the great majority of obstetricians agree as to the procedure of this step. Upon her arrival at the hospital, she should receive a warm shower bath, her bowels should be cleared by a soap-suds enema, the hair about the vulva should be clipped or shaved, the vulva and the surrounding parts should be scrubbed with tincture of green soap and washed with sterile water, her urine should be drawn off by a rubber

catheter for examination, and the vulva should then be covered with a sterile pad held in place by a narrow abdominal band. The patient should be put to bed until the first examination is made.

(*c*) *The Management of Labor.*—The aims of the obstetrician shall be to deliver a living baby, to avoid unnecessary suffering of the parturient, and to eliminate all procedures that tend to endanger the health of the mother and child.

One cardinal rule that all of us have learned is to reduce the number of vaginal examinations to a minimum, and to make only those examinations that are absolutely necessary to inform us of the progress of the case. The majority of the authorities preach against the making of any vaginal examinations. No argument can be advanced against such preaching. Many of us, however, find in actual practice that we are compelled to make vaginal examinations to assure ourselves of existing conditions. I dare say that I cannot see any greater danger in making a vaginal examination than going into the peritoneal cavity, providing that we observe careful aseptic precautions. There are men who practise the delivery of their cases by intrauterine version. I have yet to be convinced that the percentage of morbidity is greater with these men than with those obstetricians who argue against vaginal examinations.

I do not believe that it is the best practice to compel a woman to lie in bed during the entire period of the first stage of labor. The patient should be allowed to change her posture from time to time to reduce the irksomeness of this—the longest—stage of labor.

Quite frequently we meet with parturients whose cervices refuse to dilate after many hours of intense pain. Unless we are assured that the patient is making normal progress in the dilatation of the cervix, we are not only justified, but I believe it is our duty to administer a hypodermic of morphine and atropine to relieve her of needless suffering and to hasten the softening and dilating of the cervix.

Occasionally we meet with patients who have gone into labor and who have even ruptured the membranes, but have slight and ineffective pains. I believe in this class of cases we ought to administer a good dose of castor oil followed with ten grains of quinine. The practice of administering in these cases even small doses of pituitrin ought to be prohibited. If after a fair trial, and in spite of continued strong pains, the cervix refuses to yield, I believe one is justified to resort to manual or mechanical dilatation.

At the completion of the first stage of labor, many of us are tempted to administer a hyperdermic of pituitrin to hasten the expulsion of the child. I fear this practice for the effect it may have on the baby and for the reason that it may cause a premature separation of the placenta or rupture of the uterus. All of us have noticed brilliant results from the administration of this drug, and we must admit that in many instances the period of suffering has been considerably shortened. But all of us must also confess that at times, because of the administration of this drug, even in small doses, we have presented the parents with an asphyxiated baby. Should the parturient begin to show symptoms of inertia, I believe it is preferable to apply forceps and extract the child.

The obstetrician is frequently confronted in the second stage of labor with quite a different condition, causing a retardation of the birth of the child. The patient will have strong pains, but the head will be pounding tediously for a long time against a rigid perineum and an unyielding vaginal outlet. Under such circumstances the life of the child is endangered and the parturient becomes exhausted and is exposed to a high morbidity and possibly future invalidism. The obstetrician should not delay matters, but he should perform an episiotomy, apply forceps, and deliver the child.

It is not intended in this paper to review the many abnormalities that may occur in labor and where the expert's services would be preferable. There is one abnormality, however, which occurs in about 30 per cent. of all obstetric cases, and because it frequently terminates favorably, the general practitioner feels he should handle it without outside assistance. I refer to the occipitoposterior position. No doubt in the majority of instances anterior rotation takes place and the child is delivered spontaneously. But this happy termination frequently occurs only after prolonged suffering of the parturient and after considerable damage to the soft parts have been done, which may result in tearing the levator muscles, loosening and eventually prolapsing the bladder and rectum, causing the woman great misery, and exposing her to the need of a future operation. Occasionally anterior rotation will fail to take place, and the parturient is exposed to even greater danger.

Some one has truly stated that more women become invalids and more children die as a result of the occipitoposterior position than from any other obstetrical abnormality. I believe that an attitude of noninterference in cases of the occipitoposterior position, to say the least, is fallacious.

Knowing the dire results that will happen to many mothers and children if we adopt a policy of waiting for the head to rotate anteriorly, it behooves the attending obstetrician to apply his knowledge and skill, and either transform the position manually, or rotate with forceps and extract, or deliver the child by podalic version, with the mother in the semi-Walcher position. A forceps operation is perferable when the head is well engaged, and a version should be considered when the head does not readily engage and the membranes are intact or have only recently ruptured. I believe that by adopting these procedures we would reduce the morbidity of the mother and give her a better chance of having a living baby.

Two abnormalities occasionally occur, when the head is already born that may terminate seriously for the child. One of the complications is to find that the cord is wound around the neck. This condition, if permitted to persist, may result in strangulation of the child, rupture of the cord, or premature separation of the placenta with the resultant hemorrhage. When confronted with such a condition, the obstetrician should not temporize. If the cord is loosely wound around the neck, it may be slipped over the head. But if the cord is tightly wound around the neck, and the skin of the face is

puffed and livid, a condition of imminent danger to the child, the cord should be rapidly clamped in two places and cut between.

The other complication that the obstetrician may be confronted with after the head is born is an arrest of the completion of delivery, due to large shoulders. Only recently I was called to the hospital to complete the delivery after the head had been out for an hour an the baby was asphyxiated. I believe that a good procedure in such a complication is to make a median episiotomy, push back the posterior shoulder and deliver the anterior shoulder. The remainder of the delivery is then an easy matter. I believe that the child in the case referred to would have been born alive had this procedure for the delivery of the shoulders been followed immediately after the birth of the head.

Cases complicated by breech presentation are also in a group that the majority of the general practitioners feel they can handle without the assistance of specialists. While many of these deliveries terminate spontaneously, still I mention this group for the dread that many of us entertain regarding the delivery of the shoulders and after-coming head. I find that a convenient and helpful procedure is to place an obstetrical gloved hand into the uterus and bring down both legs. In case the breech is well engaged, I make an endeavor to push the child up, grasp the legs, flex them and bring them down. In the remainder of the delivery I follow the suggestion made by Dr. Irving W. Potter in his versions. I deliver the anterior shoulder, rotate the posterior shoulder anteriorly and deliver that. I then grasp the legs in an upward horizontal position, milk out the mucus from the throat, place two fingers of the other hand into the mouth of the child, and flex the head. While extracting the baby, an assistant should press down gently upon the vertex from above. Before commencing delivery of the breech, the bladder should be emptied, the cervix should be fully dilated, the vagina should be ironed out and greased with a solution of green soap, and the woman placed in the semi-Walcher position.

In the management of the third stage of labor at the Bronx Maternity Hospital we found that it was very beneficial for the patient if we administered to her a hypodermic of .5 mil. of pituitrin immediately after the birth of the child. This procedure minimizes the oozing of blood during this stage, shortens its duration, and acts as a prophylactic against postpartum hemorrhage. We should not assume an attitude of duty well performed until the placenta and the membranes are out of the uterus, the organ well contracted, and the patient safe and comfortable in her bed.

In case of delay in the spontaneous delivery of the placenta, it is wisdom to follow the teachings of all authorities, not to attempt forcible expulsion until we are certain that it has completely separated from the uterine wall. How long we should wait before attempting manual separation and extraction of an adherent placenta is a debatable question. Cases have been reported where the attendants waited from twelve to twenty-four hours with the hope that the placenta would be delivered spontaneously. I fail to see what we have to gain by waiting more than one hour from the termination of the second stage of labor, and we should not wait at all the moment there is evidence of a partial separation of the after-birth accompanied by an alarming hemorrhage. However, it is well to remember that manual separation and extraction of the placenta is fraught with great danger, and that we cannot exercise too much caution in our efforts to prevent infection or rupture of the uterus.

By following the methods here outlined for the management of the third stage of labor, and by administering another hypodermic of pituitrin if oozing of blood is very profuse after delivery of the placenta, the dangers of postpartum hemorrhage will have been minimized. However, a hospital should always be prepared with the necessary solutions, packings and instruments to cope with such an emergency. You will readily agree that in order to make the hospital efficient in its efforts to serve the obstetrician in such emergencies, the operating-room nurse should know just what paraphernalia we would expect her to have in readiness. It is important, therefore, that we agree upon a definite and efficient method of procedure. The method advocated by Dr. DeLee, I believe is as efficient as any. If hemorrhage is due to a lacerated cervix, the same should be sutured. If due to retained placental tissue, the same should be manually removed. If due to retained clots, they should be expressed or removed manually. If due to lack of uterine contraction, massage the fundus and administer a hypodermic of aseptic ergot. If the hemorrhage is not fully controlled, administer a hot intrauterine douche of 0.5 per cent. lysol solution at 120° F. As an additional precaution, pack the uterus with lysol-gauze, 0.25 per cent. strength, saturated with Merck's sterilized gelatin. This tampon is to be removed at the end of twenty-four hours. Thirty minutes should be consumed in its removal. To combat the anemia, an assistant should simultaneously administer one quart or more of saline solution at 115° F., preferably in the subcutaneous tissue of the breast. For the shock administer a hypodermic of camphor oil. The patient should be placed in bed, surrounded with hot-water bottles. The foot of the bed should be elevated about two feet.

(d) Care During the Puerpium.—The efficiency of the professional management of women during the puerperium could be greatly increased to the advantage of the patients and to the credit of the hospital by the adoption of an intelligent and effectual rountine in at least the normal cases.

I have observed, for instance, that a nurse would look for six different cathartics for six different patients, because each had a different physician, none of whom agreed on the same cathartic. Similar situations developed in the treatment of threatened mastitis. In one ward where four women at one time needed attention to their breasts, for one was prescribed ice caps, for another massage and pumping, another had hot compresses, and the fourth received applications of solution of aluminum acetate. The patients could not understand why each one was receiving a different treatment for the same affection. Had the physicians agreed upon an efficient and definite plan of treatment, there would not have been any embarrassment for some of them,

the mothers would not have been in doubt as to the propriety of the methods employed, and the nurses could have used the time they spent in various complex maneuvers to the benefit of the rest of the patients under their care.

The management of the puerperium is as important as the proper management of labor and should be based on scientific principles. Physicians of a community sending in obstetrical cases to an open hospital ought to be able to agree on a standard and efficient method of treatment for women during the puerperial stage.

This subject will be considered here under the following headings: (1) the bladder; (2) the bowels; (3) the breasts; (4) the vulva; (5) the diet; (6) posture; (7) visitors; and (8) general care and attention.

The Bladder: The bladder having been emptied during the second stage of labor, if that stage has been of short duration, no attention need be paid to this organ before eight hours after delivery. However, if the second stage has been a protracted one, the obstetrician should empty the bladder after delivery of the placenta. If this procedure is followed we will find that there will be better contraction of the uterus and it will aid in the prevention of postpartum hemorrhage. The parturient should void every eight hours. If she fails to do so catheterization under strict aseptic precautions should be done. Should catheterization have to be done a number of times, it is advisable to administer urotropin two or three times daily.

The Bowels: Dr. Herbert M. Little of the Montreal Maternity has this to say: "The fact remains that patients who do not have purgatives (administered to them during the puerperium) run a much smoother clinical course. To those in charge of clinics. I would say, try this method if for no other season than the lessening of the amount of care required by the normal case and the resulting increased time of the nurses for the care of those patients who are seriously ill." Dr. DeLee of the Chicago Lying-In Hospital, prefers the administration of castor oil on the second day. Unless the patient complains of distress and desires a cathartic, I believe we ought to make it a standing rule to administer a dose of castor oil on the third day after delivery.

The Breasts: Eight hours after delivery the breasts should be washed with a saturated solution of boric acid and dried with sterile gauze, followed by the application of a sterile gauze pad and of a loose breast binder. The child should be applied to the breast twelve hours after delivery. The nipples should be washed with boric acid solution, applied by means of sterilized pledgets of cotton on toothpicks, both before and after nursing. A pad of sterile gauze should be applied to the nipples after nursing, which is to stay on until the next nursing.

I have found that an effective method of treating cracked nipples is to apply to the raw areas a solution of 1 per cent. silver nitrate, and to cover the nipples with lead nipple shields.

In painful distention of the breast and in mastitis, the best routine treatment has been found to be as follows: Restrict the fluids, administer a dose of epsom salts, lift up the breasts and apply to them a tight binder. The breast should be covered with ice bags, which shall be removed after it returns to normal. All authorities condemn massaging or pumping of the breasts. When pus has formed, the only treatment then, of course, is incision and drainage.

Vulva: The vulva should be washed regularly after each urination and defecation, and more often if the lochia is very profuse. For this purpose it is best to use sterile water to which has been added lysol to make a 2 per cent. solution. The vulva and perineum should be kept scrupulously clean when sutures are present.

The Diet: A routine diet should be agreed upon, and we should omit all foods that have proved to be injurious to the parturient. On the first day fluids only should be given; a soft diet shall be given on the second and third days; and a full diet should be instituted on the fourth day. The following foods ought to be omitted during the first week of the puerperium: acid fruits, because they may produce colic in the baby; potatoes, peas, lentils, and beans, because they may produce flatus and extreme distress in the mother; high spiced foods should be omitted throughout the puerperium, because they throw an additional burden on the kidneys. Women suffering from nephritis ought to be limited to a milk diet until the urine shows marked improvement.

Posture: Unless a parturient has gone through a major obstetrical operation, there is no particular reason why she should be kept on her back for more than two hours after delivery. From the first to the fourth day her position should be carefully changed from the back to the left side or to the right side. On the fourth and fifth days she should be propped up at intervals, and especially during meals, and also for micturition and defecation. She may be allowed to sit up at intervals from the sixth day, and is to be allowed off the bed on the ninth or tenth day. I believe that this management of posture during the puerperium is conducive to better drainage, greater activity of the bladder and bowels, a greater feeling of well-being, and prepares the patient more rapidly to get off the bed and to leave the hospital on schedule time.

Visitors: The problem of allowing visitors seeing parturients has always been a troublesome one in hospitals. Women during the puerperium are not only in great need of sleep during the night, but they should be allowed to have a nap during the afternoon. I believe also that it is a great burden on the nervous system of a parturient to have to entertain visitors for long periods during the day and evening, and is not conducive to a full and rapid recovery from her recent ordeal. The fact that a woman occupies a private room should not carry with it a license for her to receive visitors during all hours of the day and night. We would do the parturients more justice if we would limit the visiting period of even private-room patients to a maximum of four hours a day.

General Care: Not so long ago there was doubt in the minds of obstetricians as to the real value of the abdominal binder. To-day many of us are of the opinion that the binder should be applied soon

after labor is completed, mainly to relieve the parturients from the feeling of abdominal emptiness, and also for the purpose of steadying the uterus. I believe that the binder also aids the involution of the uterus and minimizes the chances for postpartum hemorrhage. However, when the abdomen becomes distended with flatus and the parturient feels distressed, we should loosen or remove the binder entirely.

For refreshing the parturient, she should receive a 25 per cent alcohol rub daily, and she should also receive a cleansing sponge bath at least twice weekly. Attention should be paid to the patient's mouth and teeth daily, and the attending nurse should also look after the patient's hair toilet, and should be responsible for her tidiness and general comfort.

The parturient should be examined before she is discharged from the hospital to note her general condition and to be instructed how to take care of herself and baby. If the uterus is found to be retroverted, the obstetrician should correct the abnormality. If subinvolution exists, he should advise her in the use of hot lysol douches after the fourteenth day of the puerperium, urge a sufficient amount of rest daily, and perhaps prescribe small doses of ergot two or three times daily to favor involution.

In this paper I have not taken up the care of the baby, as this matter lies within the province of the pediatrician. The treatment of the cord, however, concerns the obstetrician. The majority of obstetricians are of the opinion that nothing but a plain sterile gauze dressing should be applied to the stump. I usually wipe off the cut end with a little alcohol and apply a dry dressing. In female children this dressing could be left undisturbed until the stump falls off, but in male children it may be necessary to change this dressing daily.

In conclusion, I wish to say that in order to realize any measure of standardization in open hospitals, it will be necessary for physicians who practise obstetrics to meet from time to time in their respective communities, and together with the hospital authorities discuss methods of technic of delivery and care during the puerperium, to the end that patients may receive the benefit of advanced scientific knowledge, and at the same time make it possible to improve the efficiency of nurses caring for parturients, thereby reducing the morbidity and mortality of mothers and children throughout the country.

748 Kelly Street.

POSTWAR OBSERVATIONS OF NEUROPSYCHIATRIC CASES.*

By PHILIP J. TRENTZSCH, M.D.,

WASHINGTON, D. C.

SENIOR ASSISTANT PHYSICIAN, ST. ELIZABETHS HOSPITAL.

One of the important problems concerning ex-service men with which the Government has to deal to-day is that of the psychoneuroses. Since the signing of the armistice the number of neuropsychiatric patients has increased at such an alarming rate that considerable thought is necessary to provide for them the proper treatment and management. It is quite obvious to those of us who come in contact with these cases that for the most part we are not confronted by a "war neurosis," but rather by the syndrome belonging to the psychoneuroses of everyday life plus a compensation factor plus present public opinion that we are dealing with.

Comparison Between Types of Cases Immediately After the Signing of the Armistice and Present.—In comparing the type of cases received in neuropsychiatric hospitals during the war and those of the present day, we find a considerable difference.

At Hospital No. 30, Plattsburgh Barracks, N. Y., during the latter part of the war, there was a constant influx of neuropsychiatric patients. The etiological factor in 50 per cent. or 60 per cent. of these disorders was of a physical nature due to: (1) Over-exertion; (2) insufficient sleep; (3) lack of proper nutrition; (4) fever, influenza, etc.; (5) infections following wounds; (6) injuries; (7) dysentery. The remaining cases were distributed among the following groups: (1) The constitutional inferior type; (2) cases of unstable personality; (3) cases with epileptoid seizures; (4) with sexual perversion; and (5) the mental defectives and degenerates.

In order to secure data on these patients, a Social Service Department was established and through it information was obtained from the patients' parents, their former employers, the school, church and Red Cross or Social Service in their community. After careful observation, together with the above reports and their army records, we were able to make a fairly intelligent classification of the cases and this was always done as quickly as possible after admission.

There was a marked difference in the general attitude of the two groups. Those of the first one were all eager for discharge, did not wish a diagnosis of psychoneurosis attached to their records, readily complied with requirements, took up work in the Vocational Department, and showed a definite interest in arrangements for future work on the outside and seemed eager for responsibility, for instance:

Case of A. P.—Age 23; enlisted in January, 1918; former occupation, clerk. Was in camp on this side for three months; during most of this time did clerical work, consequently received but little exercise. Arrived overseas, and immediately went under intensive training. After five weeks orders came to move to the front. While at the telephone, repeating orders, he dropped to the floor in an unconscious condition. As far as could be ascertained there was no convulsive seizure. He was sent to a hospital and was unable to join his company. After a period of three weeks he was discharged back to the outfit at the front. During the following seven weeks he was under fire continuously, lost considerable sleep, and received food and water irregularly. One morning, while waiting to go "over the top," he dropped in an attack similar to the previous one. Was returned to the hospital and had several similar attacks during a period of two months.

He was discharged to a rest camp, and after remaining there a few weeks was again ordered to the front. The evening before departure, while at a moving picture show, he had another fainting attack, remained unconscious several minutes, did not injure himself, and from reports this attack did not resemble a typical epileptiform seizure. Shortly after this the patient was evacuated back to the United States under the diagnosis of psychoneurosis hysteria. This was the last

*Read before the Washington Society for Nervous and Mental Diseases, Thursday, November 17, 1921.

attack up to date of discharge from army and for several months subsequently.

After this I lost track of him. While at Plattsburgh his fatigability disappeared, appetite returned and he gained weight, took up work at vocation school, and after several months was discharged as recovered with no disability.

Those in the second group were more unstable and difficult to treat, were more self-centered, usually complaining about their condition, complaining of no treatment, the food, and the hospital conditions in general. They were more interested in the origin, symptoms, and mechanism of the disease than the cure.

Case of A. F.—Age 25. The patient quit school at the age of 15, after finishing the grades. Obtained a position, worked about eight months, changed to another place and remained there about a week; quit and tried another position. He continued to jump from place to place until finally he secured an easy position working in a "movie" house. Remained here until he was drafted in the army. Arrived in Camp Jackson, S. C., on August 3, 1918. Received typhoid inoculation on the 5th of August, and immediately went to the hospital. Remained there three days and was returned to duty. He states he was in bad condition. He refused to work, claiming it was too hot and that he couldn't stand the heat. They then transferred him to the motor school. He got along fairly well here until cold weather set in. Then he stated it was too cold to work. He had been working with some heavy trucks and he claimed this had caused hemorrhoids. He was then put on light duty driving a touring car. Was finally discharged February 13, 1919. Returned home and in three days claimed he had considerable trouble with his hemorrhoids.

In a recent survey of 520 cases at the National Sanatorium in Marion, Ind., I found approximately 85 per cent. were of the second type. They lacked ambition, were indifferent and discontented, complained about everything, and showed absolutely no respect for rules or regulations. A few of these patients had made a complete circuit of every Government hospital in the United States and a large percentage had made eight to ten of them, while very few showed this to be their first admission since discharge. Several of the patients admitted they would try out a hospital for a while, then request their discharge, claiming their home address wherever they wished to go and thereby receive transportation. As a rule, very little thought was ever given by these patients as to the cure of their disease; the question uppermost in their minds usually was, "Is it total permanent disability?"

The compensation question is the predominant factor in this group. It seems to be the understanding of the public in general that all ex-service men are entitled to compensation on entering a hospital. But a most undesirable effect is produced on this type of men by the condition under which compensation is granted—an effect which is at once evident. I do not wish to convey the idea that there is a definite type of this compensation neurosis but rather there is a condition which occurs in the individual with a fundamental psychopathic make-up, whose adjustments have always been made with more or less difficulty, in both the social and industrial world.

Case of W. W.—Age 31; occupation, coal miner. Entered with a diagnosis of Ménière's disease; apparently got along fairly well before he was drafted in the service June 30, 1917; developed influenza in September, 1918; was ill for five weeks. After his discharge from the hospital he got along fairly well for about a year. One morning while standing at attention during reveille the patient fainted. States he had a pain underneath the skin portion of the left ear, over the mastoid process. This spell lasted about ten minutes. He knew everything that was going on; vomited afterward. At this time did not have a ringing in his ear. Has not had a spell like this since, and does not worry about not having another attack. States that at one time the left side of his body was completely without feeling. On physical examination a tender area back of left ear about the size of a quarter was found. Denied ever having had pain in the ear. There was a bluntness of sensation on the left side, ending at the median line. Has complete pharyngeal anesthesia; could not distinguish degrees of heat or cold on the left side. Astereognostic sense was dulled, also on the left side.

After several careful examination and close observation, this patient was called into the office and informed that in the opinion of the staff he was not suffering from Ménière's disease and that it would be possible for him to take up Section II training of the Vocational Board.

He became greatly agitated and indignant, informing me that the staff did not know what they were talking about, as some thirty or forty physicians, all specialists, had told him he was suffering from a very rare disease, seldom being found in any person.

The patient was very eager to retain this diagnosis because when he told people on the outside that he was suffering from a very rare disease it made him the center of attraction. Also it puzzled the physician and consequently his stay in the hospital was indefinite.

The majority of these men should really not be hospitalized. Because of existing regulations, backed up by public sentiment, they are all sent to institutions. However, this being the case, when they are once in the hospital every effort should be made to work up their cases, to treat them and put them in training and to discharge them as quickly as possible. Patients should never be given the opportunity to acquire the habit of living in an institution.

The following plan is suggested for management and treatment:

Management and Treatment.—(1) Discipline, (2) segregation, and (3) atmosphere.

1. *Discipline:* First, before any attempt is made to treat these cases, discipline should be maintained—not strict military discipline or discipline with the idea of punishment, but control through a sense of loyalty.

2. *Segregation:* In order to obtain the maximum therapeutic results, a careful separation into groups should be made as follows: (*a*) Admission Service: This service should not include treatment of any kind but should be merely a service where the patient's history is taken; a complete physical, neurological, laboratory, and dental examination worked up, and a tentative diagnosis made for the purpose of transferring him to the proper group.

The attitude of the patient is formed on this service; therefore, it is imperative that he obtain an optimistic viewpoint of the institution. No patient should remain on the admission service longer than two weeks, because (1) usually after this length of time he begins to spread propaganda to the incoming cases; (2) it is necessary to enter upon therapeutic measures as quickly as possible; (3) one must impress upon the patients that the hospital is not a permanent home, but a place for treatment,

and that it will not be necessary for them to remain over a long period of time.

(*b*) Thereapeutic Service: Immediately upon the patient's arrival in this service, an individual treatment card should be issued, which will keep him occupied each hour of the day. The outline prescribed should include rest, light work, exercise, electrotherapy, hydrotherapy, psychotherapy, and occupational therapy.

All acute conditions should be cleared up.

Keep him busy and watch his work in the occupational class carefully. If any initiative or ambition for work has been shown at the end of two weeks, transfer him to the vocational service; if, on the other hand, he is not cooperating and it appears that he may remain over a period of three months, transfer him to the chronic service. These men are very suggestible; therefore, to give those who are making an honest effort to adjust an opportunity to do so, it is necessary to be very careful of their surroundings. For instance, on a ten-bed ward was a patient with hysteria who stammered, and along with this he was the ward "clown." Within ten days three other men were stammering. One was a neurological case with a shrapnel wound on the right side of his head on the upper half of the parietal bone which caused a partial hemiplegia of the left side. The second was a toxic goiter case. The third was a veterinary surgeon who was suffering from an anxiety neurosis.

The patient with hysteria has made a good recovery, does not stammer any more, and is out in training; the other three still stammer.

(*c*) Vocational Training: Here the patient has no more rest hours during the day; the dormitories are kept locked. Immediately make an effort to impress him with the fact that his stay in the hospital is very short.

Individual attention, close observation, and encouragement are necessary to obtain the best results in vocational work. The idea must prevail that this work is for the individual benefit of patients. If it is impossible for the hospital to furnish the training an individual desires, work may be taken up that will have a close relation to his desired ambition. A patient who is capable of working six hours a day over a period of two to three months is ready for discharge to the Federal Board for Vocational Training.

(*d*) Chronic Service: This service, as you have noticed, is the "dumping ground" for the whole institution. Various industrial shops should be established, dairy and agricultural projects. Put all men to work who are able. Keep them separated from the acute cases.

3. *Atmosphere:* "Cure" should be the keynote, the constant topic of lectures to the nurses, attendants, and patients.

Each man should be impressed immediately upon admission that his case is curable or he would not have been sent to this institution.

Also establish a universal conception that the institution is not a permanent home for anyone.

Summary.—1. We are dealing with a nervous condition among ex-service men which is the psychoneurosis of prewar times, plus a "compensation" factor, plus public opinion.

2. By far the majority of neuropsychiatric patients today have a predisposed neurotic background; while immediately after the signing of the armistice over 50 per cent were due to a physical cause.

3. Strict discipline, together with close cooperation of nurses and attendants, is indispensable for success in treatment.

4. Segregation is essential to obtain maximum results.

5. Hospitalization is not advisable in a great many of these cases.

6. When they are hospitalized, they should not be retained over a long period of time, but should be discharged to vocational centers.

THE EXTERNAL USE OF DIATHERMY IN CASES OF IMPACTED URINARY CALCULI.

By RALPH L. DOURMASHKIN, M.D.,

NEW YORK.

ASSISTANT UROLOGIST, BETH ISRAEL HOSPITAL, O. P. D.

VARIOUS operative and mechanical procedures have been resorted to in cases of impacted urinary calculi. The following cases I believe are worthy of reporting because of the use of diathermy, other than by the cystoscopic route, in facilitating their expulsion.

CASE I.—K. C., male, painter by occupation, age thirty-six, referred by Dr. A. S. Berow of Brooklyn. Was operated upon for psoas abscess twenty years ago—otherwise always enjoyed good health. Married fifteen years—never had any children. Venereal disease denied by name and symptoms.

The present illness dates back to six months ago, when the patient was operated upon for inguinal hernia. The operation was followed by some acute pulmonary condition, which subsided in the course of five to six weeks. He then began to complain of a dull ache in the left lumber region, burning at the end of urination, increased frequency and urgency of urination, and nocturia. The urine was very cloudy and patient was told it contained pus. The radiological examination of his urinary tract failed to reveal the presence of any calculi at that time. The subjective symptoms gradually diminished in severity until, on the day prior to seeing me, the patient was suddenly unable to empty his bladder completely, voiding but a few drops of urine every ten or fifteen minutes. Urination was accompanied by agonizing burning, but there were no colicky pains. Rectal examination disclosed a slightly enlarged prostate gland. Repeated attempts to catheterize the bladder resulted in failure. Even a filiform bougie met an insurmountable obstruction. Whatever urine the patient was able to dribble out was very turbid and contained a heavy trace of albumin. A microscopical examination revealed numerous pus cells and a few tubercle bacilli. Curiously enough, no red blood cells were found. Codeine and belladonna were administered with no relief of the symptoms. Another attempt on the following day to pass a filiform bougie was unsuccessful.

In the belief that the underlying process was a tuberculous lesion in the neck of the bladder, it was decided to resort to diathermy by employing the rectal electrode commonly used by urologists in conjunction with prostatic massages. The dosage was 750 ma., the patient being exposed for fully half an hour.

Immediately upon leaving the consultation room the patient was seized with excruciating pains in the rectal region, shooting down the body of the penis. There was a slight hematuria. The following day, on rectal examination, a very hard, round nodule, the size of a small dried-up cherry, was palpated in the region of the prostatic urethra. The filiform bougie encountered a very distinct, grating resistance.

It was evident that the patient had a calculus block-

ing the posterior urethra. Encouraged by the effect the D'Arsonval current had upon the passage of the stone along the urinary canal, he was given another similar treatment. The patient was seen again six days later and the nodule was found to be in the same place. The dosage was increased to 900 ma., and the length of exposure to forty-five minutes. Immediately following the exposure he began to experience acute pains in the rectum, accompanied by hematuria. The nodule could now be definitely palpated along the course of the anterior urethra, near the penoscrotal junction. With the aid of an endoscope, after preliminary cocanization of the urethral canal, the stone was grasped by forceps and extracted. It was a uric acid calculus, somewhat oblong in shape, and having a rough mulberry-like surface, which would indicate its pelvic origin.

A few days later the patient developed an effusion in his right knee joint, undoubtedly tuberculous in nature. The subsequent cystoscopic examination revealed the characteristic tuberculous ulceration of the bladder in the region of the right ureteral orifice, which was retracted and presented a shelf-like appearance. The left ureteral orifice was surrounded by polypoid vegetations. The urine obtained from the right kidney was loaded with pus and contained a few tubercle bacilli. The urine from the left kidney contained a few white blood cells and no bacilli.

Case II.—B. W., male, shipping clerk by occupation, aged twenty-six, referred by Dr. H. Cohen. The patient was operated upon two years ago for a urinary calculus impacted in the right ureter, after an attempt to relieve the obstruction by cystoscopic manipulations had proved unsuccessful. Prior to the operation the patient was sick for nine months, the condition being mistaken for chronic appendicitis, until an *x*-ray examination revealed the true nature of his illness.

The present illness began three weeks ago. The onset was sudden, with severe agonizing pains in the left lumbar region, radiating down to the left iliac fossa and to the end of the penis, accompanied by vomiting, frequent and urgent urination, and dysuria. The attack lasted four hours, the patient voiding very little urine at a time. The radiological examination showed a shadow of about one-eighth of an inch in diameter in the left ureter, just above its junction with the bladder. Altogether the patient had had ten attacks of colicky pains, each one necessitating the administration of hypodermic injections of morphine. The patient was cystoscoped and a catheter was left in the left ureter for twenty minutes. He had three such treatments at weekly intervals, without any relief.

The patient came under my observation during his last attack, which was especially severe, lasting about three hours. Hypodermic injections of morphine were of no avail. He passed very small quantities of bloody urine, which, in addition, contained a few white blood cells and a moderate number of granular and hyalin casts. He was exposed to the D'Arsonval current by having two lead electrodes, five by six inches, placed one posteriorly over the left lumber region, the other anteriorly over the course of the lower portion of the left ureter. The dosage was 800 ma., and the length of exposure was forty minutes. While still on the table, the patient was suddenly relieved of pain. He spent a restful night, and the following day found him free from all his symptoms. He voided freely, without, however, passing the calculus. The urine was practically clear. On cystoscopic examination a small ragged, spiky calculus was seen almost lodged in the left ureteral orifice, which was edematous and congested. By means of cystoscopic forceps the stone was dislodged and came out with the distending fluid through the sheath of the cystoscope.

Case III.*—J. V. d. B., physician, age forty-two, married.

Previous History.—The patient had an attack of severe renal colic on the right side two years ago, but did not pass any stones at that time.

The present illness began suddenly with agonizing pain in the right lumbar region, radiating downward to the right iliac fossa and to glans penis, accompanied by nausea, vomiting and profound prostration. There was the usual increased frequency and burning on urination, and the urine contained albumin and numerous red blood cells. The radiological examination disclosed no shadows suggestive of urinary calculi. The attack lasted almost continuously for ten days with slight remissions and from four to five exacerbations each day, taxing the patient's endurance to the utmost and bringing about a state of complete physical and mental exhaustion. Numerous attempts to quiet the pain with morphine were fruitless. As much as one and one-half grains of the drug were given at a time. During this period the patient was cystoscoped four times and in each instance the finest filiform bougie encountered an impassable obstruction about eight cm. above the right ureterovesical junction.

The pain gradually subsided, but three weeks later the patient was again in the grip of his former torture, with pain, nausea, vomiting, and general prostration of no lesser severity. This time the patient was exposed to diathermy for fully one hour, 600 ma. of the current being used. This single exposure was followed by a state of complete relaxation and amelioration of all symptoms and on the following day the patient passed two ragged, spiky uric-acid calculi, each measuring about one-quarter of an inch in diameter.

Whether the use of diathermy actually aided the propulsion of the impacted calculi in these cases is, of course, problematic. One should be guarded against a coincidence. The brilliant results achieved by Buerger, who, in cases of urinary calculi impacted in the lower ureteral segments, dilates the ureteral orifices by using the D'Arsonval current in conjunction with olivary bougies, would indicate that diathermy either produces local tissue or circulatory changes which result in the removal of the obstruction, or acts directly on the unstriped muscle fibers. The exact nature of these changes is still obscure and requires further extensive study. At present, however, very little is known about it.

It may, however, be of interest to note in future the effect of diathermy, applied externally, in cases where impaction of urinary calculi is high up in the ureters or in the renal pelvis, and where the routine cystoscopic procedures fail to bring the desired results.

It must be added, that in cases associated with congenital stenosis of the ureteral orifices, or where the urinary calculi have attained a size which renders their passage a matter of mechanical impossibility, it is not conceivable that diathermy, however applied, could supplant such operative procedures as ureteral meatotomy, dilatation, ureterotomy, etc.

53 St. Mark's Place.

*The author wishes to express his appreciation to Dr. J. Van den Berg for his courtesy in permitting the report of his case in this article. Diathermy was used at his own suggestion.

Neosalvarsan by the Mouth.—A woman with syphilis took neosalvarsan internally, no reason being given for the act. She had syphilis of twenty-five years duration but the drug of which 1.8 gm. were ingested within six days did not apparently have any effect upon it. There was a short interval of colicky pain and diarrhea but no further symptons of arsenicism. The patient had been infested with the *oxyuris* and the complete disappearance of these worms from the stools was ascribed to the medicament.—*Schweizerische medizinische Wochenschrift.*

Intratracheal Injection of Antipneumococcus and Antistreptococcus Serum in Influenzal Bronchopneumonia.—A Barcelona practitioner made injections of these sera directly through the wall of the larynx into the trachea. In five cases with grave outlook defervescence soon followed. In eight others the prognosis had been better and the subjects would probably have recovered of themselves.—*Transactions of the Barcelona Society of Biology.*

THE CINCINNATI SOCIAL UNIT EXPERIMENT.

THE New York School of Social Work has recently published a pamphlet in which Mr. Courtenay Dinwiddie summarizes his experiences with the Cincinnati Social Unit. This unique and instructive social experiment was conducted for the purpose of demonstrating ways and means of arousing community responsibility and cooperation. The National Social Unit Organization selected as a suitable community for this experiment the Mohawk-Brighton District of Cincinnati, including a population of 15,000. The purpose has been to test the theory that the organization of a community, if it is to be democratic and effective, stimulating people most to meet their own needs, should be based upon the following principles: (1) The organization of the citizens of the community should be by sufficiently small primary units of population so that those living in each unit may have a general acquaintance with the problems, conditions, and personalities in that area, and so the elected representative of each primary unit may become, in the best sense of the word, a neighbor, familiar with the conditions and needs and responsive and responsible to the wishes of the other residents. (2) The organization of those who are serving the community because of special knowledge or skill, in a direct or an advisory capacity, should be with reference to units of population served, so that they may be more closely in touch with the representatives of the citizens and with the citizens themselves. (3) There should be an organic and coordinate working relationship between the representatives of the groups having special knowledge or skill for service to the community and the representatives of the residents.

No other part of the Mohawk-Brighton stands out more sharply than the "Block Worker" and the Citizens' Council, made up of the block representatives. The block worker is the representative of her own little block of neighbors. She is elected by the members of the Block Council, primarily as the spokesman of themselves and their neighbors in the affairs of the community. The block worker is a member of the Citizens Council, to voice the opinions of the residents of her block the link which brings the expert, nurse, physician, recreational worker, etc., and the average citizen into a real working relationship. Provision was made in the plans for committees of clergymen, physicians, nurses, business men, and other groups to cooperate with the Citizens' Council. In each of the services there were certain characteristics which distinguished the Unit methods from those usually followed elsewhere. For instance, the actual medical examination of the patients was conducted chiefly by physicians practising in the neighborhood. As a consequence the physicians were generally friendly rather than antagonistic, and such benefits as came from clinical experience, consultation, and study accrued to the whole medical group rather than to some medical expert brought into the district.

As a result of three years of community effort under this arrangement, and in spite of active political opposition, there is practically unanimous agreement among those who have made a study of the unit that it has increased the effectiveness of community service to an unprecedented extent, beyond what would be expected merely from the number of physicians, nurses, or other workers serving the district. It has made a generally recognized contribution to standards for nursing work and to the humanizing of the touch of the person who is serving the needs of his fellowmen. Facts that speak urgently in favor of the plan are the lowering of the sickness and death rate in this district over that of any other portion of the city. The educational value of the Unit has been what has impressed some observers, while no critic of the Unit has questioned the value of the genuine spirit of neighborliness that has been increasingly evident in the Mohawk-Brighton District. An outstanding feature of the experiment was that the people of Mohawk-Brighton have been more largely in control of community affairs than elsewhere, but not through mass action or through ill considered decisions as to policies which were ill understood; it has been the orderly process of a well informed group of citizens who have expressed their judgment through their representatives in a way that has greatly increased the value of community undertakings. The Unit plan is well worth studying as a distinctly progressive move in social organization for community betterment.

NUCLEINIC ACID AND ITS USES.

THE nucleinic acids are constituted by an atomic complexus as yet incompletely known, and are found in the viscera in the form of nucleins or pure nucleinic acids. They contain large amounts of phosphoric acid, purine and pyrimidine bases, and frequently carbohydrates. Vernoux has shown that there exist a large number of pure nucleinic acids which differ in their physiological action and chemical make-up. Neumann, studying the nucleinic acids of the thymus, distinguished two varieties which he considered isomeric, but Kostytschew thinks that these acids

are impure and he in turn extracted two new acids: nucleinic acid alpha, a white powder insoluble in cold water, slightly so in hot water; nucleinic acid beta, a red powder giving a red solution in hot water which becomes colorless by the addition of an alkali. These acids are not isomeric. Leprince believes that there is but a single acid, and Schmiedberg has given the formula: $C_{40}H_{56}N_{14}O_{16}2PO_3$. It is an organo-chemical substance constituting each cell nucleus and when combined with protein forms the nucleins. The experiments of Ascoli have shown that it is impossible to find a body richer in assimilable phosphorus than nucleinic acid; it contains 9.63 per cent. According to Paul and His this acid is an energetic solvent of uric acid, therefore it has been proposed as a remedy for gout, and we now understand why arthritics who eat sweetbreads increase the percentage of their uric acid, the thymus being an organ richest in nucleinic acid. In a work on the intraorganic changes, Loewi showed that the ingestion of calf's thymus decreased the elimination of urea and he maintains that it is nucleinic acid which constitutes the primordial element of the protoplasma on account of its content of organic phosphorus. Protagon, the lecithins, neurine spermine, choline, etc. are merely products of disassimilation. Nucleinic acid remains in the cells—especially of the liver—as a reserve, similar to glycogen, thanks to which the albumin from the food is retained, assimilated, and economized. Loewi's experiments on himself also showed that, when ingested, nucleinic acid is absorbed and fixed in the tissues without decomposition, the body therefore utilizing it directly. Consequently, it is the typical economical food-stuff.

Since Müller's experiments, it is known in what great amount nitrogen and organic phosphates are eliminated by animals in a state of inanition and that nucleinic acid can prevent this elimination. Briefly, Loewi's conclusions may be given as follows: perfect absorption of nitrogen and phosphorus introduced into the body in the form of nucleins; retention of these three bodies deposited in the tissues; a considerable increase in the elimination of uric waste products derived from the food. The nucleins are readily obtained by placing nucleinic acid in the presence of the oxide of the metal that is to be added; thus the nucleates of sodium copper, lead, silver, mercury, and iron are produced, and Vergnoux has been able to obtain complex compounds with arsenic, namely, calcium nuclearsynate.

From all the properties enumerated the therapeutic use of nucleinic acid is clear. Its very constitution, easy assimilation and above all its richness in phosphorus explain its potency as a reconstituting agent. It has been especially successful in febrile tuberculosis, the adynamic form of pneumonia, and in serious cases of typhoid fever.

Experimentally, Vergnoux inoculated seventeen guinea-pigs with a homogeneous culture of the tubercle bacillus, and obtained the following results: The control animals died within six weeks after inoculation, while the other animals were fed with a daily dose of ten centigrams of pure nucleinic acid. These animals lived from one to two months after the death of the control animals. Another lot of animals were tested with the nucleinate of iron and one lived three months longer than the control animals. A fourth lot was treated with nuclearsynate of calcium, others with calcium nucleinate, and these survived the control animals five to six months. Soon after the injection of Koch's bacillus Vergnoux noted a phase of hypoleucocytosis, followed by an abundant afflux of polynuclears accompanied by large mononuclears with bilobate nuclei, powerfully toxicophagic. Finally, nucleinic acid is a powerful leucopoietic agent. The drug can be given intravenously, subcutaneously, or by mouth, but when given by the latter route the leucocytogenous effects are attenuated.

THE DIETETIC TREATMENT OF DIABETES.

THE subject of the fasting treatment of diabetes is still somewhat in the air, as to its evolution, definition, rationale, and permanent benefit. It is not uncommon to read an article in which some one of our founders of this treatment is ignored outright and such a one has appeared in *La Presse Médicale* for December 10, 1921, xxix, 99, in which there is only the barest mention of the Frenchman Guelpa, although the author, Cheinisse, is himself French. In certain American essays the name of Allen has been suppressed. A recent comment in the *Lancet* seems to imply that the French internists, despite the pioneer work of Guelpa, are not in touch with the advances in dietetics in Anglo-American literature. Probably the war was an important element in upsetting the solidarity of international *rapprochement* in this, as in other matters. So far as the introduction of fasting days into the dietetic treatment of diabetes is concerned, this goes back to Cantani in 1870. Then at intervals the idea was developed by Naynyn and later by von Noorden, while Guelpa elaborated it still further. The merit of Allen, the American, lay in his experimental work. Any struggles for national precedence and priority had better be suspected, however, until the treatment can be shown to be truly curative of the disease.

Of recent writers Rathéry regards hunger cures as inferior to the merely strict diet of Bouchardat, whose name was once almost synonymous with the dietetic management of the disease, and the opinion has been sustained by the more recent statements of von Noorden. Attention is called to the fact that the Allen treatment is not a fasting regimen at all, for aside from the short fasts the aim is to get the patient as soon as possible on a normal diet. Labbé looks on the fasts as intended to abort acidosis but not to cure diabetes. Bouchardat said to

the diabetic, "eat as little as you can," and no fasting treatment could go further.

During the war Albu often saw German diabetics recover spontaneously under the short rations of the period, irrespective of the quality of the food. The latter was protein-poor and fat-poor and must have consisted chiefly of carbohydrates, although largely in the form of vegetables. The latter are well adapted for the management of diabetes because there is usually good tolerance for vegetable protein, and while the vegetables with low carbohydrates can be taken as they are, the content of those with high carbohydrate can be reduced materially by repeated cooking (as in the so-called thrice boiled vegetables). This cooking is otherwise undesirable for it deprives the food of its flavor and extracts its mineral matter and vitamines. It is therefore better to use vegetables like green peas and beans, with one boiling, in place of thrice-boiled articles of higher carbohydrate content. In addition to the good tolerance by the diabetic of oatmeal it has been learned that cereal wheat and barley foods are also well borne; so that at present we are faced by the paradox that the once banned cereals and vegetables are now the diabetic's mainstay, while the meats and fats which were allowed freely by Bouchardat are now tabooed. The explanation can only be that the ideal diet consists first of reduced quantity and second of special classes of foods which the diabetic in general is able to handle.

The Toxicity of Nicotine.

Nicotine, an alkaloid with $C_{10}H_{14}A^2$ as a formula, may form crystallizable salts witth acids. The percentage of nicotine in tobacco varies from 1.15 to 9. Snuff contains a goodly proportion of ammonia and acetic acid. The experiments of Claude Bernard with various toxic substances have shown that nicotine is a poison which, from the rapidity and intensity of its action, can be compared only with the most violent ones known, namely, prussic acid, atropine, and aconitine. No matter in what way nicotine enters the organism—hypodermically, ocular instillation, or intestinal absorption —one or two drops suffice to kill cats, rabbits, or dogs in a fulminating way. A horse is killed in a few minutes with eight drops. The general action of nicotine is that of a powerful stimulant of the brain and cord. The first symptoms noted are in the muscular system; convulsions, tremor, irregular contractions throughout the the body, ending in depression and paralysis. The cardiac beats are accelerated—paralysis of the pneumogastric—becoming irregular and ending in arrest when the heart itself is paralyzed. The blood pressure is raised and this phenomenon is frequently accompanied by intestinal tetanus and uterine contractions. The respiration, at first rapid, becomes very slow. Death results from paralysis of the bulb. The symptomatology of mild acute nicotine poisoning consists of headache and pallor, nausea, vomiting, epigastic pain, and diarrhea. The forehead and hands are covered with a cold perspiration; there is considerable weakness with muscular relaxation, general distress, tendency to syncope, weakness of sight, confusion of ideas, and decrease of the tactile sense. These symptoms usually disappear after the occurrence of several loose stools. It is to be pointed out that the statistical work carried out on the effects of tobacco among workers in cigar and cigarette factories shows that among the women employed tobacco has no untoward influence on pregnancy.

Simulation of Diphtheritic Croup by Tracheobronchial Adenopathy.

It sometimes happens in hospitals for contagious diseases that a child is admitted in a state of asphyxia with the diagnosis of probable diphtheritic croup. In such cases intubation or tracheotomy may be performed along with the injection of antidiphtheritic serum. It is justly urged that there is no time left for diagnosis and that every patient should be given the benefit of the doubt. In case the obstruction from whatever cause is above a certain level the operation gives relief, but it may be necessary to change the diagnosis from diphtheria to edema of the glottis or some other obstructive condition. In rare cases the operation of intubation or tracheotomy gives no relief and death occurs from suffocation as the result of compression of the trachea at a low level by some neoplasm. That tracheobronchial adenopathy can cause this confusion of diagnosis and resist any attempt to clear the air passages is apparent from a report of three cases by Tron in *Il Policlinico* for January 16, 1922, xxix, 3. All three cases ended fatally and autopsy revealed the presence of the lesions in question. In each an emergency intubation was performed on admission of the child (to the pediatric clinic of the University of Milan). In one history is mentioned the intravenous injection of serum. Only the failure of intubation to avert death by asphyxia led to the surmise of the true nature of the obstruction to breathing. There is no mention of tracheotomy following intubation. The fate of these children seems predetermined, for they as a rule are seen for the first time and autopsy shows a good general condition with the exception of the gland mass which compresses the trachea.

Diver's Paralysis.

This affection is very common on the Mediterranean coast where the business of diving has been carried on from time immemorial. A considerable modern literature has originated among medical men from Athens, Marseilles, Tunis, and other ports. A distinction must of course be made between ancient sponge fishers and modern armored divers. In an article by Lantieri of Lyons in the *Gazette des Hôpitaux* for December 31, 1921, xciv, 103, mention is made of cases of paralysis in the Greek sponge fishers who work along the Tunis coast. One case ended fatally in a man of 58 who had been diving at a depth of 30 meters and who was $1\frac{1}{2}$ minutes in coming up. He was almost immediately seized with severe pains in the legs and two hours later showed paraplegia with persistent incontinence of urine. He died comatose 5 days

after admission. In another fatal case in a diver, aged 48, the depth was 26 meters. The ascent was slow and 15 minutes later pain of severe character appeared in the abdomen followed by paraplegia and urinary retention. Death took place on the 13th day after admission. Both these men developed huge sacral bedsores. Autopsy threw no light on the mechanism of these deaths. There was no increased tension of the cerebrospinal fluid. In patients who recover there is a history of paraplegia which may be flaccid or spasmodic, temporary or persistent. In order to prevent these accidents the depth should not exceed 25 meters, the duration under water should not exceed 30 minutes, and ascent should consume from a minute to a minute and a half in order to avoid too sudden decompression.

News of the Week.

Typhus Epidemic at Minsk.—According to a report just received by the American Relief Association, conditions at Minsk are shocking. Refugees are pouring into the city at the rate of 3000 a week, and typhus is increasing at the rate of 600 cases weekly. Medical stores are almost wholly lacking and 90 per cent. of the physicians and medical personnel are sick. The majority of refugees suffering from typhus are taken to makeshift hospitals, where the mortality is 50 per cent.

Leprosy Still a Public Health Problem in the United States.—Surgeon General Cumming of the United States Public Health Service states that leprosy, though comparatively rare in the continental United States, is still a public health problem. In the past we have not escaped. In 1786 leprous beggars were so common in New Orleans that they had to be segregated in a leprosarium. In 1864 three per cent. of the population of the Hawaiian Islands were lepers. In 1890 California had to establish a leprosarium, and Louisiana and finally Massachusetts followed suit. In 1902 the Public Health Service found 278 lepers in the United States, 145 of whom had been born in this country, and only 73 of whom were under any restraint. To-day, according to the best estimate obtainable, there are from 500 to 1500 lepers in this country, a number of whom are known to have acquired the disease in the Philippines. Foci of the disease exist in the United States on the Pacific Coast, in the Northwest, in the Gulf States, and along the Atlantic seaboard. The law provides that for three years after admission, any alien leper may be deported if the cause of the disease existed before he came to the United States. Within the United States lepers may not travel in interstate commerce except under permits prescribing special precaution to prevent the spread of the disease.

Influenza Declines in New York.—According to the Health Department's records the prevalence of influenza is now but slightly above the normal for this season of the year. Many of the deaths from pneumonia, especially among children, may be attributed to measles which is now quite prevalent in certain districts of the Greater City.

Epidemic Jaundice. — During the past few months a type of jaundice which is communicable has been reported with increasing frequency to the Health Department. The disease has also been reported frequently in recent months from other parts of the State. This disease is not a new one as some reports would indicate. Pediatricians have from time to time observed the disease and have recorded their observations in the literature. As the disease appears to be more prevalent than usual the Health Department requests physicians attached to hospital service, as well as those who have treated cases in private practice, to cooperate with the Department of Health in ascertaining more fully the facts with reference to this disease, by reporting any cases that may come under their notice during the last two or three months, and submitting such important facts in the clinical history as it may be practicable for them to give.

Smallpox in New York.—The appearance of a case of smallpox in New York City has come to be regarded as an unusual occurrence. Recently three cases of this disease were reported to the Health Department within a few days. The victims were all negroes who had not been vaccinated.

Bureau of Census Reports Lower Death Rates.—The Department of Commerce, through the Bureau of the Census, has issued a statement showing deaths and death rates by age groups from different causes in 1910 and in 1920. In every age group the death rate was lower in 1920 than in 1910, the most pronounced change appearing in the rate for infants under one year of age, which declined from 13,084 per 100,000 in 1910 to 9660 per 100,000 in 1920, a decline of about 26 per cent. The death rate for old people above seventy-five years of age shows a decrease of about 6 per cent, being 13,490 per 100,000 in 1920, as against 14,360 per 100,000 in 1910. In 1910 the death rate for infants was almost as high as it was for old people above seventy-five years of age, but in 1920 the infantile death rate was only about three-fourths as great as the death rate in old age. Particularly noteworthy is the decrease from 2581 to 2280 per 100,000 population in the age group, forty-five to seventy-four, a decrease of 12 per cent., due largely to much lower rates from tuberculosis, acute nephritis and Bright's disease, organic diseases of the heart, accidents, and typhoid fever. The general death rate from tuberculosis has decreased in the decade from 160 per 100,000 population to 114. The rate from acute nephritis and Bright's disease has decreased from ninety-nine to eighty-nine. The rate from accidents has decreased from eighty-four to seventy-one, and the rate from typhoid fever from twenty-four to eight. On the other hand, increases in the rate from influenza, cancer and puerperal causes clearly show some of the danger spots.

State Health Department Opens Campaign Against Diphtheria.—The cities of Auburn, Schenectady, and Syracuse have been selected as strategic points for the beginning of a new and aggressive campaign against diphtheria which is now being conducted by the State Department of

Health in cooperation with local health and school officials, the American Red Cross, and other civic agencies. The campaign is being carried on largely through the application of the Schick test and the immunization with toxin-antitoxin of those found to be susceptible to the disease. At the department's request, Dr. Abraham Zingher of New York, under whose direction more than 100,000 school children have been "Schick-tested," is delivering addresses in a number of up-State cities at meetings arranged in cooperation with the local medical societies, health departments, school authorities, and civic associations in order to acquaint the public generally with the use of this method for the control of diphtheria. According to statistics recently analyzed by Dr. E. S. Godfrey, Director of the Division of Communicable Diseases of the State Department of Health, diphtheria in New York State, as in other parts of the country, has shown a marked increase in the number of cases and deaths during the last three years. Following the introduction of antitoxin in 1894, the drop in the mortality from diphtheria was sudden and startling. The death rate from this disease, which in 1887 was 113.2 per 100,000 of the population in New York State, fell as low as 14.8 in 1916. But the rate for 1919 took a sharp rise to 19.9, remaining at 18.2 in 1920, and fell only to 16.1 in 1921. New York City now has the lowest diphtheria rate, 15.5 per 100,000, that it has ever experienced, and the metropolitan district does not share in the recent increase indicated by the statistics for the State generally, a fact which bears witness to the value of the new method of controlling the disease. It is hoped that the results of the campaign in New York City and in the cities above mentioned will lead to a demand for similar campaigns in other large communities throughout the State.

Maternity Bill Repudiates Federal Interference.—Conforming to recommendations of Governor Miller, a Division of Maternity, Infancy and Child Hygiene will be established in the State Department of Health under terms of a bill introduced recently by Senator Frederick M. Davenport of Oneida. After many conferences the legislative leaders have decided not to accept Federal aid in maternity care, as provided in the Sheppard-Towner act of Congress. Governor Miller objected to the Sheppard-Towner act as undue interference by the Federal Government in State affairs. The bill calls for an appropriation of $100,000 for the establishment of a Division of Maternity and Child Hygiene in the State Department of Health. It further provides for holding health consultations for mothers and children in the rural districts in cooperation with local health officers and other physicians. It provides for instructing local health nurses in the hygiene of maternity and infancy. It makes available to mothers, through instruction by physicians, nurses and publications, information concerning the hygiene of maternity and infancy. It looks toward the prevention of blindness in infancy and the care and rehabilitation of crippled children not otherwise provided for.

New Jersey Law Will Require Doctor's Approval to Wed.—The Alexander bill, introduced into the New Jersey Legislature by Senator Case, requiring applicants for marriage licenses to submit to examination by a physician, was passed on Feb. 21 and sent to the Governor for his approval.

Post Office Establishes a Dispensary.—A dispensary for the employees of the New York Post Office has been established on the fourth floor of the central office, Eighth Avenue and Thirty-third Street, and will be in operation day and night, beginning to-day and to-morrow. It will care for the 3000 men and women who work there, and also for those in branch post offices. Col. E. K. Sprague has been placed in charge. The new dispensary will be conducted with the cooperation of the United States Public Health Service.

Rockefeller Gift for London School of Hygiene.—The Rockefeller Foundation has offered to provide $2,000,000 toward the cost of building and equipping a school of hygiene in London. This offer is on the understanding that the British Government shall accept the responsibility of providing for appointing the staff and maintaining the school when established.

Alabama May Change Health System.—Efforts will be made to change the health system of the State of Alabama at the next meeting of the legislature, according to current reports. Plans for a vigorous fight to take the health administration of the State out of the hands of the Medical Society are being made. The plan proposed is in favor of a board of health composed of five or seven men appointed by the governor, part of whom shall be business men and part physicians, their appointments to be ratified by the senate. This board, according to the proposed system, would elect the health officer, who would be responsible to the board for results.

Baltimore Department of Health Increases Staff.—Health Commissioner C. Hampson Jones has augmented the health staff in the Baltimore schools by the appointment of six male and two female physicians on the contract plan to examine children when their services are considered necessary. He has also appointed one colored dental surgeon. Eight dental clinics have been established under the Health Department and two more are to be fitted up.

Hospital Notes.—The International and Great Northern Employees' Hospital Association building, located at Palestine, Texas, is nearing completion. The cost of the new building is approximately $150,000.

Plans are being formulated for the erection of a new hospital at Excelsior Springs, Mo. There will be seventy-four rooms. A part of the hospital equipment will be a complete bathhouse.

The contract has been awarded for the construction of seven buildings of the Government hospital for disabled veterans of the World War, at Augusta, Ga. The contract calls for the completion of the buildings within seven months at a cost of $263,000.

Bonds to the amount of $200,000 have been issued for a $200,000 hospital for Oklahoma County, Okla. The site for the proposed hospital has not yet been selected.

The Alabama Baptist Hospital at Selma was dedicated on Feb. 14 with appropriate ceremonies. The

new hospital is a state-wide institution. The Baptist State Convention has contributed $250,000 and the city of Selma added $100,000 to defray the cost.

Los Angeles, Calif., is to have a new $3,000,000 hospital, to be known as the Los Angeles Polyclinic Hospital. It is being fostered by a number of local physicians and surgeons who form a nucleus of a representative hospital staff. The construction of the first unit of 300 beds will be started early next fall. The second or convalescent unit is planned for the spring of 1923, and other units will follow.

Contracts amounting to $229,117 have been awarded for a part of the work on the new receiving hospital addition to the Longview Hospital, Cincinnati, Ohio. A plea has been made for the erection of the new buildings upon ground adjoining the present General Hospital, or near the University of Cincinnati Medical College.

Dr. Henry H. Rusby, director of the Columbia University School of Pharmacy, who headed the Mulford Biological Exploration of the Amazon Basin, which left this country last autumn, is, we regret to learn, crippled by neuritis and otherwise broken in health. He is reported to have left his party and to be returning unaccompanied through 2000 miles of primitive wilderness to the port of Manaos, where he hopes to take ship for New York.

Dr. Victor A. Messenger of Easton, Pa., has announced his candidacy for the Republican nomination for Representative in Congress at the coming primaries.

Dr. R. J. Hutchinson has been elected chief of staff of the Butterworth Hospital, Grand Rapids, Mich.

Dr. Walter W. Palmer, Bard Professor of the Practice of Medicine at Columbia University, has been chosen a member of the Administrative Board of the Institute of Cancer Research to serve until June 30, 1924.

Dr. Horatio P. Williams has been selected as Dalton Professor of Physiology of the Columbia University School of Medicine. His new appointment becomes effective July 1, 1922.

The Italian Congress of Radiology will hold its fourth annual meeting in Bologna, May 9, 10, and 11, 1922, at the Orthopedic Institute Rizzoli, under the presidency of Professor Aristide Busi. In connection with the congress there will be an exhibition of radiological apparatus, in which both foreign and Italian firms are invited to participate. Further information may be obtained by applying to Dr. Alberto Possati, Villa Verde, Bologna.

Obituary Notes.—Dr. ADRIAN YOUNG REID of New York, a graduate of New York University Medical College in 1880, died at Pleasantville, N. Y., on February 18, at the age of 74 years. He was a member of the New York County Medical Society and the Physicians Mutual Aid Society.

Dr. WILLIAM G. HIER, a graduate of Pulte Medical College, Cincinnati, Ohio, in 1884, died at his home in Cincinnati on February 2, at the age of sixty-six years.

Dr. THOMAS ELLWOOD CONRAD died of heart disease at Philadelphia on February 13, at the age of seventy-three years. He was graduated from Jefferson Medical College in 1878. He was at one time surgeon to the First Regimental National Guard of Pennsylvania and later Major on the Medical Staff of the First Regiment Veteran Corps. He also served on the staff of the Wills Eye Hospital. He was a member of the Philadelphia County Medical Society and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. JOSEPH ROBERTS BRYAN died of pleurisy in the Misericordia Hospital at Philadelphia, February 14. He was graduated from the medical department of the University of Pennsylvania in the class of 1889. He was at one time physician to the Misericordia Hospital and to St. Vincent's Hospital. During the late war he served in the Volunteer Medical Corps.

Dr. CHARLES H. WALLACE died at Philadelphia on February 15 at the age of sixty-one years. He was graduated from the University of Pennsylvania School of Medicine in 1886. He was a member of the West Philadelphia Medical Association and of the Philadelphia Medical Club.

Dr. ROBERT WILLIAM FORSTER, a graduate of Tufts College Medical School, Boston, in 1900, and a member of the Lawrence General Hospital staff, died at his home in Lawrence, Mass., on February 8, at the age of forty-seven years.

Dr. NEWTON E. WEBB of Washington, D. C., a graduate of the National University Medical Department in 1901, died suddenly on February 9, at the age of fifty-six years.

Dr. FRED R. FARTHING of Boone, N. C., died on February 14, of pneumonia in St. Joseph's Hospital at Philadelphia where he was serving as interne. He was graduated from Jefferson Medical College in the class of 1921.

Dr. JOHN BERNARD VOOR of Louisville, Ky., Assistant Director of the American Red Cross Commission in Poland, died there on February 14 of typhus fever contracted while inspecting refugee camps at Baranew. He was graduated from the University of Louisville Medical Department in 1913, and was a Fellow of the American Medical Association. He was thirty years of age.

Dr. THEODORE FRICKENSTEIN, a retired physician of Brooklyn, N. Y., died at his home on February 22, at the age of eighty-seven years. He was graduated from the New York Medical College in 1864, and for thirty-five years was physician for the German Evangelical Lutheran Home.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

THE USE OF PITUITRIN IN OBSTETRICS.

To the Editor of the Medical Record:

Sir:—During the last ten years I have read in the various medical journals numerous and sundry articles for and against the use of pituitrin but have never taken the trouble to enter into the discussion. It was only when I read in the Medical Record of Jan. 7, 1922, an article by I. Josephson, M.D., in which he says that the one and only legitimate use for pituitrin is for post partum hemorrhage, that I decided to raise my voice in protest.

When I first began to use pituitrin in obstetrics I gave it in doses of one c.c. each as directed, and only to multiparæ who were nearing the end of labor. I soon discovered, however, that the resulting expulsive efforts were unnecessarily violent, so I gradually decreased the dose until now I never give more than two minims as an initial dose, and in some cases I begin with one minim or even one-half minim. Now I use pituitrin for primiparæ as well as for multiparæ and in the first, second, or third stage of labor, and for the induction of labor, and I have yet to see any evil results from its use.

Anyone can safely use pituitrin if he will get a tuberculin syringe so as to measure accurately the amount given and give a small enough dose. If one minim does not produce a reaction in fifteen minutes it will be safe to give a little larger dose. If the contractions become too strong or too frequent they can be promptly modified by a hypodermic injection of heroin or a few whiffs ether.

It is absurd to refuse to use a valuable therapeutic agent just because it has at some time been ignorantly and carelessly used.

Dr. Josephson deplores the fact that doctors sometimes give pituitrin to shorten labor in order that they may keep appointments with other patients. He apparently ignores the fact that by so doing the doctor not only increases his own usefulness but also shortens the period of suffering for the patient. There are three kinds of obstetricians. One kind stays away until he is told that the patient is about to be delivered or that she is absolutely exhausted and needs his help. Another kind conscientiously stays with the patient hours or days, if necessary, but has too much respect for nature to interfere in any way unless the patient's condition becomes serious. The third kind stays with the patient and does everything possible to shorten the labor and relieve the pain. Which would you choose if the patient belonged to you?

In my opinion a doctor who would let a woman suffer all day and then use forceps when a small dose of pituitrin would end her torture in half an hour should not have the opportunity to practise obstetrics.

Edith E. Johnson, M.D.

Palo Alto, Cal.

MANAGEMENT OF THE HERNIAL SAC.

To the Editor of the Medical Record:

Sir:—In a recent issue of the Medical Record was a very interesting article entitled "The Bladder Bogy," written by Dr. Alexander Nicoll. The author, while covering the point indicated in the title of the article, failed to speak of the proper methods of dealing with the sac in cases of indirect inguinal hernia. The sac should be dealt with intraperitoneally through a transverse separation of the fibers of the fascia of the internal oblique and transversalis muscles. The peritoneum should be incised above the internal ring, and at the same time it would be well to remove the appendix, whether normal or otherwise—it is usually "otherwise." This by way of parenthesis to give expression to a long held belief. After the sac has been freed it is to be inverted and pushed up into the peritoneal cavity and then dealt with either by ligature or by suture.

Dr. Nicoll refers to Ochsner's method of dealing with femoral hernia by complete removal of the sac and its fatty appendages. That plan of treatment has long been abandoned by many operators, including myself. The Ruggi method, introduced in 1892, and well described in Ashhurst's Surgery, deals with femoral hernia by the inguinal way of approach. Ashhurst gives that method the preference and I can heartily indorse it.

Richard H. Conway-Gibbons, M.D.

55 Park Avenue, New York.

A REGULAR FELLOW.

To the Editor of the Medical Record:

Sir:—In a letter to the Medical Record of this date, "A Fellow A. M. A." complains about the way the funds derived from the recently increased dues of the American Medical Association have been expended in getting out and in tabulating the result of the recent more or less questionable questionnaire. Unquestionably much of the force of this complaint is lost by the anonymous nature of its origin. "What is the use of being a fellow," it used to be said, "unless you're a h—— of a fellow?"

Does not this distinction attach to any Fellow of the American Medical Association who goes on record in opposition to the activities of the ruling powers of this organization, even if this opposition applies to such fundamental matters as the disposition of the common funds?

Another Fellow A. M. A.

New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Feb. 7, 1922.

The Pathological and Bacteriological Laboratory Assistants' Association.—As Professor Lorrain Smith said in 1912, those who are not familiar with the working of a pathological laboratory are apt to imagine that the duties of the assistant comprise little or nothing that demands skill or experience. This view is altogether mistaken, for not only does the laboratory assistant require a large amount of experience and skill, but he must be able to do a great deal that is not routine: he must have initiative and he must train himself to make observations. To be a laboratory assistant, at his best, a man must have not only original gifts of mind and character, but he must have experience and skill of a very high order. The proposal, therefore, to form an Association of the Pathological and Bacteriological Laboratory Assistants commended itself

to the Pathological Society of Great Britain, members of this society cooperating with the assistants in putting the proposal into shape. It may be stated that the movement in 1912 to establish the Association was not the first of its kind, as in 1896 Mr. McLean of the Clinical Research Association, London, when in University College, Birmingham, made an effort to found an association to embrace all laboratory assistants. Unfortunately the time was not then ripe for a movement on this scale, but the experience gained proved of great value in carrying out the preliminary arrangements. The originators of the movement to found the association were at first inclined to attempt the foundation of an association on similar lines to those of 1896, but on further consideration they thought it more desirable to start with one section, feeling that if the lesser movement proved successful, then the greater, viz., an association to include laboratory assistants in all branches of medicine, would be more easily accomplished. As mentioned before, the Pathological Society of Great Britain and Ireland, the members of which are to a large extent the employers, were in full sympathy with the movement, the success of which has been largely due to their earnest cooperation. The association was reconstituted in 1920 and its objects may be tabulated as follows: (1) To advance the interests of members. (2) To confer certificates of proficiency in pathological and bacteriological technic. (3) To keep a register of certificated pathological and bacteriological laboratory assistants. (4) To publish an official journal. (5) To form a library for the use of members. (6) To establish an employment bureau for the use of members. The association shall consist of: (1) Registered members, i.e., laboratory assistants who possess the association's certificate in pathological and on bacteriological laboratory and on museum technic. (2) Ordinary members, that is, laboratory assistants 21 years of age or over who have had three years' training in a recognized pathological or bacteriological laboratory, but do not possess the association's certificate in laboratory technic. (3) Junior or student members, that is, pathological and bacteriological laboratory assistants under 21 years of age, or with less than three years' experience. (4) Honorary members, that is, members of the medical and allied professions who are intimately connected with the sciences of pathology and bacteriology. (5) Associate members, that is, laboratory assistants in any recognized scientific laboratory other than those of pathology and bacteriology.

The examinations are controlled by an examining council constituted as follows: The president of the association; two members of the Pathological Society of Great Britain and Ireland; two registered members of the association. Candidates for examination must be 21 years of age, have had five years' experience, and have been a member of the association for six months. At the time of his death Sir German Sims Woodhead was president of the Association.

Lunacy Reform in Great Britain.—In consequence of severe criticisms launched against the management of lunatic asylums in this country and their publication in the lay press, the public has been greatly exercised in mind on the subject and have clamored for an inquiry. So great has been the movement for investigation that a conference was convened and about 200 medical superintendents of mental hospitals met at the London County Council offices to discuss the matter. Sir Alfred Mond, the Minister of Health, in opening the proceedings, said that he was glad to note that the term "asylum" had been dropped in favor of "mental hospitals." The public should be disabused of the idea that lunatics were people very largely incurable, for whom little could be done except custodial treatment. The adoption of modern methods of diagnosis and treatment would result in greater economy, and the more lunatics that could be cured the greater would be the relief in expenditure. Medical officers should be granted fuller facilities for post-graduate work, which was the only method of rapidly acquainting themselves with the subject of mental diseases. The public were still often imbued with the ideas in Charles Reade's novels; but the agitations got up in recent years were fictitious and untrue. He felt satisfied that all the kindness, care and good treatment possible were available in asylums under existing circumstances. It was unfair to brand the asylum service with any stigma, and the whole feeling of stigma in regard to lunacy should disappear. The public did not realize how many patients were cured and discharged from asylums and returned to their normal life as good citizens, and it was important that the cloud of hopelessness in these cases should be lifted. There appeared to be a unanimous opinion that permanent mental disease could be prevented by early treatment. If early treatment was to be given without certification, an alteration in the present law would be required, and any such alteration would be difficult to achieve unless there were a general agreement on the part of those competent to speak. With respect to the treatment of early incipient cases opinions differed somewhat. Alderman McTaggart and several others laid stress on the importance of keeping institutions into which it was proposed to admit patients without certification, entirely free from any reproach of insanity, and said that even visiting committees of asylums should have nothing to do with them, and that they should be wholly divorced from the existing mental hospitals. However, as the discussion proceeded it was generally admitted that some kind of supervision was necessary, and at last it was uanimously agreed that it was undesirable to establish two boards dealing with similar matters, and that it was quite for the best that the Board of Control should be the supervising body. Dr. H. C. Bond pointed out several difficulties, and asked whether it was intended that there should be any powers of detention over those patients who, after entering homes that might be established for persons suffering from temporary maladies, wished to leave before they were considered fit to do so. It was pointed out that there was nothing to prevent voluntary homes from being established now, but that the difficulties arose when persons were too confused in mind or too mentally disordered to be able to exercise volition. How long were such cases to be regarded as "early," and what, if any, limitation was to be placed upon their freedom of movement. The discussion elucidated some moot points consid-

erably, and finally a decision was reached urging the establishment of institutions for the treatment of early cases without certificates, with a rider recommending that such institutions should be under Government supervision, and that the body to exercise this supervision should be the Board of Control.

The Annual Congress of the Ophthalmological Society of the United Kingdom.—The next annual Congress of the Society will be held on May 11, 12 and 13, at the Royal Society of Medicine, 1 Wimpole Street, W.

Congress of the Royal Sanitary Institute.—The Royal Sanitary Institute will hold a Congress at Bournemouth on July 24-29, under the presidency of Major-General J. E. B. Seely, M.P. Conferences will be held on subjects relating to hygiene and sanitary science, and a health exhibition will be arranged in connection with the meeting.

Progress of Medical Science.

Boston Medical and Surgical Journal.

February 16, 1922, clxxxvi, 7.

1. Infections of the Biliary Passages. John T. Bottomley.
2. The Value of Medical Biliary Drainage for Diagnosis and Treatment of Diseases of the Gall-Bladder and Bile Ducts. Franklin W. White.
3. Clinical Notes on Hearts in Hyperthyroidism. Burton E. Hamilton.

2. The Value of Medical Biliary Drainage for Diagnosis and Treatment of Diseases of the Gall Bladder and Bile Ducts.—Franklin E. White records his experience in about 100 cases with the Meltzer-Lyon method of drainage of the bile passages by means of the duodenal tube and douching the duodenum with a magnesium sulphate solution. He thinks the early papers on this subject seem overenthusiastic and dogmatic, and say too little about the limitations and difficulties of this method. It is somewhat elaborate and time-consuming, but can be carried out on nine-tenths of the patients chosen for examination. In spite of its limitations the method has proved useful and sometimes very useful in diagnosis. It helps to show whether the ducts are open or closed. If no dark or "B" bile is obtained on repeated drainage, properly performed, we may suspect cystic duct obstruction, frequently with gallstones. If no bile is obtained with a proper drainage, but pancreatic ferments or blood are found, common duct obstruction is present, frequently malignant. Cholecystitis and cholangitis cases, unless marked obstruction exists, usually give a bile which is abnormal in color, appearance, cells, mucus, and bacteria. Gall-bladder sand may aid in the diagnosis of gallstones, but, in general, the drainage in gallstone cases was not characteristic. In treatment White thinks we cannot be sure at present how completely this method empties the biliary passages in all cases, but in many it appears to do this very well. The best field for its use is in the milder and moderate grade of cholecystitis and choledochitis cases, where no marked obstruction exists. Many such cases are apparently relieved, or apparently cured, following this treatment. It is obviously unsuited for treatment of acute, virulent infections of the gall bladder, acute or chronic empyema, gangrenous cholecystitis or cases with known stones or tumor, or severe chronic obstructive cases which will not drain. It may be occasionally useful in some of these cases when surgery is contraindicated, as in old people, or in cardiac, renal or diabetic patients.

3. Clinical Notes on Hearts in Hyperthyroidism.—Burton E. Hamilton, on the basis of personal examinations of over 200 hearts in hyperthyroidism in the clinic of Dr. Frank H. Lahey, finds that the great majority of hearts in cases of hyperthyroidism are found with no evidence of damage. Heart failure is not found in this class of cases, even where death occurs. Hyperthyroidism in the presence of (a) rheumatic heart disease, and (b) middle age (over forty-five years), has a tendency to cause established or paroxysmal auricular fibrillation. Many cases of hyperthyroidism showing auricular fibrillation without true signs of heart failure have stood operation well. All auricular fibrillation cases with hyperthyroidism can be improved by digitalization. Digitalis reduces the ventricular rate in all the fibrillators. It is suggested that digitalization has a favorable influence on the cure of auricular fibrillation in hyperthyroidism. Another inference is that digitalization does not materially lower the heart rate in hyperthyroidism cases that do not have auricular fibrillation.

1. Discussion of Angina Pectoris.—Clifford Allbutt reiterates his hypothesis that in angina pectoris the lesion is not primarily cardiac, but in the large majority of cases aortic; and that death is due not to heart failure implicit in the disease, but to a secondary inhibition set up by the pain, or kindred afferent influence; an inhibition the more effectual the worse the condition of the myocardium. Thus the prognosis as to survival is far better in the younger subjects of aortitis—so long as the coronary vessels are patent—than in the elderly in whom the heart is impaired. A number of authors who have objected to this theory are dealt with incidentally and attention is directed to recent observations on the causes of angina. Evidence is accumulating of the acute infectious origin of aortitis. Syphilitic infection has long been recognized as a cause; now reports of cases of aortitis following influenza and in rheumatic fever and many other infections are coming in. Notwithstanding all this angina may be of cardiac origin, but this happens only when its investments are inflamed or stretched, as in pericarditis or coronary thrombosis. In cases of aortic angina the pulse is, on the whole, indifferent; in case of coronary thrombosis the pulse has been thrown into great disorder, so much so as to aid in the differential diagnosis of this accident from ordinary angina. Other diagnostic points are: Pain no less severe, but more diffuse and continuous and more about the region of the heart (not so distinctly substernal); restlessness, dyspnea, and frequently palpable dilatation of the heart and audible pericardial friction. Dyspnea, if present, means not angina, but, if the case be one of angina at all, then some complication of it. The characteristic pain in angina is substernal, not precordial. Aches and oppressions about the cardiac area suggest rather disease of the heart itself. Where presumably the aorta is not much degenerated or not so profoundly altered, an angina due mainly to excessive pressures may subside as these are moderated. In the treatment of angina the author says there is not much that is new. He alludes to Jonnesco's operation for the relief of angina by the division of the left sympathetic in the neck. Jonnesco reports two cases in which this procedure has been successful. Time and larger experience are necessary before any opinion on this method can be pronounced. It is pointed out, however, that Jonnesco assumes the origin of the pain to be in the chronically inflamed investment of the aorta, and proceeds therefore to cut the path of transmission to the cord and encephalon.

4. The Facies in Mitral Stenosis and Aortic Regurgitation.—Sydney Russell-Wells points out that not infrequently the different appearances presented by

mitral stenotics and aortic regurgitants are so marked and characteristic that a provisional diagnosis suggests itself by the appearance alone. There is marked cyanosis in the cases of mitral stenosis, while, on the other hand, cases of aortic regurgitation show no cyanosis. To explain this difference the writer develops the theory that in mitral stenosis the blood as a whole is more venous than normal and tends to accumulate in the systemic venules, and the circulation tends to slow down, while in aortic regurgitation the blood as a whole is more arterial than normal and tends to accumulate in the systemic arteries and the circulation tends to quicken.

6. Premature Contraction and Its Significance.—J. Strickland-Goodall, on the basis of observations carried out over ten years on 13,231 cases, summarizes his views as follows: (A) Extrasystoles indicate hyperirritability of the myocardium. (B) Hyperirritability of the myocardium is produced by either extrinsic or intrinsic causes, the latter being by far the most important. (C) Hyperirritability represents a definite stage in the physiological process of fatigue and the pathological conditions of inflammation, degeneration, and toxemia, hence extrasystoles are indications or manifestations of such conditions. (D) Extrasystoles are important according to: (a) The nature of the underlying condition. (b) The amount of intravascular strain and amount of circulatory disorganization they produce. (E) Auricular extrasystoles are practically always intrinsic in origin and usually indicate definite damage to the auricular myocardium. They often precede flutter and fibrillation and give rise to paroxysmal tachycardia. (F) Right ventricular extrasystoles are often extrinsic in origin and due to pressure, but they may be intrinsic, when they usually indicate right heart strain or exhaustion. (G) Left ventricular extrasystoles often indicate left ventricular fatigue and precede failure, especially in aortics. (H) Extrasystoles of any type in complete heart block seriously disorganize and embarrass the circulation and must always be regarded as serious.

2. The Diagnostic Value of Volume Ratio Determinations of Day and Night Urine.—Harold W. Jones has carried out investigations for the purpose of determining the normal ratio between day and night urine, and to demonstrate departures from this normal in nephritis. He finds that the normal ratio of day to night urine is 1:¼ or 1:⅓, occasionally 1:½. The ingestion of large amounts of fluid does not materially alter the ratio, or the value of the test. On a low fluid intake, with a total output of 500 c.c. or less, the volumes are nearly equal, and the ratio is of less significance. In chronic contracted kidney the normal ratio is often reversed, i.e. the night urine is greater in amount than the day. Frequently the night and day urines are nearly equal. In nephritis the ingestion of a large amount of fluid does not alter the ratio to any marked degree. In chronic parenchymatous nephritis, if the output is small, the ratio determination has less value. On a protein-free diet, with clinical improvement, the normal ratio is reestablished in many cases. The determination of the volume ratio of the night to day urine in the two hour specific gravity fixation test is a more reliable index than the measurement of the night volume alone. The determination of the ratio is of value in differentiating between nocturnal polyuria and nocturnal frequency. In normal persons who work at night the ratio of the work period to the rest period remains unaltered, the work period volume being three to four times that of the rest period. In patients with chronic nephritis, who work at night, the volume of the day or rest period is greater or equal to that of the night or work period. The alteration of the normal ratio is one of the earliest signs of functional impairment of the kidney.

3. Hematogenous Staphylococcus Infections Secondary to Foci in the Skin.—D. B. Phemister calls attention to the fact that while much interest has been shown in this country during recent years in foci of infection, from which microorganisms gain entrance into the circulation and produce remote lesions in various locations, it has been directed chiefly to the streptococcus. The portal of entry of the staphylococcus has not received proportionate attention, but there has been a growing tendency to consider it also as the nasopharynx or mouth in nearly all cases, to the neglect of consideration of other regions as possible portals of entry, of which there is no better example than the skin. It is an old observation that staphylococci not infrequently enter the blood stream from skin foci and produce inflammation in various structures of the body. This is illustrated by a group of cases coming under the writer's observation in the course of twenty-months previous to September, 1921. This group of cases included eight of osteomyelitis, two of multiple renal abscesses, three of perinephritic abscess, four of myositis, and two of arthritis. There is evidence in favor of the view that certain strains of staphylococci, regardless of their virulence or portal of entry, possess special power for attacking certain tissues. Lesions of the nose and accessory nasal sinuses are probably an important source of hematogenous staphylococcus infections. There is as yet little proof that chronic staphylococcus infections in the teeth and tonsils are both the source of and responsible for the continuance of hematogenous lesions as chronic osteomyelitis. It is contended by Roth and others that the staphylococcus may penetrate the intact skin without producing a local lesion.

4. A Dietary Consideration of Eczema in Younger Children.—Edward Scott O'Keefe asserts that while fats and carbohydrates have claimed attention as factors in the etiology of eczema, the proteins have escaped suspicion. Among 131 cases of eczema in breast fed babies he has found forty-five, or 35 per cent., showing sensitization to one or more of the common food proteins. This is in striking contrast to the percentage of protein sensitization in normal children, in whom Baker reports the incidence of protein sensitization to be an almost negligible factor. In exclusively breast fed infants the writer has had apparent cure in about 40 per cent. and definite improvement in about 20 per cent. more following omission or limitation of certain articles of food in the maternal diet. The aim of treatment should be to secure complete digestion of ingested protein, either by improving the digestive function or by limiting the intake of offending proteins. Sensitization of the nursling apparently does not occur through foreign proteins ingested with breast milk.

7. Outbreak of Epidemic Jaundice Among College Students.—Ira V. Hiscock and Orville F. Rogers, Jr., record observations on sixty-nine cases of epidemic jaundice occurring at Yale University, sixty-three of them having an onset within a period of fifteen days. The most prominent symptoms were pronounced weakness, loss of appetite, and the appearance of the jaundice itself. It appears from the study that the majority of the sixty-nine cases reported originated in contact infection either by direct transfer from person to person or in some instances perhaps by infection of eating utensils at two eating clubs patronized by the majority of students affected.

8. The Schick Test: Standardization of Diphtheria Toxin for the Control: Method of Diluting the Toxin.—Abraham Zingher, in a previous communication, called attention to the fact that in a number of com-

mercial preparations of diphtheria toxin, the toxic strength of the dilution was considerably below that of a standard dilution of toxin. In view of this finding he strongly advises standards for official control of Schick outfits. Careful standardization of Schick outfits in guinea pigs necessitates that there should be at least one minimal lethal dose in each individual outfit. Such an outfit would be sufficient for from thirty-five to forty-five tests. Outfits for the Schick test sufficient to make five to ten tests cannot be tested for accuracy in the human being. Undiluted bulk toxin, accurately and carefully diluted, is most suitable for the testing of large numbers of individuals in schools, institutions, hospitals, clinics, etc. Two methods for the dilution of bulk toxins are described in detail. The dose of toxin for the Schick test is 1/40 minimal lethal dose in 0.2 c.c. This amount was found to be the equivalent of 1/50 minimal lethal in 0.1 c.c. The larger amount of the more diluted toxin is easier to inject, and the results are more likely to be accurate. The positive Schick test reactions also in susceptible individuals who have not even a trace of antitoxin are not likely to be so severe and show the superficial necrosis of the skin noted with the more concentrated dilutions of the toxin recommended by Schick. The dose of heated toxin for the control test has, in addition, a 20 per cent. excess to allow for slight deterioration by heating of the reacting autolyzed protein. Too much emphasis cannot be laid on the accurate dilutions of the toxin for the Schick test and the control test.

3. A Case of Acute Anaerobic (B. welchii) Infection of Uterine Fibroids, with a Reference to the Etiology of Necrobiosis.—W. B. Gabriel and A. Neave Kingsbury report this case of acute emphysematous gangrene of a uterine fibroid terminating in a rapidly fatal anaerobic septicemia both because of its extreme rarity and also because its leading features suggest a resemblance to the condition known as acute necrobiosis or red degeneration of fibroids of the uterus. The striking clinical features of the case were the patient's mental alertness and sense of well-being until about six hours before her death, an extreme jaundice though no bile-duct obstruction was found post-mortem, and the very marked hyperresonance of the abdomen, particularly in the umbilical and hypogastric regions. This was proved post-mortem to be due to gaseous distention of the large fibroid which lay immediately beneath the anterior abdominal wall. The case establishes the following facts: (1) The fibroids have been infected by *B welchii*, derived most probably from the cavity of the uterus. (2) The infection has remained localized to the fibroid and resulted in local changes and general effects. Hemolysins produced in the fibroid will account for the hemolysis upon which all observers are agreed, and which would account for the marked jaundice in this case. The initial infection will cause a vascular engorgement which by distention of the capsule will cause the pain of which these patients complain. Later, infective periphlebitis may involve the capsular vessels, and the condition may proceed finally to an established phlebitis and thrombosis. The histological changes of hyaline and fatty degeneration, and loss of nuclear staining, are consistent with the theory of anaerobic infection. The general effects were produced by the absorption of these toxins. The case has, then, much in common with more typical cases of acute red degeneration; it differs in that the infection proceeded to a well-established septicemia, but, as in puerperal sapremia, infection may remain localized to the uterus, so it is suggested that it may remain localized in necrobiosis and hemolysis. The theory of anaerobic infection as the primary cause of this condition is more satisfactory than the current theories of primary thrombosis or septic necrosis, and the immunity from red degeneration which ovarian fibroids show is well explained by this theory in virtue of their non-contact with the uterine cavity. Although all varieties of uterine fibroids may become necrobiotic, interstitial and submucous tumors are most liable to become so affected.

4. Chronic Deep Infections of the Jaw.—Stanley Colyer holds that many failures or partial failures in the treatment of oral sepsis may be explained by the fact that the infection has been by no means limited to the teeth and their immediate neighborhood, but has passed into the body of the jaws and there formed breeding-grounds which in time cause changes in the bone sufficiently coarse to alter the radiographic shadows peculiar to cancellous bone. To discover infection of the jaw one must study the radiograms with a magnifying glass. The general impression that one gains from a radiogram of infection of the jaw is a suggestion of wooliness or fleeciness about the negatives, and the presence of blotches or patches of increased or decreased translucency. The fleeciness appears to be due to a thickening of the trabeculæ of the cancellous tissue and to a decreased translucency of the cancellous spaces, as though lime salts were diffused throughout the medullary substance. Under the magnifying glass one of the most important features of chronic infection may be discovered, namely, the presence of small, roundish, blackish spots surrounded by a layer of sclerosed bone. To be of diagnostic value they must be present in fair numbers. From analogy with a similar condition often found at the apex of infected inter-radicular bony septa these points are assumed to be small masses of inflammatory tissue dependent upon a low grade infection. As it would seem impossible from the evidence of radiograms to curette away satisfactorily the whole of the infected bone, it might be well worth while, after the removal of the ports of infection, to test the possibilities of vaccines and ionization.

7. The Virulence of Diphtheria-like Organisms. A. J. Eagleton and E. M. Baxter.

1. Tuberculosis of the Lymphatic System.—Robert Philip stresses the following points: (1) The part played by the lymphatic system, in the early spread of tuberculosis, requires to be emphasized. (2) Patients should be examined with that in mind, and the more important groups of glands should be systematically reviewed. In cases of general delicacy, all the readily accessible lymphatic glands should be carefully investigated. (3) In young children the lymphatic system should be investigated with special care, from time to time. (4) Lymphatic tuberculosis, conspicuous in children, becomes less marked in later life. (5) In cases of gross enlargement of one or more glands, exacting search should be made into the state of adjacent glands and other groups of glands. (6) Operative treatment should be limited to emergencies, and, save in exceptional cases, such operative treatment should not involve extensive incision. Tuberculous involvement of the lymphatic system can be effectively combatted by continuous vaccine therapy. Under the continued use of tuberculin—whether subcutaneously or by inunction, as the writer has practiced with excellent results for many years—the grosser tumors gradually melt away. *Pari passu*, the glands at a distance are influenced, and the advance of disintoxication is registered by the improved appearance of the patient, increase of weight, and recovery of muscular tone.

3. Febricula and Influenza.—A. I. Simey divides the influenzal group of diseases for convenience into two groups: (a) Localized infections, with slight toxemia, namely, coryza, catarrh. (b) General infections, with much toxemia and possibly septicemia, namely, febricula, influenza. Statistics are presented of an outbreak

of febricula in Rugby school, during the summer term of 1918, where it is safe to say that every student was exposed to infection. One-third of the school, 187 cases, succumbed during the term; whilst others, perhaps amounting to 250, contracted the disease during the holidays. In the following term, when influenza in its severest form was epidemic everywhere, and especially severe in the Rugby district, there was not a single case among the school boys, and only seventeen cases of mild "febricula" were admitted to the sanatorium. During the next term, when another wave of influenza passed over the district, the school was again visited by febricula in epidemic form. Of the 187 boys who had contracted it in 1918, 170 still remained in the school, and of these thirty-one succumbed out of 140 cases admitted. From these statistics and the examination of a large number of individuals, Simey concludes that febricula is closely allied to coryza and the febrile colds on one hand and to influenza on the other hand; that an attack of febricula renders most patients temporarily immune to febricula and influenza; that such immunity lasts from three to nine months, and that there are some individuals highly immune to both diseases. He is inclined to think that the bacillus of Pfeiffer is rightly named *B. influenzæ*. In the writer's experience prophylactic treatment with vaccines has been much more encouraging than the therapeutic. Vaccines to be most efficacious should be specially prepared from local material, and in an epidemic these vaccines should be systematically reinforced to keep pace progressively with the advance of the disease. The possession of an autogenous vaccine from a given patient is useful for the direct contacts of the patient from whom it is obtained, and possibly also, in a less degree, for the more remote contacts.

4. Spasmodic Stricture of the Uterus.—M. A. Dobbin-Crawford reports a case of this condition, and discusses the treatment, bringing out the following facts: (1) The difficulty, danger, and high mortality attending active interference. (2) That the only abnormal condition is a localized spasm of the uterine muscle. (3) That deep anesthesia diminishes muscle spasm. (4) That repeated examinations increase spasm and are therefore contraindicated. (5) That in the case reported deep and prolonged anesthesia alone resulted in the spontaneous delivery of a healthy child. (That in previous confinements of this patient forceps were applied on every occasion with an infant mortality of 50 per cent. The correct treatment for this condition is deep anesthesia, if necessary prolonged, and nothing else. This treatment will, in the opinion of the writer, nearly eliminate the necessity for cesarean section.

6. Some Functions of the Suprarenal Glands.—Evelyn Hewer describes feeding and inoculation experiments in white rats from which she concludes: That the suprarenal cortex plays a part in fat metabolism and in calcium metabolism; that it stimulates the thymus to involution; that it controls the gonads in both male and female with respect to both reproductive and interstitial cells, and that it acts as a whole in controlling general health, in controlling hemoglobin breakdown, in regulating the function of lymphocytes, in regulating the production of mast cells, and in stimulating the thyroid. The suprarenal medulla is connected with the formation of melanoblast cells. Inoculation with various suprarenal extracts appears to lower the resistance of experimental animals, as is indicated by the condition of the lymph and hemolymph glands.

2. Transorbital Puncture of the Gasserian Ganglion.—Chester M. Van Allen traces the history of needle puncture of the trigeminus, and describes the technique of Harris and Härtel, both of whom used the foramen ovale as a pathway to reach the ganglion. These methods are uncertain in execution and involve dangers. A hitherto untried needle-approach to the Gasserian ganglia is the orbit, the path followed is the medial orbital wall, and the portal of entry to the cranial cavity the sphenoidal fissure. The needle is guided by the sense of touch along a smooth, bony surface, until its progress is obstructed by the bony fossa lodging the Gasserian ganglion. The needle can do no harm in its prescribed channel, but does not have to wander far afield to inflict serious damage. The anatomical study of this method has been carried out on 24 cadavers and, of 52 consecutive punctures, 43 have been shown to enter and successfully infiltrate the ganglion root; four punctures did not have to do with normal adult skulls, and five punctures were failures, four because the needle terminated within the cavernous sinus. When this occurs it can be recognized immediately, for blood flows slowly from the needle, and under these circumstances injection with alcohol is contraindicated. In five cases in which this method of puncture has been employed in the human being, the needle was introduced without the slightest difficulty in the recognition of the pathway, and the technique was successful in producing anesthesia of the entire trigeminal field. Other experiments carried out by the writer show that whatever injury is inflicted upon the root of the ganglion by the injection of alcohol will be shared to a less extent by neighboring nerves. This is true no matter by what approach or technique the needle is entered. Accordingly, until some method is found for preventing this widespread diffusing of the alcohol, he cannot recommend puncture in the therapy of trigeminal neuralgia. Other possibilities for the employment of the technique suggest themselves. It affords a method of withdrawing cerebrospinal fluid directly from the basilar cistern. Wider experience may justify an attempt to use this route for therapeutic applications to the central nervous system. The effect of air injections in the *x*-ray diagnosis of intracranial disorders is likewise worthy of consideration. The results of this work lead the writer to believe that transorbital puncture of the Gasserian ganglion furnishes a relatively simple method of securing block anesthesia for operations in the territory supplied by the trigeminus, fully justified in cases in which general anesthesia is contraindicated, as in aged and infirm patients with carcinoma in this region.

4. Observations upon the Surgery of the Lung.—Samuel Lloyd summarizes the present indications for operations on the lungs as follows: (1) For tuberculous cavities where gas injections into the pleural cavity, either because of too rapid absorption of the gas or because adhesions prevented the collapse of the lung, extrapleural thoractomy should be performed. This may be completed in stages, depending upon the condition of the patient. (2) For bronchiectasis, extrapleural thoractomy may be performed, although incision and drainage or lobectomy offer a better chance for a radical cure. (3) For foreign bodies which cannot be removed by bronchoscopy, thoractomy, with direct removal by incision through the lung, would be the method of choice. (4) For hemorrhage with increasing hemothorax, compression of the lung and displacement of the heart and mediastinum, thoractomy with suture of the bleeding points is indicated. (5) For abscess, thoractomy and drainage of the abscess, attaching the pulmonary pleura about the opening of the lung to the parietal pleura in order to effect direct drainage, will give the best results. (6) For tumors of the chest wall, including the ribs and pleuræ, complete removal with a pediculated skin flap from the abdomen has been successful. (7) For tumors of the lung, thoractomy and direct excision by partial or complete lobectomy offers the only chance of curing the patient. (8) For empyema, early and frequent apsiration, followed, if

necessary, by intercostal incision and drainage. If these methods are not efficacious, one of the radical operations should be performed.

8. Experimental Intestinal Obstruction.—Harry Belleville Eisberg describes observations made to show the existence of a distinct duodenal obstruction entity in which the pancreas plays the dominant rôle; to show the existence of a distinct intoxication resulting from intestinal segments or loops, and also to record observations made in a group of experiments conducted to clear up certain points of discord between the various observers. It appears from these observations that in severed gut obstruction in the duodenal region the pancreas is probably the main source of the toxin. Bacteria are apparently not a determining factor in this type of obstruction. In the pure segmental type of obstruction (*i.e.* an isolated segment with the continuity of the gut restored) the damaged intestinal tissue is the deciding factor as regards lethal outcome; if no devitalized tissue is present death does not occur. In nonvitalized segments bacteria alone will not be responsible for a lethal outcome. At times a devitalized segment appears to be responsible for a lethal outcome long before there has been time for bacterial action to play a part in the result. When a severed gut and segmental obstruction are present together and there is no damage to the intestinal mucosa in the segment, the lethal outcome is due to the oral severed gut obstruction and not to the undamaged segments. In both types of obstruction the breaking down of the host protein molecule appears to be an important factor in the formation of toxic substances. Whether the actual ends products in both instances are chemically allied or not has yet to be proven. In the severed gut obstruction death appears to be essentially a physiological one. In the devitalized segmental type this is true in the main, the added element being the presence of bacteria. The theory of Draper that in severed gut obstruction the administration of the scrapings of jejunal mucosa suspended in water detoxicated the poison originating in the duodenal mucosa is now regarded as fallacious, and it would seem that the beneficial results may be properly ascribed to the watery contents of the mixture and not to any specific effect of the jejunal scrapings. The point of view of Hartwell and Hoguet that dehydration of tissues is the important factor, with a secondary intoxication the result of dehydration, as the cause of death in severed gut obstruction, does not appear to be in accord with present views.

9. A Fundamentally New Technique for Inguinal Herniotomy.—Marsh Pitzman describes the technique of a modified Bassini operation, the underlying principle of which is the reproduction of physiological valve reaction by (a) resection of the hernial sac; (b) actual effective repair of the enlarged opening in the transversalis fascia, and (c) the avoidance of injury to the internal oblique and transversalis muscles. The essential step of the operation is to sew the transversus fascia and aponeurosis—and only these layers—down to the inguinal ligament of Poupart before the peritoneal cavity has been closed. The technique, it is claimed, is universally applicable to all inguinal hernias, small or large, direct or indirect, primary or recurrent, and is especially recommended for medium and large necked hernias.

7. When Shall We Do the Ethmoid Operation?—William Mithoefer asserts that the ethmoid operation should never be done without a careful study of each individual case. During the progress of examination, which may require several weeks or months, simple means, such as infraction of the middle turbinate, treatment of the ethmoid floor, correction of a general systemic dyscrasia, or treatment of a nasal neurosis, should be tried. By the use of these simple means the patient is often relieved and operative intervention is not required. Bacteriological examination of the nasal discharge is of prime importance. Neglect of this precaution may mean the death of the patient. Close analytical study brings better results in the end and prevents the operation from falling into disrepute; it also demonstrates the important fact that latent disease of the ethmoid is of frequent occurrence and may be easily overlooked if the examination is done in a cursory manner.

9. Preoperative and Postoperative Radium Therapy: Report of Cases, Dosage, and Methods.—Benjamin R. Kirkendall, after an experience of four years' use of radium on 817 patients, concludes that cases of carcinoma of the vagina and prostate are best treated with radium alone. Cases of cancer of the cervix and uterus, which have responded well to the treatment, should rarely be hysterectomized later, as distant, quiescent diseased cells may be stimulated to recurrence. Radium can be used to great advantage before surgery to make nonsurgical cases operable. Radium after surgery may make a success of the operation. Its use in recurrences is usually palliative, but it may cure.

2. The Non-Operative Treatment of Retroversion of the Uterus.—William H. Cary classifies retroversions of the uterus into non-operative and operative. The non-operative he groups into (1) those in which treatment is not required, as the symptomless, uncomplicated cases and those complicating neurasthenia or gastroenteroptosis; (2) those suitable for pessary treatment, that is, those occurring during the child-bearing period and puerperium and those in which sterility is the only complaint; (3) those in which tamponing or other palliative measures are indicated. In this group are adherent retroversions in which operation is refused, the cases of retroversion complicated with adnexal disease in young women, and cases of oopharitis, ovary prolapse, and chronic uteritis, in which palliative measures are applied preparatory to the employment of the pessary. The contraindications to pessary treatment are adherent displacements, pelvic inflammations of ovary tube or parametrium, vaginitis (gonorrheal foci suspected), pruritis (leucorrheal or diabetic), preceding vaginal operations (at least one week), hyperthyroidism (some cases), and where medical care is unavailable. The essentials to successful pessary technique are assistance, knee-chest position for reposition, gentleness, clean technique, many pessaries of all kinds, careful fitting, proper after-care and instructions to the patient. In summarizing Cary says a gynecologist's qualifications can best be measured by his skill in the management of retroversion of the uterus. Because cases are not properly selected for operative and non-operative treatment—by far the larger number belonging to the latter group—and because the proper operation is not chosen for the different types of posterior displacements, the results attained in the treatment of this disorder are often disappointing. If

truthful statistics could be tabulated giving the percentage of relapses after operations for retroversions, especially when pregnancy has occurred subsequent to operation, the figure would be appalling. It would seem that no gynecological operation is so often needlessly done. The time is at hand when operations done solely for the correction of uncomplicated retroversion of the uterus should be condemned.

Pathology of the Instincts.—Laignel-Lavastine delivered a lecture on this subject, based in part on the work of Pieron, Larguier des Bancels and the Englishman Rivers. The subject of instinct is many-sided and comprises such well marked behavior as the instinct of self-preservation, the instincts toward nutrition and reproduction, the various defense reactions, the gregarious instinct, etc. The rôle played by them in psychiatry has been neglected save in certain directions such as the innumerable perversities of the sex instinct. The author seeks to show that delusions of persecution represent aberrations of the instinct of self-preservation. Vanity and allied emotions are allied to the latter and in paranoia with its systematized delusions the ego is greatly magnified. The anxious states with the sensation of insecurity show the same want of touch with the environment in a smaller way. The author enumerates some cases, as that of a girl with chronic hallucinatory psychosis and hallucinations of special sense developed on a paranoiac basis. She believed that a band of sacrificers were after her and had already removed two of her cervical vertebræ. In another subject with persecutory delusions there was no paranoiac basis but an anxious state which supplied the substratum. In the melancholic these delusions are naturally found, as this psychosis may be of the anxious type. Several authors have reported combinations of paranoia with anxious melancholia.

Laminectomy for Lumbago.—Sicard and Forestier write of the condition variously known as chronic lumbar rachialgia, lumbarthria, chronic rheumatic lumbago, etc., of authors, which may not by any means apply to the same syndrome. Leri has isolated a type due to the presence of osteophytes and naturally the Roentgen rays at times make it possible to isolate some special mechanism. Attempts have been made to classify the painful affections of the spine through the underlying pathology, recognizing spondyloses and spondylites. There still remains a residue in which no objective findings or pathology figure. This is the familiar lumbago or simple lumbalgia. Its occurrence as an acute or subacute affection need not detain us here, but the chronic type of this affection is a serious incapacitating affection. Its characters are localization in the lumbar region, pain, certain contractures which result from a defense or antalgic attitude, and chronicity. The subject becomes crippled in standing or walking. Radiography is invariably negative. In June, 1917, after several years of invalidism, Dambrin performed laminectomy on a military man limited to the twelfth dorsal and fourth lumbar vertebrae. Adhesions were evident between the dura and the vertebral rings which bled when separated. Two months later the patient had quite recovered and joined his command. Four similar cases are recorded. The basic condition is probably a radiculitis or localized funiculitis, essentially bilateral. The sole clinical distinction between the two is that funiculitis is associated with some muscular rigidity or contracture. The laminectomy was evidently in part exploratory and in part a general operative procedure comparable to trephining in obscure cerebral disease.

Revue Médicale de la Suisse romande.

Noma of Leucemic Origin.—Alikhan describes a case of an association so rare that no mention of it is said to occur in French literature. The patient was a woman of 24 years of negative antecedents. On February 5 her face began to swell—region of left cheek and submaxilla—the ear also giving symptoms. A diagnosis of erysipelas was made, and the patient sent to the Cantonal Hospital. Here she received a thorough examination and on the 18th the diagnosis was made of noma of the buccal mucosa, with marked general reaction. Officially the diagnosis was entered as gangrenous stomatitis, with general intoxication. Death occurred in coma after a fortnight in the hospital. The diagnosis of acute myelogenous leucemia was made at the autopsy. In commenting on the case the author sums up as follows: Gangrenous stomatitis may rarely complicate acute leucemia, therefore when confronted with a case of clinical noma one should always study the blood counts, as in some of these cases at least the mechanism is obscure. In the presence of lecemia surgery would probably be of no value. The patient was given neosalvarsan without benefit and the bacteriological studies threw no light on the pathogenesis. In regard to literature, Askanasy, the Swiss pathologist, published in German in 1904 an article on ulcerous processes in the digestive tract in acute leucemia which contains a mention of noma and in which it is suggested that desquamation within the month as a result of a deposit of lymphoid tissue in the submucosa favors the development of that accident.

Geographical Distribution and Polyclinic Treatment of Epilepsy.—Wyrsch gives statistics of epileptics in Unterwalden and in Zürich who are under treatment. In the former Canton the population is 1.846 per 1,000 inhabitants, while under polyclinic treatment in the city are slightly over 2 per 1,000. According to these figures, the total, including the unregistered, is high in proportion to the incidences which are mentioned in textbooks. Two per 1,000 is the mark usually quoted, but in Zürich there must be over 3 per 1,000. Over a third of all cases appear about the time of puberty and the three causal factors in the order of importance are alcoholic heredity, heredity outside of alcohol, and injury. The treatment is thoroughly unsatisfactory and may be summed up as 21 per cent. of improvement, with half the Unterwalden population unable to support themselves. There is about 78 per cent. of improvement in the city dispensary cases under salt-poor diet and some form of bromine medication. Bromine does not appear to give better results in one causal type than another. Of the bromine-intolerant patients, two-thirds have improved under luminal and salt-poor diet. Further, half a gram to a gram of luminal will spare daily 1.5 to 2 gm. of bromine. Luminal is toxic and cannot be pushed. It appeared to improve the association facility in one patient tested. A psychiatric polyclinic seems a decided asset in a community to handle the ambulant uninterned material. Unterwalden is a rural hill community with a sparse population relatively free from degeneracy. The total number of epileptics for the entire Canton was fifty-seven. There is no mention of any institutional epileptics in the Canton, but as a rule such inmates are added to the uninterned, which sometimes gives a false idea of the amount of epilepsy in rural districts. The epileptic naturally seeks the city and when interned is usually moved back to the country, as most of the asylums are in rural districts, and this movement tends to disturb statistics.

Case of "Bouba" in Rio de Janeiro.—Bouba is a form of yaws, although in past years the name was applied to syphilis and was even used to describe some infectious disease before the discovery of America, the primary significance of the word boubas being pustules. The patient was a young man who, while working as an excavator developed lesions on his feet, then on the nates and head and finally on the genitals. The latter location is very unusual. The Wassermann was positive and the *Spirocheta pertenuis* present in great abundance. For some unknown reason the case was refractory to neosalvarsan.—*Brazil Medicó.*

Book Reviews.

CLINICAL SURGICAL DIAGNOSIS FOR STUDENTS AND PRACTITIONERS.—By F. DE QUERVAIN, Professor of Surgery and Director of the Surgical Clinic at the University of Berne. Third English Edition. Translated from the Seventh Edition by J. SNOWMAN, M.D. Price, $14. New York: William Wood & Co., 1921.

SINCE the appearance of the second English Edition in 1917, Professor de Quervain has issued two further editions of the original work. The present translation is therefore made from the seventh German edition. The 841 pages of the 1917 edition have been increased to 914, and the illustrations number 731, an increase of 126. The subjects which pertain to civil surgery have been fully revised and brought up to date, while it has now been possible to incorporate fully the lessons of the war, which will be found distributed under the proper captions, and not, as heretofore, in a single chapter on military surgery.

A MANUAL OF MIDWIFERY FOR STUDENTS AND PRACTITIONERS.—By HENRY JELLETT, B.A., M.D., F.R.C.P.I., L.M. Late King's Professor of Midwifery in the School of Physic, Trinity College, Dublin, and DAVID G. MADILL, B.A., M.B., B.Ch., B.A.O. (Dublin), L.M. Gynecologist to Monkstown Hospital. Third edition. Price, $10. New York: William Wood & Company, 1921.

THE authors of this well-known textbook are respectively an ex-master and ex-assistant master of the Rotunda Hospital, and the present edition is apparently the logical culmination of the short treatise on midwifery first published by Jellett in 1897. The latter volume contained but 323 pages, while the present one contains 1199 pages, and includes articles by a number of subeditors who are not obstetricians but identified with anatomy, clinical medicine, pathology, and forensic medicine. There are 570 illustrations, not including 20 plates. This volume well shows that the day of the small, compact, one-man textbook has vanished, at least for the time.

OPERATIVE SURGERY.—By J. SHELTON HORSLEY, M.D., F.A.C.S., Attending Surgeon St. Elizabeth's Hospital, Richmond, Va. Illustrated by Miss HELEN LORRAINE. Price, $10.00. St. Louis: C. V. Mosby Company, 1921.

THE appearance of a new work by a surgeon of Dr. Horsley's repute is an event in medical literature. Without disparagement to his other attainments, it may be said that the author is perhaps best known for his brilliant work in plastic and reconstructive surgery, and it is therefore not a matter for surprise that he lays special emphasis in his technique on the restoration of the physiological function of the parts. As he says, "Merely following anatomical landmarks and making a beautiful dissection with accurately placed ligatures and sutures should not be the sole aim of the surgeon. . . . It is even more important that the operation results . . . in the restoration of the physiology of the tissues or organs." The author has made no attempt to describe all possible operations, but notes only those which he has himself performed, or which are regarded by him as the most suitable in the special case under consideration. The work is profusely, though judiciously, illustrated, and what is to be specially noted, the pictures, 613 in number, are for the most part entirely original, though some few have been redrawn from other works. They are all beautifully executed. The book is one that should be in every surgeon's library.

THE FOLLY OF NATIONS.—By FREDERICK PALMER, Author of "The Last Shot." "My Year of the Great War," "America in France," etc. New York: Dodd, Mead & Company, 1921.

FOR twenty-five years as war correspondent Frederick Palmer has seen all the wars of any consequence. He has studied the causes of these wars and of others more remote, and analyzes the emotional complexes that lead to war and its effects on men's minds. Most wars, he finds, have come from differences in language, race, habit, and custom. He believes the time has come when these need no longer stand in the way of universal peace. He presents the usual arguments of the militarists, showing why we must have wars as long as human nature remains as it is, and then endeavors to show the fallacy of these arguments, but fails utterly to convince us that the human emotions and passions that have incited wars in the past are not as operative today as they always have been. The time that has elapsed since the ravaging of Belgium and the sinking of the *Lusitania* is far too short to justify the belief that brutality which needs must be controlled by force no longer exists. Mr. Palmer traces war to selfishness and greed. Surely, when we need an armed force to guard our mail trains within our own borders and have an unrepentant Germany without, a disrupted Russia, and general political and social confusion everywhere, there is no ground upon which to base the assumption that we have progressed to the stage where we are ready for peace however alluring and desirable it may be theoretically. In a world as it is at this stage of human progress it may still be well to remember Emerson's lines, "'Tis man's perdition to be safe when for the truth he ought to die."

THE PRACTICE OF UROLOGY.—A Surgical Treatise on Genito-Urinary Diseases, Including Syphilis. By CHARLES H. CHETWOOD, M.D., LL.D., F.A.C.S., Former Professor of Genito-Urinary Surgery, New York Polyclinic; Visiting Surgeon to Bellevue Hospital; Consulting Urologist, French Hospital; Special Consulting Surgeon to Knickerbocker Hospital, St. John's Hospital (L. I. City), Nassau Hospital (Mineola), St. Agnes and White Plains Hospital; Member American Association of Genito-Urinary Surgeons, American Urological Association; L'Association Internationale D'Urologie, etc. Profusely Illustrated. Third Edition. Price, $8.00. New York: William Wood and Company, 1921.

WHEN any book attains to a third edition in eight years it becomes a standard work on its subject. Such is the volume under consideration. Despite the minor changes and additions, this third edition shows its author's handiwork in modern nomenclature and description of newly accepted therapeutic agents. The sanity of thought and wisdom of judgment which pervaded the previous editions justified the praise bestowed in these columns (MEDICAL RECORD, March 29, 1913, page 726; and January 13, 1917, page 80). Because of this volume's maintained standard of excellence the reviewer predicts its survival and a continuance of its popularity.

KRANKHEITEN DER ÄUSSEREN GESCHLECHTSTEILE und der Vagina, der weiblichen Blase, des Harnleiters und der Harnröhre. Gonorrhoe, Syphilis und Tuberkulose der weiblichen Geschlechtsorgane. Von Prof. Dr. HENKEL, Direktor der Universitäts-Frasenklinik Jenas. Leipzig: Georg Thieme, 1921.

THIS brocure of 95 pages is one of a series of five numbers devoted to the "Diagnostic and Therapeutic Errors of Gynecology and their Prevention." There appears to be no valid reason for regarding the work as especially diagnostic in scope, for there are but few illustrations, no illustrative cases, no talbles of differential diagnosis, etc. The proper title of the volume as stated above, covers the content of the book sufficiently.

DIAGNOSTISCHE UND THERAPEUTISCHE INTÜMER UND IHRE VERHÜTUNG IN DER GEBURT. Von Geh. med.-Rat Prof Dr. FEHLING. Leipzig: Georg Thieme, 1921.

THIS brochure is the obstetrical section of a series devoted to the diagnostic and therapeutic errors in gynecology and their prevention. It comprises 102 pages and as the title implies is devoted to labor, similar volumes covering gestation and the puerperium. The diagnostic errors deal naturally with the positions of the fetus *in utero*, life or death of same, twin pregnancy, causes of dystocia, recognition of preclampsia, rupture and inversion, causes of hemorrhage, etc., etc. The chances for therapeutic error are naturally numerous and costly. The subject does not lend itself especially well to the author's plan and the book could have been written as well under the title of "management of labor."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 6, 1922.

DR. CHARLES EVERETT FARR IN THE CHAIR.

Result of Old, Conservative Treatment of a Double Forearm Compound Fracture.—Dr. CLARENCE A. MCWILLIAMS presented this patient.

Extensive Plastic Operation of Face, Following Excision of Epithelioma of Cheek and Orbit.—Dr. JOSEPH E. J. KING presented this patient, an elderly woman whose trouble began some six years before she came under his observation. She had an epithelioma of the lower eyelid on the right side which had been treated with caustics, pastes, ointments, etc. In March, 1920, she came to the New York Skin and Cancer Hospital with a basal-cell epithelioma involving the eyelids, eyeball, orbit, frontal sinus, anterior ethmoid cells, side of nose, cheek, malar bone, and antrum of Highmore. The growth was excised by making an almost circular incision, the contents of the orbit were removed, the frontal sinus, ethmoid cells, and the antrum were cleaned out, so that the tumor was removed en masse with a fair margin of healthy appearing skin surrounding it. The defect thus made was dressed with dakinized gauze dressings for about 2½ months, during which time the wound had become smaller and the surface covered with firm healthy granulation tissue, except that certain parts of the cavity were lined with mucous membrane, remaining from the sinus and antrum. The cavity was so large and deep that the skin flap-to-be could not be carried down into the depths and completely obliterated the cavity. This also could not be done on account of the cavity containing mucous membrane. Therefore it was necessary to cover the defect with a flap lined with epithelium on both sides, stretched across the cavity like a drum-head, leaving an air cavity beneath which communicated with the nasal cavity. In order to allow of sufficient drainage, the lateral wall of the right nasal cavity was removed, making a drainage opening about the size of a five cent piece. On June 4, 1921, a temporo-frontal flap, bearing a Wolff graft on its under surface, corresponding to the area which would cover the air cavity, was lifted up (after the Wolff graft had been in place for two weeks and had become firmly attached to the under surface of the flap), and sutured into position. The margin of the flap was sutured to the freshened margin of the defect. The incision was carried up into the hair-line at the upper inner border of the flap so as to obtain hair-bearing scalp for reconstructing the inner two-thirds of the eye-brow. The pedicle of the flap "buckled" in the temporal region, the temporal vessels being the base of supply for the flap. The remainder of the ungrafted portion of the forehead was covered with Thiersch grafts. This operation was done under colonic anesthesia as well as the first incision operation. On August 16, 1921, the major portion of the skin of the "buckle" was superficially excised, so as not to divide the blood vessels and lymphatics of the pedicle. The patient was soon discharged from the hospital to her home. The flap had healed kindly in position, was not edematous, and was well nourished. The patient was able to irrigate the cavity behind the flap by passing a curved female metal catheter through the opening in the external nasal wall. With a pair of dark glasses and with her hair properly arranged, the defect was not of an unsightly appearance and was hardly noticeable on casual observation. She worked as a cook and washwoman until November 2, 1921, when she returned for examination. There was a recurrence of the epithelioma about the size of a pea at the upper inner corner of the flap at the bridge of the nose and also recurrence along the inner lower border of the flap, external to the ala of the nose. There was an interval of healthy skin between the two lesions. On November 5, 1921, the recurrent lesion over the bridge of the nose was excised, and a forehead flap, using the left angular artery, was turned down into position over the defect and sutured. About ten days later, the lesion external to the ala was excised, and a flap from the right cheek, extending downward and forward over the mandible, was lifted up and sutured into position. When the excision was done, it was necessary to extend the incision into the flap, and thus remove a portion of the flap adjacent to the lesion. The cavity behind the flap was inspected and found to be clean and free from recurrence of the growth. The under surface of the original flap was in good condition and had the feeling of soft skin. This was the old Wolff graft. After three weeks, the pedicle of the flap was divided, and the distal and proximal ends were sutured into place. This completed the operative work for the two recurrent lesions, all of which was done under local anesthesia. The patient was presented, showing the various defects which had been repaired with three pedicle flaps; temporo-frontal, frontal, and cheek. The last was the only one divided. It probably would have been better to have left the pedicle undivided, for these flaps did not become edematous when the pedicle was not divided due to the fact that the lymphatics were preserved.

Dr. SINCLAIR TOUSEY asked whether this patient had been treated with *x*-ray or radium.

Dr. KING replied that the patient said she had been treated with the *x*-rays somewhere in the country, to what extent he did not know. She had had no radium treatment. In reply to a question as to whether anything such as gauze had been placed between the Wolff and the Thiersch graft, Dr. King said nothing had been interposed. Aside from using a small rubber tube drain for 24 hours for the initial oozing, no drainage was needed. There was usually a serous accumulation between the grafts, which was evacuated by inserting the end of a forceps between the skin edges where the drain was removed. This might be repeated every few days. None had become infected causing loss of the grafts. He preferred a flap from the forehead or face rather than from the arm for several reasons; the blood supply was better, it was more convenient, it was more comfortable for the patient, the color of the flap was more nearly that of the remainder of the skin of the face. Arm flaps remained white much longer and were more conspicuous. The dressing used on practically all of the plastic cases was a gauze dressing moistened in Dakin's solution. This dressing was changed every day and sometimes twice a day. In order to keep the Wolff graft in position beneath the flap when it was first placed there, he closed the incision with interrupted sutures of black silk, which sutures just barely caught up the margin of the graft to keep it stretched out in place until it became adherent to the under surface of the flap.

The Efficient Treatment of Compound Fractures.—Dr. CLARENCE A. MCWILLIAMS read this paper. (See page 354.)

Essentials in the Treatment of Compound Fractures. Dr. JOHN J. MOORHEAD made this contribution, in which he classified fractures into three grades as follows: (1) Punctured wound of soft parts; fracture of the transverse or oblique type. (2) Lacerated wound of soft parts, with or without stripping of skin and fascia; fracture often comminuted. (3) Crushing wound of soft parts with or without maceration; fracture usually comminuted. This grading was not absolute and in each grade many variants would be noted. After discussing the differences between compound fracture of civil life and those of military life and mechanical and chemical methods of sterilization, Dr. Moorhead mentioned as essentials of routine treatment, irrespective of the grade of fracture or type of wound, the following: (1) First aid sterilization; (2) immediate temporary reduction, and (3) immobilization. For first aid sterilization preference was given for the free use of iodine about and into the wound. Thereafter a wet dressing of iodine water was applied (tincture of iodine one dram, saline solution one pint), next was the administration of an immunizing dose of tetanus antitoxin in divided small doses to test out and prevent anaphylaxis. A few drops of antitoxin was mixed with 5 c.c. of saline solution and injected. After a wait of 10 minutes an identical amount was injected; then after a similar interval one-third of the remaining antitoxin was injected. If after 10 minutes no reaction appeared, the remaining antitoxin could be given with safety. A reserve hypodermic of adrenalin solution was at hand in the event of unfavorable reaction. Im-

mediate temporary reduction should be attempted by traction or suitable manipulation for experience taught that early reduction meant easy reduction, lessened local irritation, and the prevention of further traumatism. Immediate immobilization should not be of a too constricting type; it should first of all be safe, next simple and efficient. The Thomas splint for the lower extremity met well all requirements. The Jones splint for the upper extremity was excellent; the hinged Thomas splint was almost equally effective. The second phase of treatment was now entered upon and depended upon the grade group of the fracture. If the compound fracture was of the first grade, after removal of the first aid dressing, the area about the wound was cleansed with benzine or gasoline, tincture of iodine was injected under pressure and then a dressing of iodine water applied, the splintage was selected and the patient put to bed with the part elevated. If the puncture was larger than the diameter of a lead pencil, a small rubber band was inserted for drainage. In the second group mechanical sterilization, partial suture and drainage was the treatment followed, except when: (a) a period of 36 hours had elapsed since the receipt of the injury; (b) the fracture was in a well-muscled area so that complete debridement was impossible (femur fractures were in this group); (c) the fracture was much comminuted so that the bony fragments were detached to such an extent that they virtually acted as foreign bodies; (d) there was gross damage to important vessels, vascular or neural. Primary or immediate suture without drainage was rarely employed by the writer because it was dangerous and gained little in point of time over partial suture with drainage. The safest procedure in the average case was complete debridement, the placing, but not tying of sutures until the fourth day. This was virtually intermediate or primo-secondary suture. The iodine dressing was unchanged until the sutures were tied and if the clinical evidences of non-infection were not well enough established, the bacteriological examination of the wound secretion would determine the presence or absence of streptococci. With a moderate staphylococcus infection, primo-secondary suture with drainage added little if any hazard. Late suture was employed in that group in which infection required a relatively long period before it came under control. In the third group, where the wound was of a crushing type, the soft parts more or less macerated and the bone much comminuted, the patients were often in shock so that mechanical sterilization was hazardous. If conditions permitted debridement was carried out, hemostasis was made as absolute as possible, stitches were placed but left untied, and iodine water dressing applied. Late suture was often necessary in this group. Drainage in any of the grades was rarely used for more than 48 hours as thereafter it tended to produce rather than prevent infection. This was the management practiced in the vast majority of cases; but in the exceptions previously mentioned, the time element, the site and type of the fracture in relation to contiguous heavy muscles, and the damage to vessels made mechanical sterilization inadvisable. Recourse was had in this group to late closure after chemical sterilization and the technique of introducing the chosen antiseptic was, as already indicated, almost a matter of individual choice and experience. Dakin's solution applied by the Carrel technique was excellent, but in many instances could not be employed because of inability to obtain the fresh solution or inability to apply the technique which was a most important and time-consuming part of the treatment. Personally, Dr. Moorhead said he had discontinued the Carrel-Dakin treatment for both of these reasons. Reliance was placed more upon iodine, open air and sunlight and red light than upon any other combination in cases in which infection was already present. They had been making some observations at the Post-Graduate recently as to what might be termed the germ content of various skin surfaces of the body, using for the experiment a large number of unselected apparently normal individuals. Thus far they had proven in the laboratory what we knew clinically, namely, that the surface of the body harbored organisms of many kinds, particularly staphylococci. The importance of this observation in relation to compound fractures was that sound skin about the wound should not be neglected in our attempts to prevent or limit infection. Dr. Moorhead concluded that: (1) Efficient first aid treatment often determined the outcome; (2) iodine sterilization was the treatment of choice in the minor grades; (3) mechanical sterilization was the treatment of choice in the severe grades; (4) primary suture was rarely permissible; primo-secondary suture was the safest; (5) in old cases, late or secondary suture would shorten convalescence; (6) immediate reduction and immobilization were important elements in treatment.

Dr. H. H. M. Lyle said that with reference to the principles in the treatment of compound fractures in civil or military life, the first thing was immediate splinting. That was the most important point in first aid. All who gave first aid should be taught the proper application of the splint. It was due to the proper application of first aid splints more than to any other thing that they had been able to bring down the mortality from compound fractures. Dr. Lyle objected to the Carrel-Dakin method being called a chemical method. It was both a mechanical and a chemical method. He had begun using the method at about the same time that they began to use it in the De Page Hospital. The third important point in the treatment of compound fractures was suspension and traction, the proper balancing of the muscles. The value of those three things were proven in the war; they were not merely ideas or speculations. A fourth principle definitely proven was that of Willems. All other things were matters of opinion, but these had been demonstrated. As to the use of iodine, the Tenth French Army stopped the use or rather the abuse of iodine. Dr. Lyle said he still had some pictures showing the effects of iodine. It had produced burns that were worse than the original wounds. In another hospital iodine had been used along with Dakin's solution. Nobody who had seen the facts could say anything else than that the Carrel-Dakin method was superior to iodine. The facts were there. In order to prove the proposition one must have a number of patients and they must be treated at the same time. This had been done and the facts as he had given them had been demonstrated. Dr. Lyle expressed the opinion that the interne or hospital that could not use Dakin's solution properly should go out of business.

Dr. John F. Connors said he was a firm believer in the use of iodine before he went to France. As to the use of iodine and Dakin's solution in compound fractures, he had charge of 12 wards with 120 cases of compound fractures of the femur. The men in charge of the wards were told by him that they might use anything they wanted to use provided they gave him good results. The best results were obtained at first by a man who used Dakin's solution but he did not use it as Carrel recommended. He used it in the following way: He packed all wounds with 2 x 2 sponges soaked with Dakin's solution and removed and replaced every three hours except at night. He worked hard and obtained wonderful results. He was then transferred to another ward and told to try iodine. With iodine he obtained exactly the same results. It was not the solution but the man behind the solution. So far as the treatment of compound fractures went, Dr. McWilliams had started a good movement and the war had taught a good lesson. If fractures were properly splinted at first, devitalized tissue removed and a good position of the bones secured, one had accomplished about as much as was possible.

Dr. Sinclair Tousey stated that he had had a case which illustrated a principle connected with the treatment of compound fractures not alluded to thus far to-night. The case in question was a compound fracture of the tibia and fibula, with severe crushing, and a gap of a couple of inches between the two fragments of the tibia without any corresponding destruction of the fibula, so there was no difficulty in securing a full length fibula. This was in the days before they knew anything about filling in defects with bone chips. It came to his mind to allow the defect to fill with blood clot using careful antisepsis. The man left the hospital with a fairly sound limb. He did not see the patient for some years. Later he met him accidentally and found that the tibia with the defect was as sound and complete as the other.

Dr. JOSEPH E. J. KING said that compound fractures of the tibia were met with frequently in the hospitals, and the treatment of those fractures was a question brought up almost weekly at the conferences. One must decide whether to debride and suture up the wound, or debride and leave open, or not to debride but treat with a wet dressing. The typical case in his mind was a compound fracture of the tibia, from within, where the perforating fragment was withdrawn into position when the leg was splinted and traction was made. He had seen several cases of this type recently. One patient was thrown from his bicycle on a country road. The doctor who treated him put the limb in a plaster cast. On account of the pain and discoloration in the limb, the cast was removed on the third day. When seen by Dr. King on the fourth day, the leg and thigh up to the inguinal region were gangrenous and crepitated, and the patient died a few hours after high amputation of the thigh on the afternoon of the fourth day. The culture showed Welch bacilli and streptococci. A somewhat similar case was debrided within a few hours after the injury, washed out, and sutured. This case also developed a Welch bacillus infection, and the limb was amputated. Some cases were debrided, sutured, some with and some without drainage, and no infection occurred. Some only had a wet dressing applied after the wound was swabbed out with iodine and they did well. The question was: should one debride as a matter of safety in all cases or not?

Dr. JOHN C. A. GERSTER said it was a great pity that the principles just enunciated were not recognized and followed by many who accepted the responsibility of treating any compound fractures which might come their way. In a recent series of over 300 fractures of all types occurring in New York he had seen all sorts and degrees of needless deformity and preventable disability. Some of these patients had received hospital treatment, others had been given office treatment. If standardization of treatment as suggested by Dr. McWilliams were more widely adopted by the profession at large, it would be a great boon to humanity.

Dr. EDWIN BEER stated that Dr. McWilliams treatment was recognized as the correct treatment of war fractures, but the question came up whether it would be introduced in the treatment of civil compound fractures. He thought that if these wounds in civil practice were cleaned out and iodinized most of them would do better than the cases Dr. King had cited, for it was a fact that almost all these cases got well without infection. Those that were severely crushed would have to be laid wide open, debrided, and treated by the Carrel-Dakin technique.

Dr. JAMES N. WORCESTER pointed out that although they had learned the value of immobilization of compound fractures during the war, this was not being carried out in our cities. For a number of years he had been interested in fractures at Bellevue. When a fracture was received at other hospitals it was regarded as a bugbear and was transferred to Bellevue. If an ambulance surgeon brought a fracture case into other hospitals he was reproved and usually was careful not to repeat it. For years it has been a rare occurrence to have fractures brought in with any adequate immobilization. The use of a Thomas splint was a rarity. At Bellevue they had tried to have other hospitals cooperate with them and had even supplied them with Thomas splints hoping that in time surgeons would insist upon primary immobilization. Until the time came when all compound fractures were primarily splinted the results would be exceedingly poor.

Dr. FENWICK BEEKMAN said compound fractures might be classified into two types according to the way in which they were produced. In one class the skin wound was produced from within out, and in the other from without in as in crushing injuries caused by being run over by a wagon. These two types to his mind should be treated differently. Those produced from within out were not as likely to be as diffusely infected as those from without in. The only danger of their becoming infected was that the points of bone that had pierced the skin might pick up infection and carry it in, and then the infection was likely to be more limited. In the compound fracture produced from without there was likely to be dirt and clothing ground into the wound. This type should be treated as the war wounds were treated, with debridement and Carrel-Dakin treatment. Of course all cases of compound fracture should be splinted immediately.

Dr. WALTER M. SILLECK said there was one thing about splinting fractures or any other injury requiring subsequent dressing, and that was to see that the splint was so placed and fashioned that it was possible to dress the wound without removing the splint. In applying the splint there should be sufficient immobilization so that the wound could be dressed without taking off the splint.

Dr. CHARLES EVERETT FARR said that he should regret having it go out from this meeting that the Carrel-Dakin method was the official and only method of treating compound fractures. If this were allowed to go out some men might spill Dakin's solution about the operating room and say they were using the Carrel-Dakin method. It would be a mistake to standardize the treatment of fractures to the Carrel-Dakin method. One obtained bad results with all methods and if this were allowed to go out the courts would hold that Dakin's solution should have been used. He hoped it would not go out from the meeting that there was a standard method for treating compound fractures. He did not like the division of compound fractures into civil and military fractures. Of course he understood what was meant by that division, but it was not an accurate classification and led to confusion. He would like to see that distinction corrected in the literature. As to the use of iodine under dry pressure, he had used it, and had found that iodine under any pressure might cause a condition something like gangrene. Some slurs had been cast on the old method of treating compound fractures. He had been brought up on those old methods and had had something like 90 per cent. primary union without the use of Dakin's solution and without iodine, but with proper splinting. There was much criticism because the Thomas splint was not applied in first aid. It must be remembered that it took time to apply a Thomas splint and if a compound fracture was to be brought to him he would rather have it without the splint than with the splint improperly applied. An ambulance surgeon might put on a splint improperly and the patient be brought in and the interne seeing that a splint had been applied might neglect to give the patient attention for some time, since he could not see what was underneath the splint. Furthermore, the hospitals might not wish to send splints to Bellevue to be lost. There were simple ways of treating compound fractures, but the application of a splint was dangerous unless properly done.

Dr. DANIEL M. STIMSON said he had served on the staff of the Hudson Street Hospital before the days of Dakin solution at a time when the house surgeon had responsibilities. It was then the invariable rule that compresses should be used until the patient reached the hospital, when he was taken to the operating room, and many were sewed up, and fully 90 per cent. resulted in primary union. Compound Potts' fractures were sewed up without drainage, and some fractures of the elbow were sewed up with very little drainage, and Dr. Stimson said that he was satisfied that if as good results were obtained today as they obtained the profession would have gained a great deal. It was a slur to say that fractures were not properly treated at the Hudson Street Hospital. They were properly treated; they were treated at once and not allowed to wait two or three days until the attending surgeon came around.

Dr. JOSEPH E. J. KING said that during the latter part of 1915, 1916, and the early part of 1917 he was in a reserve hospital in Germany where he had observed probably between 500 and 600 old compound fractures, *i.e.* cases from three to four days to several weeks after the injury. Therefore, what he had to say did not have directly to do with the very recent fractures now under discussion. The injuries involved the joints in many instances and there were also old cases in which sinus formation had taken place. These wounds were irrigated with iodine solution, some were packed with iodine or iodoform gauze. A number of the patients with old fractures were up walking about the wards for a long time without debridement, or radical operation, on account of fear of violent infection following the operation. Several developed erysipelas

with septicemia and died, cases which in a short time would have been transferred to another hospital for chronic cases. Dakin's solution was not known of until the last few weeks in 1917, and the Carrel-Dakin treatment was not done. When he returned to this country, he treated a number of cases by radical operation followed by the Carrel-Dakin treatment. The results obtained were very much better than by other methods as all knew who have had similar experience. Any man who could not appreciate the difference in the two methods of treatment either never used the Carrel-Dakin method properly, or he would not acknowledge what he saw.

Dr. Reginald R. Sayre said that the men who said that fractures were treated in a most "rotten" way during the last fifteen years were right; they were not treated as well as they were thirty years ago. Thirty years ago the surgeon was interested in a patient with a fracture but after he found that he could open the abdomen and take out gallbladders and appendices with comparative immunity to the patient he went on seeing how much of his anatomy he could take out and he did not want to be bothered by the common or garden fractures. Fractures came to be treated not as emergencies but were simply attended to when the surgeon had nothing else to do. If the patient recovered with a shortening or 45 degree deformity it was a pity but the surgeon was more interested in actinomycosis cysts or some other weird thing that happened only once in a while. Then the war came and we looked about and realized the horrible conditions that resulted from our inadequate ways of treating fractures. Something had to be done and we went to work to learn how to apply a splint so that we did not have a wabbling fracture. The treatment of fractures was like a great many other things, there was a great difference in doing a thing the way a man who invented a procedure intended it to be done and the way some one else thought it ought to be done. There were different ways of employing the Dakin solution and the different results were according to the differences in the intelligence with which the method was carried out.

Dr. McWilliams, in closing the discussion, said that in answer to what Dr. Moorhead had said of Dakin's solution, he thought it was, as Dr. Lyle had said, that one obtained a mechanical as well as a chemical effect. One of the most valuable effects of Dakin's solution was simple irrigation. If one packed a wound with gauze it soon became very foul and the pus-soaked gauze retained the infection. Iodine solution acted as an antiseptic for a half hour or an hour, but with Dakin's solution properly employed, one had the constant irrigating effect, together with its antiseptic action for the whole 24 hours. If the tablets had an antiseptic effect, it was something worth while paying attention to. The Abbott tablets made a good solution. How Dakin would consider it, he did not know, but if one could not obtain fresh Dakin's solution, it was a perfectly good substitute. Dr. Moorhead's classification was complicated. He did not think it advisable to divide compound fractures up into four or five groups with a method for treating each group. To his mind it was better to divide them into simple punctured and larger compound fractures and to treat them accordingly. The safest thing was to dakinize the wound; there was nothing against it and it did not prolong the treatment but on the contrary shortened it. Dr. King spoke of debridement vs. Carrel-Dakin treatment. If one had to choose between the two, Dr. McWilliams would take the Carrel-Dakin treatment in preference to debridement. If one was in the country, where operative facilities were not at hand, one might use salt solution where one could not add debridement. Dr. McWilliams said Dr. Gerster went further than he had gone in his paper. He had not considered the treatment of old compound fractures where one had sequestra, etc. He believed there should be a standard treatment that the country practitioner as well as the city surgeon could adopt knowing that nothing better could be used. As to Dr. Farr's remark that if Carrel-Dakin treatment was adopted as a standard method "some would sling it about the operating room" and then say they had employed the method, he, of course, took it for granted that it would be used properly. Dakin had spent his life experimenting with all sorts of antiseptics and Dakin considered the question as to the value of this solution closed. Under these conditions it seemed that one could follow his experience rather than that of the men who merely dabbled in various antiseptics occasionally in the operating room. As it took the courts some time to come to the conclusion that *x*-ray examinations were necessary in the proper treatment of fractures, so it would not be long before the courts would look upon the Carrel-Dakin treatment of infections as the standard, necessary method and would consider the surgeon who did not use it as negligent in his duty towards the patient.

Dr. Moorhead, in closing the discussion, said it seemed to be a question of who won the war. He also had had some comparative experiences in the use of Dakin's solution, but what he had to say did not bear on war wounds but on the average civil wounds. He had tried to show from the clinical standpoint the large difference between the fractures of war and those of civil life. Of course automobile and other accidents sometimes caused the large crushing wounds of the soft parts with comminuted fractures which were in a measure comparable to war wounds, but there were many elements which were different, particularly that element having to do with infection. Dr. McWilliams had narrowed the question down when he said he did not care whether Dakin's solution or a substitute was used as it was not the solution but the technique that was effective in washing away infection and debris. It was the technique that was important. If there was the mechanical washing away one often obtained better results than with wet dressings. The point was not an insistence upon the use of the Carrel-Dakin solution but on the technique by which it was applied. He had seen Carrel-Dakin solution used very assiduously at the DePage Hospital, and he had also seen them using saline with the same technique, and the results were similar with both solutions; the technique was the thing that told. It was the careful regular instillation of the solution that washed away the debris which was one of the effective things. When he returned to this country Dr. Moorhead said he used the Carrel-Dakin solution until he had demonstrated that except for two conditions it was not usually needed; one of these was empyema and the other was osteomyelitis, whether the outgrowth of fracture or a metastatic lesion. Dakin's solution was the sovereign remedy for certain forms of osteomyelitis. The point he wished to emphasize was that the average run of compound fracture cases could be divided into three tvpes, mild, moderate and severe and could be dealt with by the procedures outlined in the paper. He did not wish to be understood as saying that the Carrel-Dakin method was a bad form of treatment, but that it involved the use of a complicated technique and that the same results could be obtained with other simpler and more easily applied standard methods.

Pericecal Tumor, X-ray Diagnosis Benefit from X-ray and Radium Therapy for Postoperative Recurrence. Dr. Sinclair Tousey presented this communication. (See page 356.)

SOUTHERN SURGICAL ASSOCIATION.

Thirty-fourth Annual Session, Held at Pinehurst, N. C., December 13, 14 and 15, 1921.

The President, Dr. Randolph Winslow of Baltimore, in the Chair.

(*Concluded from page* 348.)

Further Umbilical Cases.—Dr. Thomas S. Cullen of Baltimore gave a brief report of all the umbilical cases coming under his observation since the appearance of his book on "Diseases of the Umbilicus," in 1916. He first described a most unusual procedure he adopted when operating on a man, 78 years old, for an umbilical hernia where many loops of bowel were densely adherent to the sac. After cutting the sac loose from the abdominal wall at the hernial ring he dissected the skin away from the sac and then separated loop after loop of bowel from one another until all loops were free. He then trimmed off all loose pieces of the sac wall from the various loops, leaving

only the densely adherent patches attached to the bowel. At least thirty or forty such patches were left on the gut. The bowel was then put back into the abdomen. The patient is now 82 years old, and is perfectly well. He reported cases of amniotic hernia, Meckel's diverticulum associated with an umbilical polyp, Meckel's diverticulum containing a pin in its wall, granulation tissue at the umbilicus, infected umbilicus and tuberculous abdominal abscess opening at the umbilicus. He also demonstrated moles and nevi at the umbilicus and reported atheromatous cysts, condylomata, papillomata and adenomyomata of the umbilicus. He referred to the blue navel, a new sign sometimes found in tubal pregnancy where rupture had taken place and where an abundant amount of free blood was present in the abdominal cavity. He related a case of pseudomucinous cyst at the umbilicus secondary to an ovarian cyst of this character. He also reported several cases of secondary carcinoma of the umbilicus and one case of secondary sarcoma of the umbilicus following primary intraabdominal growths.

The Straight Vessels of the Terminal Ileum.—Dr. R. L. PAYNE of Norfolk, Va., demonstrated by illustrations the presence of one, two, or three small straight vessels running parallel with the long axis of the small bowel and situated in the last inch and one-half of the terminal ileum. This anatomical feature was found to be constant in one thousand laparotomies and he recommended this distinctive feature as a means of quick recognition of the last inch and one-half of the terminal ileum with special reference to its value as a guide to the ready and accurate location of the appendix.

Final Results in 183 Cases of Myoma of the Uterus and Myopathic Bleeding, Treated with Radium.—Dr. C. JEFF MILLER of New Orleans stated that since early in 1914 to July, 1921, 230 cases were treated by radiation, but satisfactory records were recorded in only 183 cases. The most striking feature revealed in the review of the cases treated by surgical intervention and by radiation was the increasing percentage of myomectomies performed. The decision to adopt myomectomy in many cases formerly subjected to hysterectomy was prompted by the assurance that if myomectomy failed to control hemorrhage, radium could eventually complete the cure. With such assurance the scope of conservative surgery had been materially widened and the number permanently relieved and the percentage of pregnancies that subsequently occurred, further justified the conclusion. One hundred and seven of the 183 cases of this series presented myomata varying in size between small tumors detected during the course of diagnostic curettage to ascertain the cause of bleeding and the massive growths extending above the umbilicus. There were only a few of the latter group treated, practically all of which presented contraindications to operation. The ideal type for treatment with radium was the small or moderate sized interstitial myoma. Submucous growths, while responsive to radiation, should be selected with extreme care, owing to their well-known tendency to infection and sloughing after intrauterine manipulations. One hundred and two of the 107 cases reported complete relief from hemorrhage within five months after radiation. Two of the remaining required a second application before being relieved; two others were not relieved by a second exposure and the remaining case did not return. Fifty-seven cases returned within five years for other conditions, or for examination. In 37 of these the growths could not be determined at the subsequent examination, or were so reduced as to be classed as negligible. In two instances massive growths as large as a seven months' pregnant uterus had shrunk below the umbilicus. They had been bad surgical risks and were radiated to control bleeding. Both were subsequently operated on successfully. Seventy-six of the 183 cases were instances of myopathic hemorrhages, such as were commonly classified as chronic metritis, hyperplasia, fibrosis, uterine insufficiency, etc., a condition most frequent in women approaching the menopause. In this type radium approached more nearly the ideal specific than any therapeutic agent at command. Of 18 cases under 45 years of age, in which it was desirous of controlling bleeding without producing permanent cessation of menstruation, radium was applied from eight to twelve hours until from 200 to 800 mg. hours exposures were given. Six ceased to menstruate promptly, three reported a return in one year; one was profuse, the other two a normal flow. Five continued menstruate scantily, the flow lasting the normal duration of previous menstruation. In four instances menstruation was reduced and remained regular; three cases menstruated irregularly and reported scanty menstruation every two or three months. Subsequent reports as to the symptoms of the menopause were interesting. In women over 40, where preservation of function was not considered, about 60 per cent. reported flushes and the usual phenomena of the climacterium. In many the symptoms were reported as severe, and almost invariably their history showed that the bleeding had been of the aggravated type. The duration of symptoms lasted about the average of the normal menopause, but in two cases the flushes had persisted for six years, and the patients complained that the flushes were as frequent and severe as during the first four months following radiation.

Special Points in the Surgery of the Stomach.—Dr. GEORGE W. CRILE of Cleveland said that duodenal ulcers were more strikingly relieved by operation than were gastric ulcers. In cases of acute perforation from gastric ulcer the patient was operated on at the earliest possible moment, merely a closure by suture being made. Apparently this was sufficient for, as a rule, perforating ulcers were self-cured. The management and treatment of bad risk patients was based on the probabilities rather than on the state of the patient at the moment, and just as in preventive medicine, prophylactic measures were applied in advance of the emergency. In extreme cases it might be that no striking improvement could be secured; but it should be borne in mind that even a slight gain might establish the outcome, and the patient was entitled to even the smallest advantage which no one could say might not mean the difference between life and death. As a prophylactic precaution, therefore, the following routine was rigidly enforced in all bad risk cases: (1) Before operation, water 2000-4000 c.c. by Bartlett's method of hypodermoclysis if anemia was marked; transfusion of blood, repeated if required. (2) Divided operation. Nitrous oxide oxygen only to the stage of analgesia, with local anesthesia; the briefest and slightest possible exposure; sharp knife dissection, avoidance of traction; wide excision of tumor; round needles for stomach suture; cobbler stitch; lightly tied sutures. (3) Postoperative. Warmth, transfusion of blood, maintenance of nutritional and water balance, prompt use of a stomach tube in case of vomiting. Prolonged (a year or more) control of ulcer cases. By the employment of these general measures which were always strictly adapted to the indications in the individual case, the range of operability had been extended; postoperative morbidity had been minimized, and the mortality of operations upon the stomach, including gastroenterostomies for ulcer and resections for cancer, had been reduced to 3.2 per cent.

The Treatment of Cancer of the Tongue.—Dr. CURTIS F. BURNAM of Baltimore stated that in a series of 281 tongue lesions, studied at the Howard A. Kelly Hospital, there were 207 cancerous and 74 noncancerous conditions. Among the 74 noncancerous were decubitus ulcer, syphilitic ulcer, syphilitic nodule, tuberculous nodule, tuberculous ulcer, fibroma, adenoma, and angioma. In one tuberculous lesion there was no evidence of tuberculosis elsewhere. The presence or absence of a history of syphilis or of a positive Wassermann reaction was of subordinate importance and could be misleading. The association of cancer and syphilis was frequent and both conditions when present demanded treatment. Negative general findings, as well as history and blood findings did not exclude syphilis. In two of his cases there were apparently extensive cancers of the tongue, tonsil, and contiguous lymph glands, and nothing in either history or findings to suggest syphilis, and yet both were syphilis. He believed that complete removals of the tongue were unjustifiable in early cases, and usually useless and harmful in advanced cases; that the sum total of removals in extensive neck metastases, where the disease was outside the glands, did much more harm than good. Between the years 1916 and 1920 nearly all his opera-

ble cases were treated by operation and radium employed externally as an adjunct to the treatment. During these years a large number of inoperable cancers were treated by needling, local applications in the mouth, and heavy distance radiation from the surface. In spite of shrinkage of the growth, sometimes disappearance in the tongue, and undoubted amelioration of symptoms, the results were nevertheless disappointing, for there were no cures. It was only fair to say that the technique employed in these cases was not nearly so theoretically good as that which they could employ now. Since 1920, under the stimulation received from the General Memorial Hospital, and particularly from Dr. Douglass Quick, he had taken up again the treatment of early operable cases with radium, and he agreed with his conclusion that radium had a much more definite field in treating the tongue and mouth lesions than had surgical removal. This advance in radium therapy had been made possible by the bare tube technique. It was possible by this method to eradicate, not only small and moderate sized tongue lesions, but also very large ones in a high percentage of cases treated. In the treatment of certain radiosensible sarcomas, notably lymphosarcoma, the employment of radium was more like a specific drug or serum. This was not the case in tongue cancer. Here radium methods were completely analogous to surgical methods, that is, the radium must be used in a way that would bring intense radiation to all tissues affected or likely to be affected by the cancer, but must spare surrounding undiseased normal tissues.

Surgical Treatment of Facial Paralysis.—Dr. C. C. COLEMAN of Richmond, Va., stated that operations upon the facial nerve for paralysis were indicated in those cases in which the disease or injury had produced a permanent and more or less complete interruption of the nerve trunk, or destruction of its nucleus, provided the paralysis in such cases was not associated with other serious brain lesions. Division of the nerve at the point where it branched was rarely favorable to operations upon the nerve itself, unless such operations were done promptly. The cases of facial paralysis in civil life which most often required surgery were those due to injury of the nerve during mastoid operations. Direct suture of a severed facial trunk, or its main branches, if delayed until faradic response of the peripheral segment was lost, was very difficult, or impossible. It was generally accepted that the outcome of severe traumatic paralysis of the facial nerve was uncertain in so far as regeneration of the nerve itself was concerned. Recovery might set in two or rarely three months after injury, and progress to complete restoration of function. The recovery from paralysis through regeneration of the nerve, not only permitted voluntary movement of the previously paralyzed muscles, but restored normal facial expression. These results, in so far as facial expression was concerned, were certainly superior to those obtained by fusion operations. It was advisable to allow a reasonable time for nerve regeneration while avoiding such delay as would expose the facial muscles to permanent degenerative changes. Following the suggestion of Ballance, he had waited six months before operating upon these cases, although it did not seem probable that the delay would be followed by spontaneous recovery in one of the patients. If the paralysis was complete at the end of the third month in traumatic cases and the reaction of degeneration was present, and, what was still more important, if there was a high threshhold to condense stimulation, a permanent lesion of the nerve was extremely probable. The only appropriate operation for the large majority of cases of permanent paralysis of the facial nerve replaced the inaccessible central segment of the paralyzed facial, with the corresponding segment of either the hypoglossal or spinal accessory. The value of this type of nerve fusion could not be questioned, if the operation was well conducted in suitable cases. With many others he had preferred the hypoglossal for the fusion because of its functional similarity. Movement returned after faciohypoglossal anastomosis in about three and a half months, and appeared first at the angle of the mouth in most cases, although in one patient movement was first observed in the orbicularis oculi on the one hundred and thirty-second day. The recovery of movement was preceded by improvement in the tone of the paralyzed muscles, and this had been observed about the seventy-fifth day after operation. Facial expression, imitative or actual, might be acquired after fusion. It was secondary to the recovery of isolated facial movements, and it depended upon persistent efforts at reeducation of the muscle groups. Viewed from the standpoint of relief of deformity and functional disability, the operation was a highly efficient substitute for the muscle action of a normal neuromuscular mechanism.

Notes on Enteroptosis.—Dr. ROBERT T. MORRIS of New York stated that the present day movement toward group diagnosis was gradually disposing of the tendency to treat various phases of enteroptosis separately as diagnostic entities. An immense amount of unsatisfactory surgery was still being done in this direction. However, his object was to help hold up the hands of the men who were insistent upon the study of every case of enteroptosis as a whole. Some of the cases of dilatation of the duodenum dependent upon mechanical pressure of dragging omentum or mesentery were still treated at great length by gastroenterologists without reference to the quick relief which would be obtained by methods giving relief from the mechanical obstacle. Cases of loose kidney with their various complications in these enteroptosis patients were subjected to ineffective surgical operations and this was perhaps particularly a fact with cases of congested appendix due to circulatory disturbance which was secondary to relaxation of the peritoneal supports. Various pexies of abdominal viscera in enteroptosis cases sometimes gave remarkable results for a few months, perhaps because this group of patients seemed to be particularly susceptible to suggestion. Suggestion, added to temporary relief of some one symptomatic phase, allowed these patients to gain in weight and in spirits and in general good health. A year or so later there was in general a relapse with suffering from some other complication of the original enteroptosis or some feature introduced by the surgical procedure. His enteroptosis patients represented stigmata of decline with arrested development of various organs, the endocrine group being pretty regularly defective. We should have more cases of general enteroptosis to treat because our methods of today were frankly to save the weak, giving us more of the weak in our population and these would hand on a defective progeny.

Gastrojejunocolic Fistulas Following Gastroenterostomy.—Dr. CHARLES H. MAYO of Rochester, Minn., stated that the six cases of gastrojejunocolic fistulas reported were observed among 101 gastrojejunal ulcers at the Mayo Clinic. Case histories were given. A definite syndrome accompanied gastrojejunocolic fistulas and their existence could be revealed by the roentgen ray examination in practically all cases. The onset of symptoms might occur from five weeks to nine and one-half years after gastroenterostomy. Usually symptoms developed within six months or a year. The fistula might be intermitently patent and closed. Pain was not of a definite character, but was usually lower than the pain accompanying duodenal ulcer and often a palpable mass was produced by the scar tissue in the area involved. Diarrhea, wasting, and fecal vomiting were prominent symptoms. The cause of the condition was obscure. Failures after gastroenterostomy, according to Moynihan were due to three factors: (1) Absence of a primary lesion. (2) Residual focus. (3) Technical fault. Gastrojejunal ulcer occurred in about 1 to 3 per cent. of gastroenterostomies, while in about 10 per cent. of the former a colonic fistula occurred. Thirty-four cases had been previously reported in the literature. No definite etiologic role could be assigned to trauma or mechanical factors, although it was conceded that the short loop gastroenterostomy gave the best results. The question of nonabsorbable sutures was of some importance, although jejunal ulcers sometimes followed even when absorbable sutures were used. If infection was a factor, a nearby ulcer was not necessary as a focus, but infection might possibly come from a distant lesion, such as teeth, appendix, and so forth. The action of the acid stomach secretion on jejunal mucosa should be considered in the production of these ulcers whose chronic perforation led to colonic fistula. Suturing the rent in the transverse mesocolon to the line of anastomosis was also a positive cause.

Separation of the colon from the stomach with closure of the fistula might be the only treatment necessary. It might be advisable to undo the gastroenterostomy, as patients with fistulas did not tolerate it well and a pyloroplasty could be done after excising the original ulcer. In the 31 cases of fistula reported by Bolton and Trotter the mortality was not high considering the seriousness of the condition; 27 patients were operated on; 21 recovered. There was no operative death in this series.

Ureteral Stricture, an Important Factor in So-called Idiopathic or Essential Hematuria.—Dr. Guy L. Hunner of Baltimore said an important urological problem long considered as belonging in the border zone between medicine and surgery was that of the so-called essential hematuria, occurring either with pain and colic or as a symptomless bleeding. Since the publication of James Israel's monumental work in 1901, entitled "Surgical Clinic of the Kidney Diseases," and the confirmatory work of Kretschmer in 1907, the profession had accepted Israel's views that in these cases of so-called nephralgie hematurique and essential and angioneurotic kidney bleeding there could be shown organic changes in the kidney. He accepted this view that the hemorrhages in these cases were due to inflammatory changes in the kidney, but that these changes were brought about in most cases by an obstruction to the urinary outflow due to inflammatory disease in the ureter. The local ureteral inflammation and narrowing was usually caused by a distant focal infection, and it was likely that in some cases the bleeding was due to repeated direct injury to the kidney substance by the same focal infection that started the ureteral stricture with its prolonged injury due to back pressure. Omitting many cases with slight hemorrhage or with massive hemorrhage occurring with an acute attack of renal colic, readily proven to be due to stone or stricture, and selecting only those with prolonged macroscopic or repeated massive hemorrhages, such as the profession had been classifying under idiopathic hematuria, he had seen 18 cases in women in the past three years. Three of these were patients before seen and diagnosed as essential hematuria and 15 were his last consecutive cases suffering with this malady. In all of these cases ureteral stricture was demonstrated.. In six cases with bilateral hemorrhage stricture was demonstrated on both sides. The bleeding ceased in many of these cases with no other treatment than the passage of a wax bulb. If the bleeding ceased promptly one could then inject fluids to measure the capacity of the pelvis, take pyelograms and do the other work necessary for a complete urological diagnosis. If the bleeding did not cease after two or three dilatations with the bulb, one should not lose more time, but proceed at once with the measures necessary to a full diagnosis. If these measures demonstrated the presence of a stricture and the absence of evidence of stone, tumor, or tuberculosis, one could then proceed with further dilating until the bleeding ceased. Removal of the original focal infection might be necessary before the bleeding ceased. Persistence of the bleeding and failure to find stricture or to demonstrate a definite cause for the bleeding still called for an exploratory kidney operation. Recognition of the important role that ureteral stricture played in causing essential hematuria would stop the appalling sacrifice of approximately normal kidneys, and would make unnecessary most of the customary operations of nephrotomy, decapsulation, and nephropexy.

Ideal Cholecystotomy, a Valuable Procedure in Certain Cases of Cholelithiasis.—Dr. A. Murat Willis of Richmond, Va., stated that where patients gave a history of attacks of colic, often associated with jaundice and fever, and where the physical examination revealed tenderness or tumor in the region of the gall-bladder, there was little question as to diagnosis. Opening the abdomen disclosed definite structural changes, removing all doubt as to the existence of gall-bladder disease. Here the institution of appropriate surgical treatment seldom failed to afford at least relative relief. Unfortunately, such cases as had been described represented the terminal stages of the pathological process. The patient could be spared much suffering and relief obtained with a greater degree of certainty if the diagnosis were made earlier and proper surgical treatment employed before crippling local lesions and involvement of other organs had occurred. That this attempt was accompanied by danger had been shown by the recent paper of Jacobson and by his own experience. In Jacobson's series of 365 cases, noncalculous cholecystitis was encountered 50 times; of 49 of these patients subjected to cholecystectomy, histological examination of the gall-bladder showed that in 16 instances this organ was normal. In his last 100 operations, he had made the diagnosis of noncalculous cholecystitis in 25 cases, with the result that in 10 instances the gall-bladders were found normal on histological examination. In those series where the incidence of noncalculous cholecystitis was reported as almost 40 per cent., one could not wonder how many normal gall-bladders had been sacrificed. He could not help but feel that there were instances of silent gall-stones. Such calculi might have arisen from a metabolic disturbance, unassociated with infection, or even though infection was primarily responsible for the occurrence of the stones, it was conceivable that it had been overcome and that the stones remained as sterile foreign bodies. There were thus encountered two classes of cases where it seemed unwise to employ either of the usual methods of surgical treatment; that was cholecystostomy for drainage or cholecystectomy. If the former were used in the cases of practically normal gall-bladders, in the absence of infection and pericholecystic adhesions, it would result in rendering the patient worse in many instances. On the other hand, we should hesitate to remove a normal organ. Therefore, he recognized certain definite indications for the old ideal cholecystotomy with the omission of drainage. First, in the cases of doubtful cholecystitis, where the operation was undertaken largely because of a suggestive history and where examination failed to reveal any gross changes in the gall-bladder; second, in those instances where calculi were encountered in the course of some other abdominal operation and where the patient failed to give any history of marked disturbance referable to the gall-bladder, but one must recognize that the calculi were potential sources of danger.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of North Carolina.

Raleigh, June 20, 1921.

ANATOMY.

1. Give origin of a dermoid cyst of the ovary.
2. Name the muscles of the orbital region and give their nerve supply.
3. Describe the circle of Willis.
4. Describe the portal circulation.
5. Name the nerve of expression, give its deep origin and foramen of exit.
6. Describe the thoracic duct.
7. Describe the Gasserian ganglion.
8. Bound Scarpa's triangle and give name and relation of the structures that pass through it.
9. Describe the jugular foramen, and name the structures that pass through it.
10. Name structures and in order that would be cut in an amputation at junction of middle and lower third of the thigh.

MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY.

1. Give the principal alkaloid of belladonna and indications for its use; also dose.
2. What is incompatibility in medicine, and what are the different kinds of incompatibles? Give an example of each.
3. Give a brief description of some conditions in which serum therapy has proved successful.
4. State the effect on the circulation of medicinal dose of nitroglycerine, digitalis, and strychnine.
5. Explain the effect of acetanilid and the cyanosis it sometimes produces; dose.
6. Name three useful emetics. Give dose.
7. Mention four preparations of opium and two alka-

loids; dose of each; its physiological effect; symptoms and treatment of toxic dose.

8. What remedies are useful in cerebral anemia and in cerebral hyperemia? Give doses and methods of administration.

9. Give the symptoms and treatment of strychnine poisoning.

10. Write a prescription for acute conjunctivitis. What is a mydriatic? Name two or more. What is a myotic? Name two or more.

ANSWERS.

ANATOMY.

1. *Theories as to the origin of dermoid cysts of the ovary*:—"Some believe that early in fetal life, certain portions of the fetal layers, especially the epiblast, get included in the developing ovary. While the main part is epiblastic, it is likely that mesoblastic elements are also included, helping to explain the development of bone and muscle.

"Others, *e. g.* Waldeyer, think that the epithelial elements in the ovary may in these cases have some special formative power, producing elements other than epithelium. (As Olshausen points out, if this be the case, the production of such a varied assortment of elements might deserve the name of a "parthenogenetic development.")

"Bland Sutton thinks that 'the epithelium of the ovarian follicle is the source of all the structures found in ovarian dermoids.' He makes a sharp distinction between dermoids and teratomata.

"Olshausen, on the other hand, thinks that the development of teratomata in the ovary is due to fetal inclusion, and that there is no practical genetic distinction between ovarian dermoids and teratomata.

"It is important to note that an old tubal pregnancy which had undergone lithopedion formation, and with which the ovary has been closely blended, has often been wrongly described as either a teratoma or a dermoid.

"Bland Sutton has pointed out that 'in women *dermoids have never been found growing primarily from any abdominal viscus, save the ovary.*'" (Webster's *Diseases of Women.*)

2. *Muscles of the orbital region*:—Levator palpebræ superioris, rectus superior, rectus inferior, rectus internus, inferior oblique, all supplied by the motor oculi nerve; external rectus, supplied by the abducens; and superior oblique, supplied by the patheticus.

3. The *circle of Willis* is an arterial anastomosis situated at the base of the brain. It is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

4. By the *portal circulation* is meant the capillary circulation of venous blood in the liver, between the portal and hepatic veins.

Portal Circulation: "The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins, which terminate on the posterior surface of the liver in the inferior vena cava." (Bain's *Medical Practice.*)

5. The *nerve of expression* is the facial; its *deep origin* is from the floor of the fourth ventricle; the *foramen of exit* is the stylomastoid foramen.

6. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli*, to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward, and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins. (From *Aids to Anatomy.*)

The *portions of the body drained by it* are: Both lower limbs; abdomen, except upper surface of the liver; left half of thorax; left side of head and neck, and left upper extremity.

7. The *Gasserian Ganglion* "is somewhat crescentic in form. It lies upon the sutural junction between the apex of the petrous bone and the great wing of the sphenoid bone, where it is enclosed within a recess or space, called the *cavum Meckelii*, formed by a separation of the two layers of the dura mater. The concavity of the ganglion is directed postero-medially, and it is upon this aspect that it receives the interlacing fibres of the sensory root of the trigeminal nerve; the convexity of the ganglion is directed anterolaterally and from it emerge the three main divisions of the trigeminal nerve. These are—(1) the first, or ophthalmic division; (2) the second, or maxillary division; and (3) the third, or mandibular division. The medial border of the ganglion is connected with the internal carotid sympathetic plexus by filaments of communication." (Cunningham's *Manual of Practical Anatomy.*)

8. *Scarpa's triangle* is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

9. The *jugular foramen* is formed by the temporal bone in front and externally, and the occipital bone behind and internally; it *transmits:* The inferior petrosal sinus, lateral sinus, meningeal branches of occipital and ascending pharyngeal arteries, and the glossopharyngeal, vagus, and spinal accessory nerves.

10. In a cross section of the thigh, at the junction of the middle and lower thirds there are severed: *Muscles*, Vastus internus, Rectus femoris, Crureus, Vastus externus, Biceps, Semitendinosus, Semimembranosus, Gracilis, Sartorius, Adductor magnus: *Nerves*, sciatic, long saphenous; *Arteries*, superficial femoral, anastomotic, deep femoral, perforating; skin, fascia, and the femur. The order in which these are cut in an amputation will depend upon the style or type of amputation.

MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY.

1. The *principal alkaloid of belladonna* is atropine.

Therapeutic indications: For the relief of pain, to dilate the pupil, to check secretions, for diarrhea, for asthma, for shock and collapse, for colic of all kinds, for delirium, for epilepsy, chorea and migraine, for paralysis, for cough, in constipation, in chorea, spermatorrhea, or cystitis.

Dose of atropine, 1/160 of a grain.

2. *Incompatibility* is that relation between medicines

which renders their admixture unsuitable. Incompatibility may be chemical, pharmaceutical, or therapeutic. *Chemical incompatibility* is seen in compounding an acid with a base, and forming a salt. *Pharmaceutical incompatibility* is seen in compounding a resinous tincture with an aqueous solution. *Therapeutic incompatibility* is seen when two agents are administered together which have an opposite action, such as belladonna and physostigma.

3. "*Serum-therapy proper* is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are."—(Potter's *Materia Medica.*)

Those that have proved most valuable are the diphtheria antitoxin and the antitetanic serum.

Antidiphtheritic serum (against diphtheria); administered subcutaneously; dosage, average about 3,000 units, immunizing dose for a well person about 500 units. *Antitetanic serum* (against tetanus); administered subcutaneously, or into the spinal subarachnoid space; dose, 10 to 20 c.c. repeated if necessary. *Meningococcus serum* (against cerebrospinal meningitis); administered into the spinal canal after lumbar puncture and withdrawal of about 40 c.c. of the spinal fluid; dose about 20 or 25 c.c. *Antirabic serum* (against rabies): administered subcutaneously; for about two weeks several injections are made daily with viruses of gradually increasing strength.

4. EFFECT ON THE CIRCULATION OF A MEDICINAL DOSE: of *nitroglycerine*, is a dilatation of the blood vessels, a lowering of blood pressure; of *digitalis*, is constriction of blood vessels, an increase in blood pressure, and a stronger and slower heart beat; of *strychnine*, is slight, and is due to the effect of the strychnine on the nervous system; the heart beat may be slower and stronger.

5. *Acetanilid* is an antipyretic, and acts by lowering the action of the heat regulating center and lessening heat production; at the same time it increases loss of heat by its action on the skin. It is also an analgesic. It causes cyanosis by its action on the blood—decomposing the red corpuscles, changing the hemoglobin to methemoglobin, and perhaps liberating aniline.

6. THREE EMETICS. *Apomorphine hydrochloride*, dose 1/10 of a grain given hypodermatically; *syrup of ipecac*, dose 4 drams; *antimony and potassium tartrate*, dose ½ to 1 grain.

7. FOUR PREPARATIONS OF OPIUM:—*Extract of opium*, dose ½ grain; *tincture of opium*, dose 8 minims; *camphorated tincture of opium*, dose 1 dram; *tincture of deodorized opium*, dose 8 minims.

TWO ALKALOIDS OF OPIUM:—*Morphine*, dose ⅛ grain; *codeine*, dose ½ grain.

Physiological action:—It is analgesic, hypnotic, diaphoretic, narcotic, a respiratory and cardiac stimulant (later a depressant), it checks most secretions (not perspiration), it stimulates the brain, and contracts the pupil.

Therapeutic uses:—As an anodyne, a hemostatic, in inflammations, as an expectorant, in diarrhea, in alcoholism, manias and diabetes, as an antispasmodic, in insomnia, and as a diaphoretic.

The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

Treatment: "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropine. The urine should be drawn by the catheter."—(Witthaus' *Essentials of Chemistry.*)

8. CEREBRAL ANEMIA. *Treatment.*—"In simple syncope a horizontal position, fresh air, and simple stimulant inhalants such as the familiar smelling salts are usually efficacious. In more severe attacks cold water or the electric brush externally, with coffee, alcohol, or ether internally are indicated. Tight bandaging of the abdomen (preferably) or of the limbs is frequently of value by returning blood to the general circulation. When complicating heart disease or general anemia, the treatment must be directed to these conditions."

CEREBRAL HYPEREMIA. *Treatment.*—"Venous congestion is best combated by rest, removal of any constricting clothing from the neck or abdomen, and moderate purgation."—(*Reference Handbook of the Medical Sciences.*)

9. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment.—"The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible."—(Witthaus' *Essentials of Chemistry.*)

10. For *Acute Conjunctivitis:*—

℞:—

Saturated solution of boric acid ʒij

Sig:—Use to irrigate the conjunctival sac, t.i.d.

A *mydriatic* is an agent which will cause dilatation of the pupil of the eye; *examples*, homatropine, hyoscyamine.

A *miotic* is an agent which causes contraction of the pupil; *examples*, physostigmine, pilocarpine.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

NOUVEAU TRAITÉ DE MÉDECINE, Vol. VI. By Professors G. H. ROGERS, FERNAND WIDAL, and P. J. TEISSIER. 506 pages, with illustrations. Price, 35 fr. Published by Masson et Cie., Paris.

REPORT OF THE MEDICAL RESEARCH COUNCIL FOR THE YEAR 1920-1921. By the Committee of the Privy Council for Medical Research. 114 pages. Price, 3s. 6d. net. Published by His Majesty's Stationery Office, London.

Medical History.

NEW BOOKS AND OLD.

XXIV.—SOME McDOWELL ITEMS.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

EPHRAIM McDOWELL was born, lived, died and was buried many years before it occurred to anyone that he was one of the most remarkable medical men that America has produced. In 1873 John D. Jackson, M. D., of Danville, Ky., wrote a biographical sketch, which appeared in the *Richmond and Louisville Medical Journal* and was reprinted in an "Historical Number" of the *Kentucky Medical Journal*, November, 1917. His material has been utilized by all subsequent writers. In 1890, McDowell's granddaughter, Mary Young Ridenbaugh, afterwards Mary Valentine (which has caused some confusion to McDowell's bibliographers) published a life which has been reprinted several times. It is a crude piece of work by a novice, given to extravagance at times, to vague meanderings at others, and there are errors, but in the main she has given an account of McDowell's life and work and the history of ovariotomy, and subsequent writers, while critizing severely, seem only too glad to use her laboriously collected material, often with scant or no credit.

In 1898 there appeared a short note in the *Practioner*. In 1909 J. Riddle Goffe delivered his Presidential address before the American Gynecological Society and as it was the centennial anniversary of the first of McDowell's operations he chose our worthy for his subject. His address was published in *Surgery, Gynecology and Obstetrics*, in May, 1909. In 1912 August Schachner of Louisville read a paper on McDowell before the Johns Hopkins Historical Club and this was printed in the *Bulletin of the Johns Hopkins Hospital* in May, 1913, and now the same author appears in 1921 with a complete life with an appendix on Jane Todd Crawford. This is a valuable contribution to American medical biography. It seems to be correct as far as it is possible to be correct about McDowell, who wrote next to nothing and was not chronicled by his contemporaries. It has its defects, however, which need not be dwelt upon further than to note that Schachner gives scant credit to Ridenbaugh and he gives in the text long correspondence concerning the failure to secure McDowell's house as a memorial, and his searching out of various facts. All this had better been put in an appendix, for it gives one an impression of too much Schachner where McDowell is the only interest.

Schachner gives a good bibliography, from which the above items were gleaned. The ones noted were the only ones consulted. There are many more, but one can get a very fair estimate from what I have mentioned. Schachner's book also contains a number of good illustrations and various items of historical interest. It is a pity he did not reprint the address of Samuel D. Gross at the dedication of the McDowell monument. This is well worth reading, even if a bit oratorical. It may be found in Ridenbaugh and in the number of the *Kentucky Medical Journal*, mention of which has already been made.

Ephraim McDowell was born Nov. 11, 1771, in Rockbridge County, Virginia. His ancestors were Scotch people who came to this country by the way of Ireland, hence it is often stated that he is of Scotch-Irish descent. His parents removed to Kentucky, where his father became a judge of the First District Court, which was eventually removed to Danville, the first capital of the state. In 1790 it boasted of 150 inhabitants. Not much is known of his early education. He was thirteen years old when he reached Kentucky and just what schooling he had is conjecture. When he was about nineteen he began the study of medicine with Dr. Alexander Humphries, a graduate of the University of Edinburgh, and it was to the same University that McDowell repaired in 1793. He attended the sessions of 1793 and 1794 but did not receive any degree. In 1825 the University of Maryland conferred on him an honorary M.D. In 1795 he returned to Danville and began the practice of medicine and fourteen years later on Dec. 13, 1809, he was called to see Jane Todd Crawford, the wife of Thomas Crawford of Caney Fork, some sixty miles away from Danville. The diagnosis of an ovarian cyst having been made McDowell explained the nature of the disease and the possibility of removing the cyst by operation, which he promised to do if the patient would come to Danville. McDowell described the operation in one of his two short printed articles. Nearly ten years elapsed before he saw fit to print in the *Eclectic Repertory* in 1817 the description of three cases of ovariotomy. His contribution is commendably short and his description of the operation of Mrs. Crawford is as follows:

"Having placed her on a table of the ordinary height, on her back, and removed all her dressing which might in any way impede the operation, I made an incision about three inches from the musculus rectus abdominis, on the left side, continuing the same nine inches in length, parallel with the fibers of the above-named muscle, extending into the cavity of the abdomen, the parietes of which were a good deal confused, which we ascribed to the resting of the tumor on the horn of the saddle during her journey. The tumor then appeared full in view, but was so large that we could not take it away entire. We put a strong ligature around the Fallopian tube near the uterus, and then cut open the tumor, which was the ovarium and fimbrious part of the Fallopian tube very much enlarged. We took out fifteen pounds of a dirty, gelatinous-looking substance, after which we cut through the Fallopian tube and extracted the sack, which weighed seven pounds and one-half. As soon as the external opening was made the intestines rushed out upon the table, and so completely was the abdomen filled by the tumor that they could not be replaced during the operation, which was terminated in about twenty-five minutes. We then turned her upon her left side, so as to permit the blood to escape, after which we closed the external opening with the interrupted suture, leaving out, at the lower end of the incision, the ligature which surrounded the Fallopian tube. Between every two stitches we put a strip of adhesive plaster, which, by keeping the parts in contact, hastened the healing of the incision. We then applied the usual dressings, put her to bed, and prescribed a strict observance of the antiphlogistic regimen. In five days I visited her, and much to my astonishment found her engaged in making up her bed. I gave her particular caution for the future, and in twenty-five days she returned home as she came [*i.e.* on horseback], in good health, which she continues to enjoy."

This contribution eventually started up a very considerable controversy, accounts of which are

given both by Schachner and Ridenbaugh. Two years lated McDowell made another contribution to medical literature in the form of a letter addressed to Dr. James, entitled "Observations on Diseased Ovaria," printed in the same medical journal. There exist records of eight cases of ovariotomy performed by McDowell and there may have been others. Five of these eight cases were complete operations and three were incomplete. There was only one death. This is a very remarkable record, certainly as good or nearly as good as the results obtained at the present time. When one considers the conditions under which McDowell had to operate and the fact that he was performing an operation which had never before been attempted, one gets some idea of the quality of mind of the man, of his courage, of his understanding, and of his technical skill, which must have been very great indeed. McDowell was not the first to operate on an ovarian tumor. Houston in 1701 opened and drained a cyst but he did not make any attempt to remove it and so did not obtain a perfect cure that resulted in McDowell's successful cases. It is said that the removal of healthy ovaries was practiced by the ancients and during the middle ages. Schachner states that Felix Plater of Basle considered the possibility of taking out abnormal ovaries as a curative measure and Schorkopff five years later held the same opinion but of course nothing was done but to mention a possibility.

Anyone interested in the study of this subject will find an account by W. L. Atlee in the Transactions of the American Medical Association, 1851, in which he gives a table of all the known operations of ovariotomy from 1781 to 1851; and a very considerable amount of material is given also by Ridenbaugh and by Schachner.

John D. Jackson in the biographical sketch mentioned above gives the following account which has been much quoted, often indeed without acknowledging the source.

"Dr. McDowell, in person, was nearly six feet in height, of commanding carriage, of a rather florid complexion, with black eyes and dark hair, and deemed in youth a quite handsome man. He was always remarkable for his strength and agility, and while at Edinburgh was pronounced the swiftest foot-racer of the whole university. He was one of the kindest-hearted and most amiable men, overflowing with cheerfulness and good humor, and readily approachable by the world. He seemed to be totally devoid of all reserve and austerity, a tinge of which is generally characteristic of the scholar and professional man, and never appeared to assume that there was any difference between the place of his vocation and that of the humblest unlettered artisan. This seemed instinctively to strike all who came in contact with him, and an easiness amounting almost to familiarity existed between him and his fellow-citizens. So true was this that with the masses, probably because of this very fact, he was not generally appreciated for his true worth. A man in manner arrogating to himself nothing above the populace, as may readily be believed, would not, save by those gifted with something above common penetration be acknowledged to be superior to their sphere. Never, however, was any of this air of familiarity in the slightest degree tinctured with professional demagoguery. His bitterest enemies did not once accuse him of this. By a gentleman of keen perception, yet living, whose father's family physician he was, I am told that never was there a man whose life was freer from the acts of the charlatan, or more entirely devoid of all the petty "tricks of trade," which too frequently disgrace the medical profession. While in the sick room, though he was fond of gossiping about local matters and the events of the day, he habitually refrained from discussing things medical, or any of the affairs of his rivals, with some of whom he was publicly known to be on anything but good terms. While in daily competition with certain members of the profession, whose chief strength was in the application of such arts, they and their artifices were held in supreme contempt by him. From what we can learn, one of the constant endeavors of these gentlemen, who knew that they never could approach McDowell by fair competition, was to try to train the community to believe that there was a sort of essential incompatibility between surgery and medicine, and that because he was infinitely their superior in surgical knowledge and manual dexterity, just by so much was he their inferior in all the intricacies of the practice of medicine, whose arcana were not so appreciably evident to the public as the more demonstrable work of the surgeon. Or, as they were in the habit of putting it, that while he was a bold surgeon, he was but a poor "fever doctor." So far from this being the case, however, he kept himself fully abreast with the progress of medicine by reading all that was new on the subject, and was probably really as far in advance of his competitors in physic as in surgery."

McDowell died when fifty-nine years of age on June 20, 1830, and he was buried in the family burial ground of the Shelby's, one of whose daughters he had married at Travelers' Rest, about five miles from Danville. His wife was interred by his side when she died some ten years later. From this time until 1879 his grave was neglected but through the activity of tthe Kentucky State Medical Society the old Danville Cemetery was bought and made into McDowell Park and the bodies removed and buried near the shaft which is erected as a memorial to Kentucky's greatest surgeon. Schachner devotes a chapter to the McDowell portraits, which he reproduces, and he also uses as one of his illustrations Knapp's painting entitled "The First Ovariotomy."

McDowell is such an outstanding figure in the history of American surgery that this new volume is most welcome and the author is to be congratulated on the mass of facts which he has accumulated. The book should be on the shelves of very medical library. At some future date some one will make McDowell the subject of a biographical essay which will at once contain all the essential facts with the charm of diction of an Osler or an Allbutt.

Chaulmoogra Oil and Leprosy.—The United States Public Health Service has issued a statement with the object of preventing optimistic and extravagant claims recently appearing in the newspapers in regard to the curative effects of chaulmoogra oil derivatives on leprosy. The statement asserts that, while the use of the oil and of its derivatives has resulted in a considerable number of apparent cures, it is as yet too soon to tell whether these will be permanent. The ethyl esters of chaulmoogra oil, the use of which has largely supplanted the oil itself, constitute a most valuable agent in the treatment of leprosy. In treating young persons and those in the early stages of the disease, the improvement has been rapid and striking; in older persons and older cases it is less so. Of the cases paroled from the leprosy stations in the Hawaiian Islands so far about 8 per cent have relapsed and returned for treatment. On the whole the results have been very favorable.

THE BIOLOGICAL DOSAGE OF *X*-RAY.*

BY FRANCIS CARTER WOOD, M.D.,

NEW YORK.

THE treatment of malignant disease by the roentgen ray is passing through the same phases that were observed in the course of development of radium therapy, in that a period of indifference was followed by enormous enthusiasm and overestimation of the real value of radium, and this in turn was succeeded by a sharp reaction, well voiced by the statements of Dr. John B. Deaver and others implying that radium was of no value in the treatment of cancer, and corroborated by the very important letter appearing in the daily press and signed by two trustees of the Memorial Hospital to the effect that the physicians in charge of the work in that institution were issuing no published statements concerning cures, preferring to suspend judgment until such time as final decision might be reached. Such a conservative attitude on a question still in the experimental stage is of course highly desirable.

Unfortunately, roentgen-ray treatment is now apparently entering the phase of exaggerated enthusiasm. A number of absurd claims as to the great therapeutic value of the rays, especially those from the newly developed types of *x*-ray machines have been made. These new machines, however, yield effective voltages at the most not much more than 40 per cent. higher than those of the old type; and that a machine running at 200,000 or even 250,000 volts could produce miracles, where one running at 150,000 volts did not, would be an interesting phenomenon indeed, especially when we consider that the only advantage of the higher voltage is in the greater output of short wave-lengths from the tube, with a corresponding ability to put a larger dose of *x*-ray in a shorter time into the deeper tissues of the body. The phenomenon would be the more remarkable since radium, which gives off an abundance of rays corresponding to 200,000 to 250,000 volts, is still acknowledged by even its most enthusiastic supporters to be powerless to effect a cure in many types of internal cancer.

Another reason for deprecating the raising of any undue hope concerning the effectiveness of the new *x*-ray apparatus in the permanent cure of cancer is the fact that, as shown experimentally in the Crocker Institute, the rays produced by high voltages are no more potent in killing standard animal tumors than are any other types of *x*-ray, about five erythema doses being required, no matter what the voltage or the filtration. Hence, as the erythema dose is still the limit of the amount of radiation which can be given to internal tumors, the sole gain from the therapeutic point of view is, as stated above, the increased penetration and greater output of useful radiation from the tube.

While, therefore, it may be confidently expected that the employment of voltages up to 300,000 will offer a distinct advance in the effectiveness of our methods of treatment as soon as *x*-ray tubes which will run effectively at a voltage of 250,000 or above are built, it is equally certain that the operation of these machines will require so much technical knowledge and will be fraught with so many perils to the patient (not on account of short circuits, as is commonly assumed by the layman, but because of the large yield of *x*-ray which can be passed through the body) that their use will be limited to institutions or to highly trained specialists. The therapeusis of cancer will by this simple step be placed on a much better basis than it is at present, when so many physicians in the possession of a few milligrams of radium are treating all types of cancer, and those with old-fashioned low voltage transformers are attempting deep therapy, with the sole result that the tumor either is not influenced or is stimulated.

The dosage of radium is comparatively a simple matter to determine, because of the constancy of the energy output of the material. The measurement of the actual biological dose is not so easy, because of the complications produced by the shape of the containers and by the inverse-square law. Nevertheless, a fairly satisfactory body of information has been obtained as to the dosage of this substance. With *x*-ray, on the contrary, we have had to rely mainly upon a single biological unit, that required to produce erythema of the skin. The older methods of estimating this dosage, such as the Sabouraud pastille, the Kienbock strips, and so on, while satisfactory for unfiltered rays and short dosage, have not proved reliable when applied to the evaluation of highly filtered *x*-rays. The mere physical constants of the machine are not sufficient to determine the dose. For example, it has long been assumed by the practitioners of the art of superficial roentgen-ray therapy that the voltage and current through the tube determined the dose, but as a matter of fact, this is far from being generally true, as is concretely illustrated by the fact brought out by Coolidge and Duane, and suggested by Lilienfeld in one of his papers, that the output of the tube at the same voltage and the same milliamperage increases with the number of cycles of the current, and, when a continuous current is em-

*Read at a meeting of the New York Academy of Medicine, January 5, 1922.

ployed, is considerably greater than when the alternating current is used. Thus, the voltage and the current do not determine the yield of the tube. In addition, these differences have also been verified at the Crocker Institute by determining the lethal dose of *x*-rays from a commercial 60 cycle rectifying transformer as compared with those from an experimental continuous current *x*-ray machine. The latter is more effective.

Even the measurement of the output of the tube by the ionization method implies several assumptions, one being that the saturation current varies directly with the quantity of *x*-ray absorbed in the gas of the chamber. This assumption is generally made, but is regarded by some physicists as still open to question. Assuming ionization measurements to be the correct method of determining the total quantity of *x*-ray energy in a given beam emitted by a tube, we are by no means in a position to correlate the figures so gained with what we want to know practically, and that is the death point of malignant tumors. The future of radiotherapy is dependent upon the answer to this question. If it be true that most human tumors require at least five erythema doses for their complete destruction, then the ultimate conquest of internal cancer is still very far off, because the human body can not stand the exhibition of the amount of radiation required to place such a dose in the deeper tissues, especially those of the abdomen. Of course, it is understood that the basal-cell tumors of the face are always excepted, since it has been known for years that most of them will disappear with one or two erythema doses, provided that they have not invaded cartilage or bone, when the effective dose becomes much higher.

What are the facts concerning the susceptibility of human tumors? There has, unfortunately, been only a little accurate information published. Bumm has stated that about four erythema doses are required to kill a tumor, and he is speaking of the type which is often, though not always, especially susceptible, notably carcinomata of the cervix. Seitz and Wintz, on the other hand, have published the statement that carcinoma can be killed by a dose of about 120 per cent of a skin erythema, and that sarcoma requires less. Krönig and Friedrich give a carcinoma dose slightly different; but in a very cautious footnote they call attention to the fact that they by no means assume that this dose will cure a cancer, and that it is only the quantity which will cause a secondary subcutaneous nodule to disappear. Inasmuch as anyone who has run an *x*-ray machine therapeutically knows that secondary nodules of the skin disappear with very different dosages, the absurdity of attempting to set up a standardized dose by this means is evident. My own clinical experience in this regard has been somewhat limited, as I have been interested in the therapeutic phase of *x*-rays for only the last five years, but during that time a very large number of patients have applied for and received treatment at the Crocker Laboratory. Many of those who were inoperable were willing to permit the use of fairly heavy doses in testing the susceptibility of skin metastases. My own impression from these tests is that while a light erythema would cause a disappearance of nodules in a small proportion of cases, in general a larger dose is required, and some tumors are exceedingly resistant. I feel also that the radium resistance of tumors is comparable to that of *x*-ray, and fortunately have had the opportunity for many years to watch the effects of small and large doses of radium on human tumors. The impression gained has been that while in some instances it is easy to cause a shrinkage of highly malignant neoplasms, yet they readily return, showing that the effect was largely on the capillaries and mitotic cells, and that ultimately such tumors recurred from the better nourished peripheral portions where the active blood supply sustained the injured tumor cells during the radiation and prevented their death. Our experiments with animal tumors have confirmed this impression. Of course it is well known that there are some tumors, especially the osteochondro-sarcomata, which resist any dosage, either of *x*-ray or of radium, that can be applied to them. Similar variations in radiosensitivity have been observed in a large series of mouse and rat tumors at the Crocker Institute, some of these tumors being killed by two erythema doses, and some requiring nine, while the average on such a growth as the Flexner rat carcinoma is five.

The standard erythema dose for clinical use has usually been considered that established by Sabouraud on his barium platino-cyanide pastilles. This gives a light erythema of the skin with unfiltered rays, but, as is well known, the skin of different portions of the body varies in its sensibility, and the skin of different persons also varies slightly, so that the Sabouraud erythema is not a fixed quantity. In this country most of those who have been engaged in the therapy of malignant growths have tried not to produce an erythema of the skin during the course of treatment. In Germany, however, the earlier workers, especially the gynecologists, produced serious burns in their effort to introduce large doses into the depths of the pelvis. Such a burn precludes any further administration of *x*-ray for a long time, and may result in prolonged disability to the patient. Warnekros has established as the erythema dose which he considers necessary to enable him to give sufficient radiation to a deep seated tumor one which produces vesiculation but does not cause irreparable damage to the skin. This is perhaps fifty per cent. higher than the dose of Seitz and Wintz, who define an erythema as a reddening appearing at the end of eight to ten days after the treatment.

Thus, we have an equation with three variables: the dose of the tumor to be treated, the amount which the skin will stand plus the capacity of the patient to bear a sufficient dosage. And yet every time a treatment of an internal malignant tumor is undertaken these three factors should be known. In this dilemma it seems to me not impossible that it may be of advantage to use some of the facts obtained by treating highly malignant mouse tumors with *x*-ray or radium. The usual way to determine an erythema dose is to make a series of cautious exposures on complacent patients, until after a period of several months the dose is determined. This implies, however, that every time the machine is readjusted or the apparatus is changed there may be slight differences in the yield of the tube. It is probable that the wave form of the transformer

may be slightly altered by adjustments of the rotating switch and give quite a little difference in the output without this fact being indicated on the milliammeter; such is the common belief of the electrical engineers of the manufacturing corporations. It is extremely time consuming to check the erythema dose continually on patients.

On the other hand, the determination of the lethal dose for a mouse tumor is a fairly simple matter. A few hours' exposure of such a mouse tumor as the Crocker Institute No. 180, the lethal dose for which is about five and a half erythema doses, with subsequent inoculation of a few hundred mice, will give an approximate determination in a few weeks time, and every machine in the United States so calibrated will be comparable to every other machine. We would thus at one stroke all be speaking the same language. It is further possible that, if a general agreement were reached among radiologists, the commercial makers of electrical apparatus might be induced to construct a simple and rugged ionization apparatus which could be then calibrated in biological units, using this mouse tumor as a basis. This would be necessary because the ionization chamber of the ordinary type does not read biologically, but only physically, and the two values do not necessarily coincide. If this standardized procedure could be generally effected the dosage for any treatment could be read instantly, filter and tissue absorption of the patient read off and we would immediately have a basis for attack of the second problem, that is, the accurate determination of the amount of *x*-ray required to kill a human tumor, considering this either in erythema doses or in standard mouse tumor doses.

For example, I happen to know that with a given machine running at 165,000 volts through a filter of 0.5 mm. zinc plus 1 mm. aluminum, and 5 milliamperes of current, the threshold erythema at 40 cm. distance is 40 minutes. Mouse tumor No. 180 is killed under the specified conditions in about 3 hours and 30 minutes continuous running. At 120,000 volts, with 3 mm. of aluminum as a filter, at 23 cm. distance, 65 minutes are required and the corresponding erythema is 12 minutes. I have applied two erythema doses under both these sets of conditions; that is, a dose considerably larger than the Seitz and Wintz cancer dose, to a number of superficial tumors of various types without curing any one of them. Some of these have been so located that larger doses can be applied, and even three erythema doses have been given to certain tumors without permanently influencing them. This is an illustration of the way in which we may obtain data. Unless such observations are collected in various portions of the country and various types of machines standardized biologically as has been suggested we will not have a body of facts sufficient to warrant our making any assumption as to the ultimate value of radiation in the treatment of tumors. The difficulty has been in the past that no two workers had the same technique; the tumors were rarely examined microscopically; sections for check-up diagnosis between two individual radiologists were rarely available; and the erythema dose of each worker's machine was not accurately known. It is of the greatest importance that the problem be attacked as quickly as possible by a large number of radiologists who are willing to cooperate and collect data with a common basis. Every one of us has patients who are inoperable and incurable by any method of treatment. I have always found such patients willing to help science by undergoing even more than temporary discomfort. By testing the dosage on these patients as soon as microscopical diagnosis is available we can soon have a large amount of information, and possibly get a basis on which the morphology of the tumor would indicate its biology. This has not been possible to decide with animal tumors, except that in general fibrosarcomata are more resistant than the more rapidly growing and vascular types, either epithelial or connective tissue; but in many we have two classes already determined, the lymphosarcomata, and the basal-cell epitheliomata, both of which yield in most instances at least to an erythema dose or even less. It has also been shown by the work at the Memorial Hospital that the embryonic type of teratomata of the testicle is in general radiosensitive. Occasionally, however, marked exceptions are met with, as further experience has shown. Certain types of carcinoma of the body of the uterus and of the cervix have also been shown to belong to the radiosensitive group of tumors, notably by Regaud. This is a small harvest of fact for many years' work.

Unfortunately, it is difficult, if not impossible, to compare the results of the different radiotherapeutic clinics, and it is to be hoped that the committee appointed by the American Surgical Association to study the end results of radiation therapy will be able to report the facts obtained in the next few years in such form and with suitable illustrations, so that not only may the pathologist be informed as to which types of tumor have yielded, but a better standardization of radiation methods may be developed.

Optimism is a poor cure for cancer, and it has not been apparent that the current practice of some radiotherapeutists of criticising the results of cancer surgery has added in any way to the number of cures produced by radiation. The Census Bureau reports that the cancer death rate has risen again this year, and evidently the combined labors of surgeons and radiologists have not made a great impress as yet on the total cancer mortality of the country. The only way to meet the challenge of the disease is, in the first place, by wide publicity as to the importance of early diagnosis and treatment, second, by perfect frankness as regards the relatively small number of patients who come in time for any curative procedure, and, finally, by a close cooperation between the pathologist, the surgeon, and the radiotherapeutist and careful analysis of the ultimate results. At the present moment it is only the quack who is optimistic about the cure of any large proportion of persons suffering from cancer.

1145 Amsterdam Avenue.

Seat of the Pain in Bellyache.—According to Bruning the pain of bellyache cannot be seated in the intestines, which are innervated by the sympathetic, but is localized in the large intermediate ganglia. The umbilical pain in beginning appendicitis is in reality due to contraction of the musculature of the appendix and perhaps of the cecum as well.—Wiener klinische Wochenschrift.

THE CHEMISTRY OF PHOSPHORUS IN BRAIN ACTIVITY.*

By WILLIAM HENRY PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, ETC.

Phosphorus, like iron, sulphur, and manganese, is classed among the inorganic elements. As such it acts within the body and upon the system in the same manner as do all inorganic compounds. All inorganic compounds act by virtue of their irritating and, in this sense, poisonous properties, some being more highly toxic in their action than some of the other elements or their combinations. By virtue of this irritative action they excite sluggish and inactive protoplasmic masses or cells into a higher and more normal biological activity. This is always accomplished without any change in the chemical composition of the inorganic compounds or substance administered.

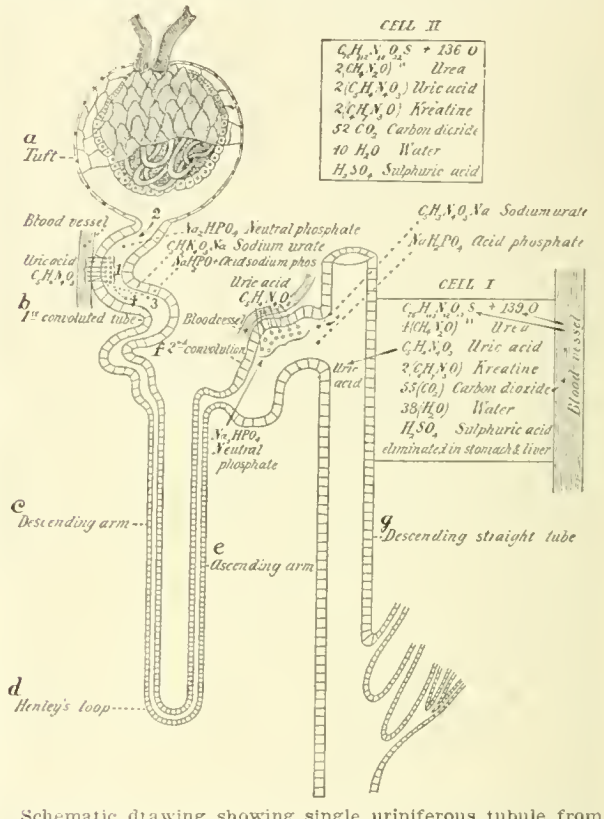
Phosphorus when pure is highly toxic, but when combined with soda or calcium and magnesium it loses almost all of its poisonous properties and becomes one of the essential constituents of the human economy.

Phosphorus in combination with soda serves the physiological economy in three distinct processes:

First, in connection with the digestive functions. At this point the trisodic phosphate is acted upon in the lumen of the intestinal tract, which is outside the body, by the hydrochloric acid and converted into a disodic monohydrogen phosphate. Thus $2(HCl) + 2(Na_3PO_4) = 2(Na_2HPO_4) + 2(NaCl)$. As stated by all physiologists, the disodic monohydrogen phosphate is the true alkalinizer of the body fluids and tissues. As a high state of alkalinity is essential to a perfect oxidation and assimilation, it is necessary to continuously supply the system with this particular phosphate compound; otherwise the socalled acidosis condition will develop from depletion of the alkali reserve. As this particular salt does not exist in the food elements, it must be produced by the chemical mutation in the intestinal tract as already described. In this manner we rid the chyme of the hydrochloric acid that was produced in the stomach in connection with the elimination of the sulphur atom in the protein substances, and by which process sulphate of sodium is continuously produced and supplied to the system in larger amounts than is secured as sulphates ingested with the food. These chemical mutations restore the chloride of sodium lost in the stomach in the manufacture of hydrochloric acid. So that by these two processes the intake and output of sodium chloride is normally always the same, while the output of sodium sulphate is always in excess of the intake.

Second: The disodic monohydrogen phosphate, as already stated, is the true alkalinizer of the fluids and tissues of the animal economy, and by virtue of this high alkalinity keeps body oxidation at the highest possible level, thus making assimilation more nearly or absolutely perfect.

Third: After the disodic monohydrogen phosphate has served its purpose in the fluids and tissues of the body, it is excreted through the malpighian tufts of the kidneys. From this point the disodic monohydrogen phosphate flows down the lumen of the uriniferous tubules until it meets a uric acid molecule, as this acid drops from the renal cell into the lumen of the tube. At this point, which in the true sense is again outside the body, the uric acid attacks the disodic monohydrogen phosphate and transforms it into the acid, monosodic dihydrogen phosphate which is the true acidifier of the urine. Thus $C_5H_4N_4O_3 + Na_2HPO_4 = C_5H_3N_4O_3Na + NaH_2PO$. In this manner the uric acid is changed to a urate, which is a much more soluble substance than uric acid, and also less irritating to the bladder mucous membrane. (See the illustration.)



Schematic drawing showing single uriniferous tubule from Malpighian tuft to papilla or its outlet. (*a*) Malpighian tuft and blood vessels. (*b*) First convolution. (*c*) Descending arm of loop. (*d*) Henley's loop. (*e*) Ascending arm of loop. (*f*) Second convolution. (*g*) Straight or collecting tube. 1. Uric acid molecule dropping into lumen of tube. 2. Neutral phosphate of soda molecule as it unites with the uric acid to form. 3. The acid phosphate of soda; and 4. The urate of soda formed by this chemical mutation. Cell. I. Magnified single renal cell, with lumen of the tube on one side and the blood vessel on the opposite side, illustrating normal oxidation of proteid molecule within the protoplasm of the cell. The proteid and oxygen coming from the blood into the cell, where it breaks up into its reduction products. The uric acid dropping into the lumen of the tube, while the carbon dioxide flows back into the blood. All the other reduction products dropping into the tube as does the uric acid. The sulphur being eliminated as a sulphate. Cell II. Magnified cell illustrating abnormal or suboxidation in the renal cell. Urea diminished one-half, while the uric acid is overproduced fifty per cent. In both the normal and abnormal oxidation the sulphur is found in the urine as a sulphate. The sulphuric acid molecule represented by the formula H_2SO_4 in Cell II, when it reaches the urine, is in the form of a sulphate Na_2SO_4 or "Glauber's" salt. This salt being produced in connection with the oxidation reduction of the protein elements, in some of the gastric epithelia, in the process of producing sulphuric and hydrochloric acid.

The phosphorus is found also in combination with calcium, forming several types of salts, some of which are fairly soluble, while others are absolutely insoluble. This latter class, when enmeshed with the protein substances, gives the solodity to the bony structures of the body.

*Read at the Three Hundred and Ninety-third Regular Meeting of the New York Neurological Society, January 3, 1922.

Phosphorus is also found in the animal economy in combination with magnesium and potassium. The two combinations already mentioned, sodium and calcium, however, are the most important. It must, however, be remembered that the amount of phosphorus entering the system daily in these mineral combinations is exceedingly small; far less than will account for the phosphorus eliminated as phosphates.

The second manner in which phosphorus reaches the fluids and tissues of the body is when it is combined with carbon, hydrogen, nitrogen, and oxygen, to form lecithine, nucleoalbumen, nucleic acid, phytin, etc. Phytin is the phosphorus principle of green plants but contains no nitrogen; its molecule is represented by the formula $C_6H_8P_2O_9$; that of Lecithine is represented by the following formula: $C_{44}H_{90}NPO_9$.

When the phosphorus is combined in these complex molecules it is often (but erroneously) called organic phosphorus. This, however, leads always to a misconception of a fact, for phosphorus itself is always an inorganic element.

This group of complex bodies carrying phosphorus is, however, an exceedingly interesting and important class of substances. The manner or process by which they are produced is pretty well understood; but how they act within the system, and the precise method by which they ultimately are eliminated from the body, have never been satisfactorily elucidated. At the same time there seems to be an abundance of empirical data in support of the therapeutic value of these phosphorus bearing compounds. The purpose of this study of these phosphorus bearing compounds is with the hope that their action can be more clearly defined.

Bunge makes the following statement: "In the plant, phosphoric acid takes part in the formation of very complicated combinations—of the various forms of lecithine and neuclein, which are integral constituents of every vegetable and animal cell. It is chiefly in these combinations, and only to a small extent as salts, that phosphorus enters the animal body, which it leaves in the same form that it enters the plant—as a phosphate." In other words, phosphorus enters plant life as a phosphate to be synthesized into these highly complex bodies containing a large number of carbon and hydrogen atoms. Bunge, as we have already stated, makes the positive statement that phosphorus is eliminated from the body as a phosphate. Therefore, the explanation of the physiological action of these substances must be along the lines of oxidation reduction and the conversion of these complex phosphorus bodies into a phosphate.

My contention for years has been that oxidation reduction takes place in the protoplasmic structure of the fixed cells only as found in the various glands of the body and not in the fluids and tissues of the body; that this process constitutes in a large measure the biologic activity of the body cells, as it occurs, for instance, in the cells of all the secretory and excretory structures of the body. In support of this theory, it is a well known fact that fluids within the body contain minute traces only of any of the catabolic bodies, while on the other hand both the secretions and excretions contain a high percentage of the catabolic substances which are constantly being eliminated from the system. The one exception to this general method of eliminating the catabolins is the catabolin carbon dioxide. This element is taken from the cell where it is produced by the process of oxidation reduction into the blood stream by the carbonate of soda being change to a bicarbonate by the added carbon dioxide and water. As a bicarbonate it flows on to the lungs, where the carbon dioxide and water are discharged into the air sacs and the bicarbonate reverts again to a carbonate of soda, as illustrated by the following equation: $Na_2CO_3 + CO_2 + H_2O = 2(NaHCO_3) — CO_2 — H_2O = Na_2CO_3$.

In connection with these oxidation reduction processes and the exact place where they occur, it should be remembered that the ganglion cells of the nervous system are large masses of protoplasm resembling the cellular structures of the glandular organs, not in shape but in composition; that in all probability they are the place in the animal economy at which these complex phosphorus bearing bodies are oxidized and reduced to their catabolic end products.

To produce energy emanating directly from the central nervous system, there must be some form of oxidation reduction with the production of heat energy, or some other form of energizing impulses generated at this point.

The reasons for this interpretation are the fact that these protoplasmic masses are very abundant in the central nervous system; that these complex phosphorus bearing compounds are found in larger amounts at this point than in any other parts of the animal economy; and also that there seems to be a decided generation of impulses originating in the central nervous system which controls and regulates the automatic balance of the human system—a condition which could not be maintained if the nervous energy was due solely to reflected heat energy brought to the central nervous system by the centripetal nerves and reflected out again by the centrifugal nerves. By this process alone there could be no inherent, intrinsic nerve force emanating directly from the brain and spinal system.

Again, when the central nervous system is actively at work it is always accompanied by an increased elimination of the alkaline phosphates; which tends to support the theory that these phosphorus bearing bodies are oxidatively reduced in the protoplasmic masses which constitute the cells of the central nervous system. Hence, increased elimination of the alkaline phosphates indicates a simple augmented physiological activity of the nervous system, and not a pathological state. On the other hand, over elimination of the earthy phosphates in a highly acid urine always indicates a malnutrition state in which the nervous mechanism is chiefly involved.

We have already indicated by the quotation from Bunge how these complex phosphorus bearing bodies are produced and how they enter the system in the composition of various food elements.

The question pressing hardest for an answer, however, is how and by what method these complex bodies can be converted into energy, and phosphates and how do they pass out of the system?

If we accept the theory that the protoplasmic masses of the central nervous system have the

power to bring about the oxidation reduction of this particular class of bodies, as other cells by a similar process reduce the carbohydrates, fats, and proteins, the explanation is comparatively easy.

At this point it is well to remember that it has been fully established that there is no true synthesis in connection with animal life as occurs in plant life. That is to say, the chemical mutations in animal life cannot take up the free atoms of carbon, nitrogen or nitrates, hydrogen, sulphur and phosphorus and build them up into proteins or these more complex substances. On the other hand, animal chemistry can break down and rearrange the contained units that have been constructed by synthesis in plant life, and rearrange them so that they can be converted into the animal tissues and structures. It also has the power by oxidative elimination to throw out those units that cannot be converted into animal proteins, phosphorus and iron bearing substances that must enter into the anatomical construction of the human body. Finally when these various substances have served their useful purpose in the animal economy, they are further oxidized into the simple catabolins, in which form they escape from the system.

Therefore in the elucidation of the physiological actions and final elimination of these complex phosphorus bearing substances we must hold close to the laws governing plant and animal life. In the latter we are dealing almost exclusively with the law of oxidation reduction and selection of those elements that can be constructed into the body fluids, cells and tissues of all kinds.

Assuming, therefore, that the nerve cells have the power to draw nascent oxygen into their protoplasmic structure and exercise this oxidation selection and reduction of these complex phosphorus bearing bodies and reduce them to much less complex or simple forms, the explanation is now easy, for by this oxidation reduction the lecithine, for instance, is oxidatively reduced to a phosphate of soda, urea, carbon dioxide and water. Thus $2(C_{44}H_{90}NPO_9) + 2(Na_2CO_3) + H_2O + 264\ (O) = 2(Na_2HPO_4) + 90(CO_2) + 90(H_2O) + CH_4N_2O$.

While speaking of phosphorus in connection with some of the other inorganic substances, Brunton says that "Living protoplasm has the power of oxidizing all members of this group, and also of reducing their products of oxidation" (Binz). "It is probable that this action goes on more easily with phosphorus than with nitrogen. Hence, if phosphorus replaces nitrogen in a living cell it will quicken metabolism."

Further than this it is stated that phosphorus increases bone growth and tends to make it more dense. The general augmented metabolism would easily account for this latter fact, for it has been recognized for a long time that bone deficiency is not due to a lack of lime salts or bone producing elements, but due to a disturbance of metabolism which prevents fixation of the calcium salts. In the breaking up of this highly complex phosphorus bearing molecule it is reasonable to suppose that for an instant the phosphorus atom is free, and has this oxidative stimulating action upon the protoplasmic masses, thus generating an inherent central nervous impulse, which not only augments the cell activity *per se* in which this change occurs, but is reflected to all parts of the economy by the nerve fibers springing from the cells. This being true, it is easy to accept the generally good effects which follow the use of this class of compounds physiologically and when used as therapeutic agents. In fact, without these chemical mutations we cannot have a perfect metabolism.

The free phosphorus, after serving its purpose as such, is quickly bound up again into the disodic monohydrogen phosphate. Here again we see how nature is constantly supplying herself with this true alkalinizer of the system, which is another positive reason why these particular compounds augment oxidation and metabolism.

The urea formed by this recombination, being freely soluble and non-irritating, is easily carried by the blood stream to the kidneys for its final elimination from the system.

At this point it is well to note further that it requires the expenditure of a large number of oxygen atoms to completely reduce these lecithine compounds, the same as occurs in reducing the proteins. This in itself presupposes that a high degree of energy must be evolved from these chemical changes. There is also produced a relatively large amount of carbon dioxide at the same time with only a small amount of water.

The carbon dioxide so produced is taken care of in the same manner as that evolved from any of the oxidation reduction processes. As it separates in the cell from its more complex combination and becomes a free molecule, it at once enters into combination with the carbonate of soda always present in the fluids and tissues of the body, causing the carbonate of soda to be changed to a bicarbonate. This latter form of salt is the true and normal carrier of carbon dioxide and water from the seat of formation to the lungs. So far as known to me, the production of disodic monohydrogen phosphate from these highly complex phosphorus bearing compounds is a newly revealed fact, and gives to the physiological economy an inherent source of this absolutely essential alkalinizer of the system. How much is produced daily in this manner is an unsolved problem.

When using phytin or any of these other natural phosphorus bearing compounds as a food or therapeutic agent, they will all produce this special form of phosphate. Hence they will not only enhance brain and spinal power, but will also tend to produce more perfect assimilation.

A noteworthy point is the fact that when using phytin to supply the system with phosphorus, we secure molecule for molecule just twice as much phosphorus as obtains when using lecithine. At the same time phytin yields just as much disodic monohydrogen phosphate and no urea in its final recombination. It requires less oxygen to completely reduce the phytin than has to be furnished when lecithine is being transformed. It requires 2.3970 grams of oxygen to reduce completely one gram of lecithine, while .2689 grams of oxygen will completely reduce one of phytin, as illustrated by the equation already given in connection with the oxidation of lecithine and as here given for phytin: $C_6H_8P_2O_8 + 2(Na_2CO_3 + H_2O + 4\ (O) = 2(Na_2HPO_4) + 4(CO_2) + 4\ H_2O)$.

From these facts and explanations we find that

these highly complex phosphorus bearing bodies act in various ways: as direct protoplasmic irritants by virtue of the phosphorus atom; as a decided source of central nervous system energy by virtue of the fact that all act as oxidizing and reducing agents; that they furnish to the system the most essential alkaline salt; and that by producing an automatic balance to the whole system they largely control metabolism.

From these facts it is reasonable to argue that phytin is more valuable as a direct phosphorus stimulant to metabolism than lecithine. At the same time it is a higher alkalinizer, and in this manner aids more in perfecting assimilation. On the other hand, the fact that lecithine calls for so much larger expenditure of oxygen for its reduction makes it a much greater stimulant to the nerve cells and produces the automatic stabilization of the whole animal economy. Hence lecithine is a more highly physiological product, while phytin may be considered more in the light of a therapeutic agent.

In Professor Lusk's little work entitled, "The Fundamental Basis of Nutrition," he makes the following interesting statements: "Protein has one property out of all proportion to that possessed by the other foodstuffs: it very largely increases the production of heat in the body." Again he writes, "One may cause the heat production of a dog to double by giving a large quantity of meat. This action is due to the fact that many of the chemical units produced in the digestion of meat act to stimulate heat production in the animal. Some of these individual chemical units of which protein is composed have been fed to a dog and have been found to increase the heat production in the same way as does ingested meat. Glycocoll is the simplest of these units . . . . Hence it acts as a chemical stimulus and not in virtue of its energy content." By energy content it must refer to the caloric value. If this be true, how can nutritive metabolism be measured by caloric values?

"This heat increasing property of protein has been called its specific dynamic action (Rubner). This action may be affected by all kinds of proteins—by those of meat, fish, eggs, milk, and such incomplete proteins as gelatin" (Lusk).

The effects here quoted rather go to sustain the truth of the assertion in connection with these complex phosphorus bearing compounds, that they have stimulating and energy producing properties outside of their simple heat producing power; and if more heat is produced than can be accounted for by simple oxidation it must be generated by these active chemical mutations and by increased frictional activity of the minute molecules excited into intensified activity.

ORAL SURGERY, A DEPARTMENT OF GASTROENTEROLOGY.*

SURGICAL VIEWPOINT.

BY JOHN WILLIAM DRAPER, M.D., F.A.C.S.,

NEW YORK.

THE analysis of a sick human being from the standpoint and for the development of modern medicine, required that the great systems of the body be segregated and each put into the hands of highly specialized groups of medical workers. The requirement was identical with that of an automobile needing repair and reconstruction; dissembling was necessarily the first step. This process has now been carried in medicine to its logical end—the human body lies dismembered, exposing not only its morphology in the dissecting room, but its function and its pathology in the laboratories. It is very natural, therefore, that on every hand is seen a desire for and a natural trend toward reintegration. The patient has been catalogued and classified,—intensive study of minute areas and of highly specialized functions has been accurately finished. Enough has been done to justify a reassembling of parts. The pendulum of progress has passed its peak and the age of specialization is merging into that of synthesization.

Of all the great systems this is most true of the alimentary canal. How crude now seem the arbitrary divisions of the past decade into stomach and rectal specialties. Fortunately to-day the fusion of all the specialties relating to the alimentary

*Read before the American Academy of Applied Dental Science Annual Meeting, at Trenton, N. J., January, 1922.

canal may be looked upon as complete,—the rectal surgeon and the old-fashioned stomach specialist alike are dying out, being supplanted by practitioners who have a broader knowledge of the inseparable relationships of the alimentary canal. These, however widely separated anatomically, are nevertheless so interwoven, particularly through the sympathetic systems that the disorders of one part could never have been satisfactorily healed without a knowledge of the pathology and physiology of the entire system. The alimentary canal is, figuratively speaking, an interlocking directorate.

To the surgical physiologists very largely, we owe our awakening to the fact of the essential unity of all portions of the entire alimentary canal, and while recognizing the great contributions that have come from those whose attention was formerly focused upon a small and supposedly isolated segment, one nevertheless welcomes the newer view of the physiological surgeon that the alimentary canal, because of its anatomical and biological unity, must be treated as a whole.[1] The corrollary from this of course is, that not only must the patient be treated as a whole, but that his place and relationship in the whole of nature must be given due consideration. From this latter viewpoint has sprung the splendid work of classifying human beings, as by Bryant,[2] according to their evolutionary development,—a helpful and far-reaching aid to medicine, and no branch of the profession has been more alert to the importance of uncovering these fundamental truths than your own.

The alternate flux and crystallization of the great stream of knowledge which constitutes modern medicine is an object of the most intense interest. At present we are witnessing the fusion into the great central stream of two highly specialized divisions of medicine, dentistry and psychiatry, which through no fault of their votaries, but because of hereditary and environmental considerations had been set aside and regarded as remote and isolated from general medicine. Your presence in Trenton, a great center of modern psychiatry, is an augury that we stand face to face with a much to be desired breaking down of artificial and misconceived barriers and an interlocking of the great truths now held more or less at random by the learned bodies here represented for the certain ultimate good of mankind.

Consider the alimentary canal. What a lack of unity there has been in man's attempts to fathom and treat its pathology! Washed and drugged at its center by the ardent gastrologist, hammered and hewed at either end by the industrious dentist and optimistic proctologist, each one carrying out his fixed and honest convictions that in his segment alone lay the secret of the patient's disability, and woefully ignorant of the amazing nervous and biochemical synthesis of the entire tube, is it any wonder results have been disproportionate to the effort and that the patients have suffered decadence and often death, not because of the ignorance of their therapeutists, but because of their lack of coordination.

The alimentary canal is the oldest and most primitive portion of organized beings. It had to be, for upon it depended growth and life itself. One has only to lay open a common pitcher plant to find that in this lowly representative of the vegetable kingdom there exists a highly developed mechanism, not only for the trapping of flies and other small animals, but for their digestion and assimilation as well. It stands on a parity with our own and yet, consider the aeons of time which separate us from this primitive plant! It is bewildering to think of the length of time during which the processes of digestion have been perfected as they are to-day, and even more so to consider what countless centuries were required to develop this mechanism.

There is no theme more engrossing than that relating to the origin of new variations, particularly in their relation to the pathology of the great systems of alimentation and of locomotion as they exist to-day. Gerould[3] of Dartmouth, has just reported the spontaneous appearance of a blue caterpillar from normal green ancestors, and which breeds true to the Mendelian law. The blue shade is due to the absence of certain blood pigments; is capable of hereditary transmission, like the blue eye, and has, therefore, come to stay. This is only one of the many classical examples which go to show that new varieties are arising about us to-day and that, therefore, we are actually witnessing the very processes which led to our own evolutionary development.

Shaler[4] of Harvard, pictured the accession of the different systems used in the evolutionary development of animal forms as "experiments." One of the most far-reaching of these, for pathological as well as for intellectual development, was man's change from the horizontal to the upright position. What benefited his brain, damaged his belly. Gravity is a potent cause of gastrointestinal invalidism, the human abdomen never having become wholly adapted to the upright position. So it is clear that one important reason why man is so prone to gastrointestinal disease is unquestionably that these experiments of his remote ancestors, while useful in many respects, have been deleterious in others. Blue caterpillars doubtless have certain advantages over green ones, but there is never an advantage without a compensating drawback. Consider the teeth from this angle and study their remote but important relationship to the entire individual. For this purpose man should be considered as a cask with both heads tight in place and through which a pipe has been snugly thrust. Water can be poured through the cask and yet without entering it. The outer surface of the cask is the skin; the point where the pipe pierces the upper head is the mouth, fringed by the teeth; the inside of the pipe is the alimentary canal,—the inner surface of the body; the exit of the pipe through the opposite head is the rectum. In the passage of fluids through the cask its protection from soiling is accorded by the tightly fitting pipe. The space between the outside of the pipe and the inside of the cask is what is known as the body cavity. All sorts of the most elaborate mechanisms, both structural and biochemical, have been devised to protect this great cavity from bacterial invasion. That the skin is an efficient bacterial barrier is not surprising, but recent researches have proved that the delicate epithelial lining of the entire alimentary canal is in health just as potent as the skin. Blood poisoning may result from an abrasion of the skin. Chronic intestinal invalidism is always accompanied, if not wholly

produced, by a leakage through the alimentary canal of its highly poisonous bacteria or their toxins. As stated by Cotton,[5] at no point in the canal is such leakage more prone to occur than around the teeth.

The writer, whose interest has centered upon surgical research relating to the alimentary canal, chiefly the colon, welcomes this opportunity to thank the progressive members of the dental profession for direct clinical proof that dental pathology is interlocked with gastric disorders and colon pathology, often being the precursor of both. Many chronic intestinal invalids under his and Dr. Satterlee's care for years, have been afforded permanent relief only when the dental and antral pathology has been removed. The homely likening of the human body to a cask affords immediate explanation of the liability of the teeth to cause serious systemic disease. When the evolutionary forces drove the teeth, as so many pegs, through the epithelial barriers, a means of food grinding was provided but a potential and serious break in the defensive bacterial barrier was also created. Nature is always coping with the antagonistic law, that over specialization tends to extinction. It is hard to introduce any innovation which does not carry with it damaging qualities. This is especially true as regards the origin and development of the teeth, and it behooves the profession in recognizing this, to remember that the grinding function is a secondary one, the loss of which can be met by replacement and that no benefit from mastication is comparable to the damage done by the breaking through of the epithelial bacteriotoxic barrier which normally protects the body cavity. It is obvious that dead, loose, and infected teeth of all descriptions and kinds are the most potent cause in the body of this breakdown. Moreover, it is the infection from the teeth which causes nervous, mental, and physical symptoms, not vice versa. Formerly it was thought that systemic disorders caused dental decay—now we know otherwise. Thus from biological, anatomical, and physiological grounds it is apparent that the alimentary canal from teeth to anus is one, and that the health and indeed the life of the individual depends as much upon the prevention of the passage of bacteria and their toxins from its inner or outer surface into the body cavity as upon its other highly important functions.

The chief areas of infection are the teeth, tonsils, and colon. Focal infections in these areas do not present, as a rule, the usual local signs of inflammation; how then are they to be diagnosed? It is helpful and instructive to consider first, the methods of bodily protection. As everyone knows there are but two subjective symptoms; pain and disability. These are essentially protective.[6] Pain limits motion and enforces surgical rest. But it must be remembered that, important as pain is, there are many and often extensive lesions in which it is absent. This is particularly true of the focal infections of the alimentary canal. I have seen the most extensive destruction of the jaw, with serious antral involvement, in patients who gave so little local evidence of infection as to have been diagnosed, because of extreme emaciation and weakness, as having pulmonary tuberculosis. Colons may be the seat of the most extensive disease and yet the pain will have been negligible. This is because of two facts. First; an organ can be almost wholly destroyed without pain until the periphery is attacked. Second; streptococcus and colon bacillus infections rarely cause the typical reactions of inflammation—redness, heat, swelling, and pain, which we have been taught to regard as pointing to infection. As most disability is due to pain, it, likewise is absent. Moreover, some of the worst of these focal infections cause no rise of temperature whatsoever; a decrease in blood pressure, and often an inversion of the normal ratio between polymorphonuclear cells and small lymphocytes. With this confusion in all symptoms it is only natural that focal infections in the past should have been overlooked. If not causing symptoms of the ordinary type how can their presence be detected?

Almost all patients having such focal infections present the symptoms of chronic intestinal invalidism, and it is necessary for dentists to be familiar with these, because from the modern viewpoint his function is not alone to care for the teeth but also to cooperate with the physician in helping the patient. Gastrointestinal toxemia, whether from teeth or bowel, is to be recognized, as Satterlee[7] said long ago, by certain definite mental and physical signs. This is best illustrated by case histories.

J. B., postman, age thirty-eight. Had been transferred on doctor's orders from indoor to outdoor work. Continued to run downhill and went from doctor to doctor only to be told that he imagined he was sick; that he had tuberculosis; that his liver was in bad order; that his stomach was ulcerated; that it was "all in your head"; that he was "neurasthenic." The man's tongue was like parchment, his bowels constipated and dilated with gas; his digestion impaired; he was filled with nervous apprehensions and baseless fears; he could work only every other day because of physical weakness and depression.

The antrum was opened and an ulcerated mass of tissue, presenting some of the characteristics of a sarcoma without being malignant, was removed. Almost immediately the man recovered and is now well.

E. T., widow, thirty-four, mother of two children; emaciated, sallow, "neurasthenic," unable to work; alternate diarrhea and constipation; vomiting attacks for seven years; had vomited steadily for past four months and had lost thirty pounds. Her physician had reported that medically there was "nothing more to offer her," and she was rapidly becoming a neurotic invalid. He was an extremely competent practitioner whose opinion was proven to be correct. I resected the right colon, which, as stated by a competent pathologist, "presented every form of inflammatory change—chronic proliferative colitis with thrombophlebitis as a base." This damaged gut was leaking bacteria and toxines into the body cavity. The vomiting ceased and she gained sixteen pounds in three weeks. Today, one year after operation, she is in perfect health.

These are typical examples of systemic effect of the toxemia from focal infections in the alimentary canal—the first from the oral, the second from the aboral end, and yet the symptoms were almost identical. In neither case was pain predominant; the complaints were vague but constitutionally severe study. The adult pathology, both physical and menand to be interpreted, it is true, only by special tal, with which we deal is too often terminal.[8] The most pressing present need is the early recognition of hidden infection, very important seats of which occur in the alimentary canal. Cooperation in all medical branches will speed the day of early diagnosis and prevention.

ORAL SURGERY, A DEPARTMENT OF GASTROENTEROLOGY.*

MEDICAL VIEWPOINT.

By G. REESE SATTERLEE, M.D.,

NEW YORK.

Modern dentistry, at least up to the last two or three years, if we are to believe the writings and constructive criticisms of leading men in the dental profession, such as Thoma of Harvard, has been responsible for a great deal more systemic medical pathology than any of us would until now have believed possible.

Just a year ago the New York City Board of Health published a bulletin which called attention to the fact that one quarter of the yearly deaths in the United States, might have been postponed from five to ten years by proper care of the teeth. The matter, therefore, is one of great interest to both professions. The ingenious methods devised by dentists which are directed mainly to the preservation of dead or badly damaged teeth, are largely responsible for this state of affairs. The result of their employment has been not only the sealing up of an extremely lethal bacterial infection in the teeth themselves, but also a crowding infection back into the jaw bone and frequently into the maxillary sinus itself. Unfortunately these conditions are not characterized by the usual sensory disturbance. They remain hidden and sealed up for years. Although relatively harmless in themselves, at least so far as the local conditions go, they are generally recognized to-day as being the frequent, if not the chief source, of damaging toxemias which cause many of the well recognized lesions of the great systems of the body.

Occasionally, however, due probably to the accidental introduction of a true pyogenic organism, these infected areas may come to the surface and give rise to the classical signs of abscess. For the bacteria which cause the true focal or cryptic bone lesion of the mouth are non-pyogenic, being usually streptococci. These streptococci, while they may do considerable local damage, do it in no sense to the degree that the pus producing organisms are capable of. The streptococci, by their own autolysis and by the circulation of their toxins, cause remote damage far outweighing that resulting from any alveolar abscess and infinitely more dangerous.

*Presented at the annual meeting of the American Academy of Applied Dental Science, Trenton, N. J., January 11, 1922.

Thus, it is not abscess formation but bone necrosis which should be primarily considered. A bone abscess is easily distinguished by the *x*-ray, while much of the bone necrosis of the type under consideration gives little evidence under the ray. Thus there are two important points of difference between the ordinary alveolar abscess due to pyogenic infection, and bone necrosis due to streptococcic infection. It is therefore evident, as will be shown in the case histories, that extraction of teeth alone is not sufficient without thorough removal of all the necrotic areas. This accounts for the fact so often noticed that no systemic improvement has followed the simple removal of teeth.

The modern viewpoint is to consider such gross pathological conditions as chronic appendicitis, gallbladder disease, ulceration of the stomach and bowels, infected colons, many kidney infections, and most cardiac disorders as secondary to focal infections. The writer[1] stated five years ago, that the so-called neurasthenic depressions and a great variety of toxic mental states, were all to be looked upon as senile pathology or at least as terminal conditions from long standing focal infection. Many of these conditions of course require major operative intervention—this comprised the surgery of the past decade. Draper[2] has shown that the surgery of the future will be largely preventive.

It is unnecessary to recount the difficulties and failures which often attend this major surgical work. In 1916 I summarized[3] a series of one hundred and thirty-six patients presenting the classical evidence of chronic intestinal invalidism, and found that in no less than thirty-three, or twenty-five per cent, the appendix had been removed either without benefit, or in some cases with actual detriment. Since that time I believe that the ratio has remained the same. This finding is not peculiar as it is the common experience of all gastroenterologists that their patients too often are not better or even are worse after operation. I do not mean to imply that major surgery is not indicated in many cases or that it is not done right, but simply to recite my own experience and to make suggestions based upon it. It has convinced me that the trouble is not with the surgery so much as with the time at which it is done. In most cases of chronic intestinal invalidism we believe that the appendix was at one time seriously involved, and perhaps was even the primary seat of the infection, but that through failure to remove it in childhood, or at the onset of the symptoms, the infection had already damaged the cecum, the right colon, and other organs irreparably. Rosenow has apparently demonstrated experimentally, that infection of the appendix may occur from focal infection elsewhere in the body, and clinical evidence gives more and more support to this theory.

As the experimental work in pathology of the alimentary canal progresses it becomes more certain that infection travels, in some unknown way, from mouth to anus. Obviously, therefore, the entire canal must from now on be treated as a single unit. I have been struck by the frequency with which notable improvement, if not entire arrest of symptoms, has occurred among well defined chronic intestinal invalids after the removal of local foci in the mouth. Could there be stronger evidence of

the importance of such removal? It is very significant of the attitude of the profession that 51 per cent. of this year's Freshman class at Harvard have had tonsillectomy.

More than five years ago the writer presented evidence, based on a large number of cases, that toxemia arising from the alimentary canal was the direct cause of many mental and neurological conditions, then still supposed to be separate clinical entities, but since that time demonstrated, both experimentally and clinically, to be simply symptomatic of focal infections. Final proof of their importance is now at hand in the splendid results obtained by Cotton[1] in his treatment of patients suffering from actual insanity.

From Cotton's extensive and thoroughly scientific studies[2] he concludes not only that these are usually nothing more than terminal manifestations of prolonged toxemia from focal infection, but, what is of at least equal importance, that the mild nervous and mental disturbances, so commonly seen by every practitioner, are often the prodromal symptoms of chronic insanity. I am aware that this viewpoint is at variance with that held by the classical school of psychiatry, but continued observation of chronic gastrointestinal toxemics, all of whom show marked nervous and mental disturbances, has long since convinced me of the close relationship between the terminal mental stages, as described by Cotton, and the prodromal stages observed by myself and other gastroenterologists. Moreover, there is in many cases a mutation or gradual merger from one to the other.

If this is so, what can be done for prevention? It is my own belief that the present confusion among gastroenterologists as to diagnosis and treatment has arisen largely from lack of recognition of the essential unity of the alimentary canal, coupled with a failure to recognize the importance of the removal of local foci of infection in the course of the canal. This interests you as dentists because you deal with one of the principal sites of focal infection in the body.

Before closing I should like to mention an incident that occurred in one of the leading general hospitals of this city.

On reviewing the yearly drug report, it was noted that the average monthly dosage of aspirin, which had been 2,000 grains, suddenly rose during three months only, to 9,000 grains per month. It was found that during these three months, owing to rotation of service, the practice of removing dental infection had been discontinued, the attending physician not being as yet convinced of its value. Surgical therapy for the removal of the cause had given place to drug therapy, affording an interesting and accurate basis for future study of the comparative value of the two methods.

While the recognition of the value of the removal of focal infection is now broadly held, the actual practice of thorough extirpation of these foci is unfortunately not usually carried out. This is not the fault of the individual physician, but of the inadequate system under which he works.

It will never be accomplished until full cooperation of the specialties is assured, preferably through the medium of group medicine.

M. W., female, aet. sixty-four. Usual symptoms of chronic intestinal invalidism past five years. Chief complaint, progressive blindness.

All the teeth were extracted thirty years ago. Not seriously ill until three years ago, when she developed pain in stomach, nausea, and occasional vomiting. Pain persistent after eating, always worse at night. Shortly after gastrointestinal trouble developed, low-grade inflammation of the uveal tract of both eyes appeared with marked increase in the intraocular tension and secondary glaucoma. Tuberculosis of the eye excluded by all known tests at Saranac Lake. Patient placed under care of competent eye specialist in Montreal for two years. Wassermann negative. Urine, faint trace albumin—few casts. Dentists reported no stumps of teeth or roots in the mouth. Vision rapidly failing.

February 21, 1921, left eye gave out, vomited all that day.

Ophthalmic examination: Right, vision 20/200; left, vision absent. Right eye coloboma from iridectomy. Diagnosis iridocyclitis with secondary glaucoma. Belladonna 1 per cent., dionin 10 per cent.

Physical: Chest normal, tenderness and rigidity in right upper quadrant marked. Fractional gastric test: free hydrochloric absent. All tests showed *Staphylococcus albus*. Renal efficiency, 48 per cent. at end of second hour. Nasal examination: deflected septum, small ulcer. Small infected tonsils. Neurological: normal. *X*-ray: third degree colon delay, residual appendix, irregular loop of colon at hepatic flexure, disturbance of motility in cecum. Intestinal tuberculosis had been ruled out at Saranac.

Abdominal Diagnosis: probable disease right side of abdomen. Dental examination: gums flabby throughout; the *x*-ray shows area of necrosis both sides, both antra infected. Operation: necrotic areas curetted, both antra opened.

Progress.—In three weeks the vision in the right eye had improved so that patient could read the fourth line on the optic chart. Intraocular tension subsiding. Abdominal distress and all gastrointestinal manifestations much improved. January reports from this patient show that she has recovered sufficiently to do her own work, is able to read ordinary print, and has gained 30 pounds. Vision left eye, permanently destroyed.

This case demonstrates the close relationship between eye conditions and oral infection. It also points to the essential unity of the alimentary canal from a clinical viewpoint.

L. G. E., female, aet. sixty-four. Under observation since 1916. Persistent dyspepsia, arthritis involving all joints of both hands and wrists. Late in 1915 she could not close her hands, obliged to eat with a spoon. Walked with difficulty; slept little; could not lie on right side because of severe abdominal pain. Constipation increasing, duration fifteen years; purgatives. Condition that of helpless invalidism.

Objective Findings: Stout, hypothyroid, skin dry, hair brittle. Finger flexion reduced to forty degrees. Joint condition subacute, right knee involved and apparent bursitis of right hip. Heart and lungs negative. Abdomen distended with gas, pain and rigidity in upper right quadrant. Right tonsil one plus. Teeth pronounced negative by a dentist of high standing. Pelvis and rectum negative. Fifty per cent. gastric *x*-ray delay at six and one-quarter hours; great irregularity of lesser curvature; large residue twenty-four hours postenema. Blood pressure normal. Polymorphonuclear and small lymphocytes equal. Wassermann negative, both spinal and blood. Urine negative.

Diagnosis: Cholecystitis probable cause for arthritis. Patient given thyroid and pituitary to point of tolerance. Marked improvement in symptoms.

Two years later, mass in right axilla, always enlarged following tonsillitis. Removal of axillary glands and tonsils; identical streptococcus found in each; autogenous vaccine. Marked improvement, patient able to reduce thyroid treatment, which had been constantly necessary.

At close of 1920 developed pain and tenderness in neck and in right upper abdominal quadrant. Polymorphonuclears fifty, small lymphocytes forty-eight.

Gastrointestinal *x*-ray negative. Five diseased teeth removed, thorough curettage of right antrum. Patient able to discontinue all previous treatment, condition better than in twenty years.

This case reflects the gradual development of modern medicine; suggests that the endrocrine system is inhibited by toxins from local colon and streptococcus foci; shows unusual direct lymphatic relationship between the tonsil and the axilla; discloses the effects of chronic bacterial toxemia upon the ratio of polymorphonuclear cells to small lymphocytes, and finally demonstrates the importance of recognition and removal of all local foci of infection.

INCIPIENT EPILEPSY: ITS DIAGNOSIS AND TREATMENT.

By EDWARD A. TRACY, M.D.,

BOSTON.

Epilepsy is a progressive disease, beginning frequently with scarcely noticeable symptoms and ending often enough with dementia. Incipient epilepsy is that stage of the disease referred to by Echeverria in his statement, "The paroxysm may well occur without muscular spasms; it does not, however, without a disturbance of the vasomotor elements in its inception, and hence paleness of the face, or loss of consciousness, or vertigo, not unfrequently are the whole symptoms of the epileptic attacks in the early stage of the disease."[1]

Careful history taking has uncovered the fact that in a considerable proportion of the cases of chronic epilepsy investigated in children there was a period, extending from six months to two years, during which the child had fainting spells or sudden weaknesses.

This early stage of epilepsy, which manifests itself by fainting spells, sudden pallors, attacks of dizziness, sudden weaknesses, and periods of irritability, is the condition to which the term incipient epilepsy is applied. The diagnosis of this condition, based upon objective signs, and its treatment are the subject matter of this paper.

Diagnosis.—The field of research wherein to seek for diagnostic features of incipient epilepsy is clearly indicated in the words of Echeverria just quoted: "The paroxysm . . . . does not occur, however, *without a disturbance of the vasomotor elements in its inception.*"

A *résumé* of results attained in this field of vasomotor research, and heretofore reported, is presented. The normal reaction of the skin to light stroking is a brief lasting red streak of vasodilation, followed by a comparatively long lasting white streak of vasoconstriction.[2]

This reaction to stroking the skin is a vasomotor reflex,* best explained by regarding it as involving the action of the sensory nerves together with both branches (the autonomic and the sympathetic) of the vegetative nervous system. The sensory fibers in the skin transmit the stimuli caused by the stroking, inwards to where the stimuli are reflected outwards along the autonomic (vasodilatation, fibers, and along the sympathetic (vasoconstriction) fibers, ending in the musculature of the blood vessels in the skin. The location of the reflex-arc is probably (for reasons presented elsewhere) in the cerebral cortex.[3]

A study of the vasomotor reflex[4] led to findings of clinical interest. It was found, *e. g.*, that when the vasodilatation component of the reflex on the face lasts longer than fourteen seconds, it—the red streak—is a sign of disease.[5] The abnormalities of the vasoconstriction component of the reflex were found to be so closely connected with epilepsy as to serve in the diagnosis of this disease. Research work[6] disclosed that in chronic epilepsy there is a diseased condition of the sympathetic nerve fibers; this diseased condition being shown by various abnormal vasoconstriction reflexes (the vasoconstrictors are sympathetic fibers), by chronic vasoconstriction spots,[3] and by a hypertonia of sympathetic fibers that had relation with the convulsive outbreaks. It may well be that these objective phenomena are but the clinical expression of the pathological sympathetic fibers that Echeverria found in his autopsies on epileptics.[7]

These objective phenomena, a majority of which are found constantly in chronic epileptics, may be tabulated thus: (1) Unbalancement of the vasoconstriction reflexes on opposite sides of the body. Normally these reflexes balance, are equal. The unbalancement may be in the time taken for the reflexes to appear (that is, a difference in the reaction times) or it may be a difference in the color of the reactions. (2) A hypertonia of sympathetic fibers (manifested by the intensity in color of the reflex vasoconstriction, or by the reflex appearing sooner than is normal). (3) A patchy reflex vasoconstriction, or an absence of the reflex (perhaps due to a degeneration of sympathetic fibers, one of the conditions noted by Echeverria, in the postmortems just mentioned). (4) Chronic vasoconstriction spots. These are evidently due to a chronic hypertonia of the particular sympathetic fibers that innervate the musculature of the blood vessels involved in the spots.

The phenomena thus tabulated and characteristic of chronic epilepsy were sought for in cases met with having the symptoms that Echeverria noted as those of the incipient stage of the disease. Not all of them were found in those cases but enough

*The investigation of this vasomotor reflex demonstrated the need of using a measured stimulus to evoke it, since the reaction evoked by a light stroking differs from that evoked by a heavier stroking. To compare reactions, therefore, a measured stimulus must be used, and this necessity led to the devising of a simple instrument, the vasomotor tester, consisting of a suitable spiral spring into one end of which is inserted a flat piece of wood, and which, when correctly applied, evokes the reflex by a pressure approximating two and a half ounces. The use of the vasomotor tester makes available the measurement and comparison of vasomotor reflexes, a condition essential for research and diagnosis based upon it.

of them to determine the positive diagnosis of the condition present. The objective phenomena found in the cases of incipient epilepsy studied were: (1) Hypertonia of sympathetic fibers; (2) unbalancement of vasoconstriction reflexes; and (3) chronic vasoconstriction spots.

Of these objective signs, the most important from a practical point of view, is the sympathetic hypertonia, for it has been found that in incipient epilepsy, this hypertonia can be overcome by drug action; and that with the disappearance of the hypertonia, the aforementioned symptoms of the disease also go.

The hypertonia is manifested, as before remarked, by the intensity in color of the white streak of reflex vasoconstriction, or also by the quickness with which it appears. There is no measure for the intensity of color in the reaction save the experience that comes with observation and practice in making vasomotor tests. The time, however, which it takes for the streak to make its appearance can be measured with the aid of a stopwatch. If this time be less than the normal reaction time, it is evident there is present a hyperactivity, a hypertonia of the sympathetic fibers involved in the reflex.

The diagnosis of incipient epilepsy is made when, in a case presenting the history of fainting spells, attacks of dizziness, sudden pallors, and periodical irritability, there are found present: (1) A sympathetic hypertonia; (2) unbalancement of the vasoconstriction reflexes; and (3) chronic vasoconstriction spots. The histories of three cases so diagnosed follow:

Case I.—Theresa H., aged fourteen years. Family history negative; mother states that when pregnant with Theresa she suffered "a great fright" occasioned by the loss of a large sum of money. Previous history: measles at two years; bad fall from a "tilt" while playing seesaw, at eight years, the mother stating that the child remained unconscious for three hours after the fall; pneumonia and pleurisy at eleven years. In her twelfth year she had several attacks of dizziness and sudden weakness. The mother states (January 7, 1917) that for the previous three months the girl has had fainting spells; that now they are as many as four in a week; the girl becomes white suddenly and falls unconscious. The mother had consulted a doctor about her daughter's condition and was informed that heart disease was its cause. Her teacher reported that the girl was irritable and frequently in trouble with the monitors. Examination: nothing abnormal detected about the heart; a small patch of gray hair noted over the right parietal region; pallor present; the girl well nourished and developed. Vasoconstruction spots observed on the dorsal surface of the left forearm. Reflex vasoconstriction after stroking the left side of the face appeared in eleven seconds and was diffuse (that is, it extended beyond the stroked surface). Reflex vasoconstriction after stroking the right side of the face appeared in fifteen seconds—an intensely white streak. January 17, 1917, vasoconstriction spots observed in the same location as before. The case was diagnosed as one of incipient epilepsy. Further history of the case, including treatment, is presented in the second part of the paper.

Case II.—Albert J., aged ten years. Family history: Father, alcoholic, dead; maternal aunt, epileptic. Previous history: bronchitis at six months; whooping cough at two years; measles at seven years. Mother states (October 30, 1917) that Albert first fainted two years before, the occasion being a visit he made to her in a hospital where she lay sick. During the past six months he has had several fainting spells; is conscious of the beginning of the attack, for he seeks assistance to prevent falling. He becomes "deadly white" and topples over. Twice he has had two separate attacks on the same day. Mother states he is becoming worse; she has ceased sending him on errands for fear something might happen to him; he has frequent attacks of dizziness and headache; appetite good, bowels regular. Examination: negative as regards the organs of the chest and abdomen. Vasoconstriction spots observed in the middle dorsal regions of both forearms. Reflex vasoconstriction on the left side of the face appeared in five and a half seconds, and on the right side of the face in fifteen seconds. This testing showed a marked hypertonia of the sympathetic fibers in the left side of the face, manifested by the quickness of the reflex, the normal time for the reflex to appear in the face being twelve seconds. It showed also a marked unbalancement of the reaction times on opposite sides of the face.

December 17, 1917: Vasoconstriction spots observed in the same locations as previously. Reflex vasoconstriction appeared in nine and a half seconds on the left side of the face, and in six and a half seconds on the right. Mother stated that Albert had had two fainting spells the day before. The mother was informed that the boy had epilepsy, the disease being in the incipient stage. This diagnosis was based on the objective signs of sympathetic hypertonia, unbalancement of the vasoconstriction reflexes, and chronic vasoconstriction spots present. Seventeen months later this diagnosis was confirmed by a convulsive seizure, the first that the boy had in his life. Other details are given under Treatment.

Case III.—John O., aged twelve years. Family history negative. Previous history: pneumonia when a year old; measles, whooping cough, and mumps at eight years. Mother states that the boy is very nervous; easily frightened; has periods of irritability. Has had several fainting spells since his eighth year, almost all of them at the sight of blood. On one occasion, on seeing his father hurt, he became suddenly pale and weak, but did not lose consciousness. Examination: February 4, 1918, heart normal. Reflex vasoconstriction on the left side of the face in eleven seconds, and on the right in nineteen seconds. Vasoconstriction spots observed on the dorsal surface of the left forearm. February 23, 1918, vasoconstriction spots observed in the same locations as previously. Reflex vasoconstriction on the left side of the face in eleven seconds, and on the right in nine and a half seconds. Diagnosis of incipient epilepsy made, there being present a sympathetic hypertonia, unbalancement of the vasoconstriction reflexes, and chronic vasoconstriction spots. The further history of the case is presented under Treatment.

Treatment.—The finding of an over-irritability, a true hypertonia of sympathetic fibers in incipient epilepsy raised the question, could this hypertonia be overcome by drug action and if so with what result? The drug required to overcome a hyperirritability of sympathetic fibers should evidently be a sympathetic paralysant. Ergotoxin is described as such in the literature.[5] A small quantity of ergotoxin phosphate was obtained, a weak solution of it in water was prepared and a few drops of this was injected into the writer's forearm. The vasoconstriction reflexes produced in the neighborhood of the site of the injection came slower than they did before the injection was made. A control injection of plain water was negative. There was this much ground therefore for inferring that ergotoxin phosphate is a sympathetic paralysant in man. About this time the writer came across the notice of a drug reported by a Dr. R. E. Waterhouse as curative in some cases of epilepsy, viz., *Œnanthe crocata.* With it in place of the ergotoxin phosphate, the previous personal experiment was repeated and the vasoconstriction reflexes were slowed in a similar manner; hence the inference that *Œnanthe crocata* is a sympathetic paralysant. The preparation available was a tincture, and the writer, having reason to consider alcohol as an

irritant to sympathetic fibers, inquired of Prof. John Uri Lloyd if an active preparation of the drug could be made free of alcohol. Professor Lloyd kindly supplied a colloidal preparation of œnanthe without alcohol, and it has been used with satisfactory results. The therapeutic dosage of this preparation carefully worked out is as follows: The writer has prescribed as high a dosage as five minims four times a day (after meals and at bedtime) in cases in which a demonstrable sympathetic hypertonia was present in children ten years of age, but he advises a very cautious approach to such dosage. A safe method to start its use is to mix ten drops of colloidal œnanthe with eight ounces of water, and to give one teaspoonful of the mixture after meals and at bedtime. This dosage can be increased by doubling the quantity of the œnanthe each time the bottle is refilled, every twelve days, until the mixture consists approximately of two drams of colloidal œnanthe in eight ounces of water. (The use of distilled water is advised.) If the medicine causes any untoward symptom, as debility, diminish the dose or omit the medicine.

The effect of this drug, *Œnanthe crocata*, in the treatment of incipient epilepsy is illustrated in the further records of the cases above reported.

Case I.—Theresa H. Treatment begun January 17, 1917. A mixture of ten drops of œnanthe in four ounces of water prescribed; one teaspoonful to be taken after meals and at bedtime. After taking the medicine in this dosage for a month the patient reported that the attacks of dizziness were less frequent and that she had had but three fainting spells during that time. The dosage was then increased by prescribing one dram of the œnanthe in four ounces of water, a teaspoonful of the mixture to be taken after meals and at bedtime. During the month of March there was marked improvement, the dizziness ceasing; she had three attacks of sudden weakness, but did not lose consciousness in them.

April 17, 1917.—For past two weeks no attack of dizziness nor fainting spell. Treatment continued. May 14, 1917.—No dizziness nor fainting since previous record. Advised to continue treatment. August 11, 1917. —No dizziness nor fainting since previous record. Feels well. Bowels now regular, two movements daily (previous to treatment was chronically constipated). Has taken no medicine for the past two weeks. Advised to take medicine regularly.

March 11, 1918.—Has not taken the œnanthe for the past three months; she feels well; no dizzy attack nor fainting spell since previous record. June 20, 1918. —No dizzy attack nor fainting spell since previous record; has taken no medicine during that time. Graduated from the grammar school. November 24, 1918.— Patient suffered the loss of her mother in the influenza epidemic two months since; has had no attack of dizziness nor fainting spell since the previous record.

April 24, 1921.—Theresa reports that she obtained a clerical situation shortly after her graduation in 1918, and holds it at the present time. Last summer she had a fainting attack and another two and a half weeks ago. Prescribed two drams of colloidal œnanthe in eight ounces of water, one teaspoonful of the mixture to be taken after meals and at bedtime.

Case II.—Albert J. Commenced treatment December 17, 1917. Prescribed one dram of œnanthe in four ounces of water, one teaspoonful to be taken after meals and at bedtime.

January 22, 1918.—Medicine has been taken regularly. Albert has had no fainting attack since beginning the medicine, but has had, twice, curious attacks of pain in the stomach and nausea. Vasomotor testing showed that reflex vasoconstriction appeared in the left side of the face in seventeen seconds and on the right side in seventeen seconds. The reflexes are balanced and not the reflexes of sympathetic hypertonia.

May 27, 1918.—No medicine (œnanthe) taken for the past three weeks. Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in eight seconds and on the right side in thirteen seconds; in the middle of the dorsal surface of the left forearm in nine seconds, and in the same location in the right forearm in six seconds. These reflexes show both sympathetic hypertonia and unbalancement.

July 2, 1918.—Mother reports that Albert has had four fainting spells during the past three weeks; that he is pettish, having crying spells if spoken to sharply. Also that he has taken no medicine for two months previous to the first of the fainting spells here reported. She promised to see that Albert would take his medicine regularly in the future. July 22, 1918.— Is taking his medicine regularly; has had no attacks since previous record. August 5, 1918.—Mother reports that Albert had a slight attack in church eleven days previously, but that he did not lose consciousness. Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twelve and a half seconds, and on the right in fifteen seconds; and on the left forearm in six seconds and on the right forearm, same location, in seven seconds. He is not taking the medicine regularly.

September 6, 1918.—The boy has taken no medicine for four days; mother reports that he is irritable and pettish as he is generally when not taking the medicine. Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twenty seconds and on the right in eighteen seconds; on the left forearm in twenty seconds and on the right forearm, same location, in ten seconds, the streak being intensely white.

February 2, 1919.—The mother reports that he is taking the medicine regularly and that he has had no attack since the previous record. She told of an emotional episode involving Albert that had occurred a week before. She heard him screaming in the street. He was being forcibly held by a neighbor who accused him falsely of having stolen a fifty-cent piece from her son. The neighbor wanted the policeman who was at hand to arrest Albert. This fright and commotion had not brought on an attack, though the mother thought his head bent as if he were about to faint.

March 13, 1919.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in fourteen seconds and on the right in seventeen seconds; on the left forearm in seven and a half seconds (an intensely white streak) and on the right forearm, same location, in six and a half seconds. Unbalancement of the reflexes and sympathetic hypertonia present; Albert is not taking the medicine regularly; he promised to get another supply of it. From his schoolmaster I learned that the mother had complained to him of an exhibition of temper by Albert a few days before, in which he threw his coat through a window, breaking the glass.

May 28, 1919.—Albert's mother reports that he has not taken any medicine for the past two months, and that two days previously she had witnessed the first convulsive seizure that he ever had. It lasted about a minute. His arms became rigid, his hands were clenched, the lips compressed, and when he came out of it he was dazed. Greatly alarmed by this attack, she regretted very much that the administration of the medicine, the beneficial action of which she had witnessed, had not been faithfully followed. May 28, 1919. —Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twelve seconds and on the right in thirteen seconds; on the left forearm in five seconds and on the right forearm, same location, in four seconds. The reflexes on the forearms indicate sympathetic hypertonia. The patient has taken no medicine for the past two months. The dosage he had previously taken was doubled.

June 23, 1919.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twenty seconds and on the right in sixteen seconds; on the left forearm in seventeen seconds and on the right forearm, same location, in twenty seconds. The reflexes are not those of sympathetic hypertonia. The boy has been taking the medicine regularly the past four days.

September 12, 1919.—Vasomotor testing showed that

reflex vasoconstriction appeared on the left side of the face in seventeen seconds and on the right in twenty-one seconds; on the left forearm in eleven seconds and on the right forearm, same location, in eleven seconds, the streak being intensely white. These reflexes show unbalancement and sympathetic hypertonia. Albert has taken no medicine for the past seven days.

November 25, 1919.—No attack since convulsive seizure in May. Has continued taking medicine since then, at times irregularly.

January 21, 1921.—Albert tells me that he has had no fainting attacks nor other seizures during the past year and that he feels well.

February 22, 1921.—The patient's mother brought him to my office; she stated that he had had a seizure the week before after receiving two blows on the hand (from a rattan), he being the fifth boy to receive the punishment. Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twenty-five seconds and on the right in twenty seconds, the latter streak being intensely white; on the left forearm in fifteen seconds and on the right forearm, same location, in twelve seconds, the latter streak being intensely white. These tests indicate both unbalancement of the reflexes and sympathetic hypertonia. Prescribed two drams of colloidal œnanthe in eight ounces of water, one teaspoonful of the mixture to be taken after meals and at bedtime.

Case III.—John O. Began treatment March 4, 1918, with a mixture of twenty drops of œnanthe in eight ounces of water, one teaspoonful after meals and at bedtime. March 11, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in fifteen seconds and on the right in eighteen seconds; on the left forearm in nine seconds and on the right forearm, same location, in eleven seconds.

April 11, 1918.—John reports that he feels better, is not so nervous, *e. g.* when his mother sweeps straw matting it does not affect him now, while before he would jump on hearing the unpleasant sound the sweeping made. The dosage was increased to one dram of œnanthe in eight ounces of water, one teaspoonful to be taken after meals and at bedtime. May 6, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in fourteen seconds and on the right in fifteen seconds; on the left forearm in seven seconds and on the right forearm, same location, in eight seconds. June 19, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in thirteen seconds and on the right in twelve seconds; on the left forearm in twelve seconds and the right forearm, same location, in thirteen seconds. Patient reports that he is not at all nervous. He recently saw a woman bleeding on the street (she had been stabbed) and he hadn't fainted.

September 10, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in eleven seconds and on the right in fourteen seconds; on the left forearm in ten seconds and on the right forearm, same location, in ten seconds. John is told to omit the medicine and to report for observation. He has taken the œnanthe faithfully the past seven month. September 16, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twelve seconds and on the right in fourteen seconds; on the left forearm in eight seconds and on the right forearm, same location, in ten seconds. November 27, 1918.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twelve seconds and on the right in fourteen seconds; on the left forearm in ten seconds and on the right forearm, same location, in twelve seconds. Three weeks before John had seen a boy fall and cut his hand. The sight of blood did not affect him.

January 15, 1919.—Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in twenty seconds and on the right in twenty seconds; on the left forearm in thirteen seconds and on the right forearm, same location, in sixteen seconds. John reports that he feels well all the time and is not at all nervous. About a week before, he saw a boy with his hand cut and bleeding and had no ill reaction.

March 20, 1920.—John reports that during the past year he felt well and had no fainting attack. Vasomotor testing showed that reflex vasoconstriction appeared on the left side of the face in thirteen seconds and on the right in thirteen seconds; on the left forearm in nine seconds and on the right forearm, same location, in eight seconds. These are normal reflexes.

January 21, 1921.—Called on John in school to-day; he reports that he is well and not nervous, and that he has had no weakness nor fainting spell since the previous record and that he does not mind the sight of blood.

The results of treatment in the cases reported may be summarized as follows: Theresa H. responded by an amelioration of the symptoms in the first month, the medicine being administered in small dosage. The dosage was then increased, and at the end of the second month, the dizziness, irritability and fainting attacks ceased; medication was continued fairly regularly for a year. The girl graduated from the grammar school, obtained a clerical situation shortly after, and holds it at present (more than three years later). In April last, examination showed slight sympathetic hypertonia and unbalancement of the vasoconstriction reflexes, and she reported that last summer she had a fainting spell and also one two weeks before the examination.

The second case treated, Albert J., proved a most instructive one, for despite advice to the contrary, his medicine was administered very irregularly, thus giving an opportunity during two years to study the effect of the drug both on the symptoms of the disease and upon the objective phenomena associated with it. In this case the dosage at the start was fairly large, and there was a quick response to the medicament, the symptoms of irritability and fainting attacks ceasing and objective signs disappearing within a month and a half after the commencement of treatment. The administration of the medicine was kept up for four months and then the mother stopped it, deeming the boy cured. A period of two months of non-medication followed, in the middle of which vasomotor testing showed a marked hypertonia of sympathetic fibers and unbalancement of the vasoconstriction reflexes, and at the end of this period, the fainting attacks returned. Then, with the renewal of medication, the symptoms of the disease again disappeared together with the objective signs. Later, the administration of the medicine was neglected for a period of two months and then the boy had a convulsive seizure, the first he had in his life. After this attack medication was persevered in with more or less regularity for eight months. The boy has had no return of the symptoms since, save once when under the stress of fear and pain he had a slight seizure.

The third patient, John O., faithfully took the medicine for seven months. All symptoms of the disease disappeared after the second month, together with the objective signs, and there has been no return of the symptoms to the present, a period of three years.

A careful study of the cases reported in this paper showed that colloidal œnanthe administered per os lessened the hypertonia of sympathetic fibers that was present, and that with the return of the vasoconstriction reflexes to the normal—the symptoms of dizziness, loss of consciousness, sudden pallor, an dirritability ceased. In Case II, in which the ingestion of the drug was very irregular, the vasomotor reflexes were nearer normal and the

symptoms of the disease were in abatement during the time the œnanthe was being administered; and when the medicine was omitted for a time, the vasomotor reflexes were those of epilepsy and the symptoms of the disease—irritability, dizziness and sudden weaknesses—returned. These and other cases since observed showing the coincidence of sympathetic hypertonia with the symptoms noted by Echeverria as the sole expression of the seizures in incipient epilepsy (*i. e.* sudden pallor, dizziness, and loss of consciousness) and the concomitant disappearance of the symptoms and the sympathetic hypertonia by the use of *Œnanthe crocata*, a sympathetic paralysant, justifies the conclusion that the essential cause of epilepsy is a sympathetic hypertonia. With this in mind, the effect of fright in bringing on epilepsy, noted by Gowers, Turner, and others, is readily comprehensible, since Cannon[9] has shown that fright acts by producing a sympathetic hypertonia. In the cases reported above a fright played no part in the production of the sympathetic hypertonia that was present. What then produced this hypertonia? Do the infectious diseases produce this sympathetic hypertonia resulting in epilepsy? Each of the cases reported had at least one of the infectious diseases of childhood. There are observations, notably that of Gowers[10] "on the peculiar effect of the scarlet fever poison upon the nervous system" that indicate the probability of the toxins of the infectious diseases damaging the sympathetic fibers and producing a sympathetic hypertonia. The question presents an aspect of the subject outside the province of the present paper, worthy, however, of special investigation.

Diabetes Immediately Following Syphilitic Infection.—Villaret and Blum report the case of a man of forty-five who contracted a venereal sore and a few days later gave a positive Wassermann, followed by a secondary outbreak. Almost from the outset he began to complain of thirst, followed by polyuria and polyphagia, and asthenia. The urine showed a large amount of sugar and there was also acetonuria. The first injections of mercury cyanate caused this syndrome to disappear. Attempts to explain this case failed, as nothing could be accused against the nervous system, liver or pancreas.—*Le Bulletin Médical.*

ACHES AND PAINS OF INTERNAL DISEASE.

By OTTO V. HUFFMAN, M.D.,

NEW YORK.

ASSOCIATE PROFESSOR OF MEDICINE, NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Without going into the subject of pain too elaborately, I wish to present briefly and rather superficially a method that I have found helpful in localizing the problem presented by a patient who complains of aches or pains that do not have an obvious cause. There is the patient who complains of pain or paresthesia in the little and ring fingers who has not injured his ulnar nerve; there is the patient who complains of pain in the great toe who has no evidence of gout; and there is the patient who complains of "sciatica" who has no pathological condition in the sciatic nerve.

My method is this: (1) The patient is asked to trace with his hand very definitely the area where he has pain. (2) The dermatomes (segmental distribution of the spinal cord) involved are noted and it is sufficient in the beginning to note whether the pain is in the cervical, the thoracic, the lumbar, or the sacral segmental distribution (see the illustration). (3) The viscera related to the dermatomes involved (see the accompanying table from Déjerine) are considered in an objective way as to the possible cause; and in making up the indictment against the possible offender (viscus) it is most essential to have the facts in regard to time as well as to place. Here "time" is the relation to some physiological activity, as for instance, in the case of the stomach, before eating, or after eating; in the case of the heart, when at ease, or after exertion; in the case of the pleura, on taking a deep breath, in the case of the rectum, during defecation, etc.

TABLE

(From Déjerine)

Spinal Segments		Viscera connected by way of the sympathetic ganglia and rami communicantes.
III.	Cervical	apex of lung liver
IV	Cervical	stomach aortic orifice
I-III.	Thoracic	heart (ventricles) aortic arch
I-V.	Thoracic	lungs
VI-VII.	Thoracic	heart-auricles
VI-IX.	Thoracic	stomach
VI-X.	Thoracic	liver—gall-bladder
IX-XII.	Thoracic	intestines
X-XII.	Thoracic	prostate
X.	Thoracic I Lumbar	kidneys and urethra, uterus (body)
X.	Thoracic	testicle, ovary, Fallopian tube
XI-XII.	Thoracic I Lumbar	bladder, epididymis and vas deferens, colon
V. Lumbar and III. Sacral		prostate
I-IV.	Sacral	rectum
I-II-IV.	Sacral	bladder
I-II-IV.	Sacral	uterus (cervix)

When an ache or pain or sensation of heat or of numbness and tingling or of cold is not accounted for by some local condition affecting the peripheral nerves, we must think in terms of the neuron rather than of the nerve trunk and seek a possible cause in the viscera related to the locality where the pain or paresthesia is felt. The viscera are not supplied with sensory nerves but the sympathetic ganglia make synapses with the successive segments of the cord *via* the rami communicantes. In the case of a lesion or disturbance in a viscus, the peripheral sensory neurons of the segment of the cord that is connected with the sympathetic ganglion that sup-

plies the involved viscus become irritated, or stimulated, giving rise to the sensation which is referred to the locality supplied by these neurons. For the general practitioner it is not necessary to keep in mind the exact limits of each dermatome (*i.e.* part supplied by each segment of the cord); it is sufficient to bear in mind the general plan of distribution of the dermatomes. This is simple enough if we place the body on all fours like a monkey. In this position, cervical segments supply the cephalad aspect of the upper extremity, while thoracic segments supply the caudad aspect. (We cannot say "anterior" or "posterior" because these terms have a definite technical reference to the classical anatomical position.) Thoracic segments supply all of the thorax and the abdomen. Lumbar segments supply very little in the lumbar region but all the cephalad aspect of the lower extremity.

C. (Shaded) Cervical segmental distribution to the neck and the cephalad aspect of the upper extremity. The artist did not get the hands exactly in the monkey position but the shaded portion is the part supplied by cervical segments. D. (Unshaded) Thoracic segmental distribution to the caudad aspect of the upper extremity, to the thorax and to the abdomen. L. (Shaded) Lumbar segmental distribution to a small area in the lumbar region and to the cephalad aspect of the lower extremity. S. (Unshaded) Sacral segmental distribution to the caudad aspect of the lower extremity including the soles of the feet.

It is not unusual to find patients with cardiac disease complaining of pain in the caudad aspect of the upper extremity extending down into the little and ring fingers. The innervation of this part is derived from the upper thoracic segments of the cord which are in communication with the sympathetic ganglia that supply the heart.

Likewise, it is not unusual to find patients with rectal disease complaining of pain just like "sciatica" in the caudad aspect of the lower extremity. Disturbance in the periphery supplied by the sacral segments, as, for instance, a fallen arch, may cause pain in the whole of the sacral segmental distribution, "just like sciatica."

Pain in the front of the thighs (cephalad aspect) may be caused by a lesion in the kidneys or lower colon.

The monkey position helps us to visualize better the succession of the dermatomes—all we have to keep in mind is that the succession of segments supply a corresponding succession of dermatomes which run down from the cord.

Most of the viscera are related to the nearest segments, the only case where there is an exception to this is because the viscus has migrated from its original location. This refers to the ovary, the testicle, part of the prostate, part of the uterus, and the Fallopian tubes. The Wolffian bodies and the Müllerian ducts evidently derived their innervation when they were located next to the kidneys.

In working with this plan in mind it becomes a pleasure to try and solve the cause of the aches and pains of our patients which otherwise might mean nothing more to us than complaints.

772 MADISON AVENUE.

Action of Thorium on Certain Chemicals and Its Possible Value in the Morphine Habit.—Berthelot recently brought before the French Academy of Sciences the discovery by Lemay and Jaloustre of the oxidizing action of thorium-X on a number of organic substances tested. Among the latter were solutions of morphine salts. Here the alkaloid was rapidly precipitated in an insoluble form, which proved to be oxymorphine. This find at once suggests that thorium-X be tested in the morphine habit in the expectation that the drug in its toxic form might be changed to the inert oxymorphine. —*Le Bulletin Médical.*

THE PROPHYLACTIC AND CORRECTIVE VALUE OF FOOTGEAR.

By AAGE H. HANSEN, M.Cp.,

NEW YORK.

PODIATRIST TO THE NEW YORK POLICE DEPARTMENT.

THIS article is submitted with the object in view of giving a concise outline of the mechanical disturbances of the feet and limbs with their causes, diagnostic points, and the correct and incorrect methods of treatment. The main object is to present facts and figures proving the prominent role that footgear plays in the prophylaxis and correction of all mechanical disturbances of the feet and limbs. These disturbances of the feet which in most cases involve the legs are divided into two groups—Weak foot and Spastic foot.

Weak Foot.—Diagnostic Points: 1. Prolapse of the longitudinal or the anterior arch, or both. There is no spasm of muscles present, and there is no limitation of the normal joint motions.

2. General insufficiency of muscle power and distinct absence of tone.

3. Feet pronated with oscalcis rotating inwardly.

4. Painful symptoms in feet, legs, back, knees, or abdomen; local anemia.

5. Presence of plantar callouses at ball of first metatarsal and along inner side of heel.

Causes: 1. Insufficient use of the muscles because of occupation, convalescence, pregnancy, general debility, etc.

2. Incorrect posture, pronounced toeing-out.

3. Long periods of standing with insufficient rest during these periods.

4. Sudden change from a sedentary to a physically active occupation.

5. Wearing leather or metal arch supports or non-anatomic shoes.

6. Wearing shoes of incorrect size, usually too long and too wide.

7. Presence of a systemic disease.

Spastic Foot.—Diagnostic Points: 1. Spasm of the adductors, abductors, etc., of the foot, and of the anterior and posterior muscle groups of the leg.

2. Partial or complete limitation of the motions of the feet.

3. Upturned or clawed toes denoting prolapse of the anterior arch with spasm of the dorsal muscles of the foot, limiting downward flexion of the toes. Presence of corns on the dorsal aspect of the toes.

4. Spastic foot is the sequel of an improperly corrected weak foot.

Corrective Measures.—There are three essentials in correcting these conditions. These are manipulation, exercise, and corrective shoes. The application of these three measures must be co-ordinated with painstaking care if permanent correction is to be achieved.

Manipulation.—In *weak foot* we manipulate to increase muscle power and tone. This is accomplished by the use of resistive movements. If the longitudinal arch is prolapsed, the internal cuneiform, scaphoid, and astragalus can be forced upward as follows: In the case of the subject's right foot, take the thumb of the right hand, having the metacarpal head resting against the patient's scaphoid with the rest of the thumb pressing on the plantar surface, and the remaining four fingers pressing against the dorsal surface. Have the tip of the thumb of the left hand pressing against the patient's internal cuneiform, with the thumb base on the plantar surface pressing the fifth metatarsal, the remaining four fingers pressing against the cuboid and the dorsal surface. Pressure from the right hand should be resisted by that from the left. The left hand adducts the foot while the right hand inverts it, raising the arch. As much pressure as possible should be exerted to keep the foot in this over-corrected position for about a minute, then a felt pad and adhesive plaster should be applied.

In *spastic foot* we manipulate to break the spasm of the soft structures. The foot motions usually affected are adduction, inversion, and downward flexion of the toes. The feet should be manipulated until these motions can be executed painlessly by the subject.

Exercise.—Depending upon the severity of the condition, the subject should exercise daily from fifteen to forty-five minutes with or without shoes on as follows:

1. Stand with the feet parallel and raise the inner borders so that the body weight is carried on the outer borders.

2. Do the same exercise, only walk ten steps forward and ten steps backward on the outer borders of the feet.

3. Subject sitting: Cross the left foot on the right. With the right hand grasp the toes of the left foot firmly, and force them downward as far as possible. Reverse the procedure for the right foot.

The above exercises will assist materially in correcting weak and spastic foot, even if complicated with anterior arch prolapse and dorsal spasm.

Corrective Shoes.—The shoe to be worn by the subject should be selected with great care. The shoe is responsible for seventy-five per cent. of correction achieved. The requirements are as follows:

1. Correct size and last.

2. Make sufficient allowance in length and width to allow for changes in the contour and shape of the foot. A misaligned foot is usually swollen, and when this is reduced the foot is smaller. The object should not be to furnish a shoe to fit the misaligned foot but rather to make the foot fit the correct shoe.

3. Construction should include a long vamp, broad box, short waist, rigid shank, long leather counter, high-lace tight fitting upper, extension rubber heel.

4. Special internal and external corrections of cork and rubber must be made to care for mechanical defects.

Cork and Rubber Corrections.—Longitudinal Arch Prolapse: In either weak or spastic foot, if the longitudinal arch is prolapsed, a cork insole should be attached within the shoe made as follows: The cork insole is cut into the exact shape of the interior sole of the shoe extending from the heel to behind the metatarsal heads. See Fig. 1, superior view at B. Internally, at the longitudinal arch, ball of the great toe and inner surface of the os calcis it is ⅜ of an inch thick. It is skived so as to taper to 1/32 of an inch externally. See posterior

view. It is also skived to 1/32 of an inch behind the metatarsal heads. See internal view. A pad of porous rubber ½ inch thick should be cut into the shape as shown in the superior view at A. This pad should be skived externally so as to fit into the

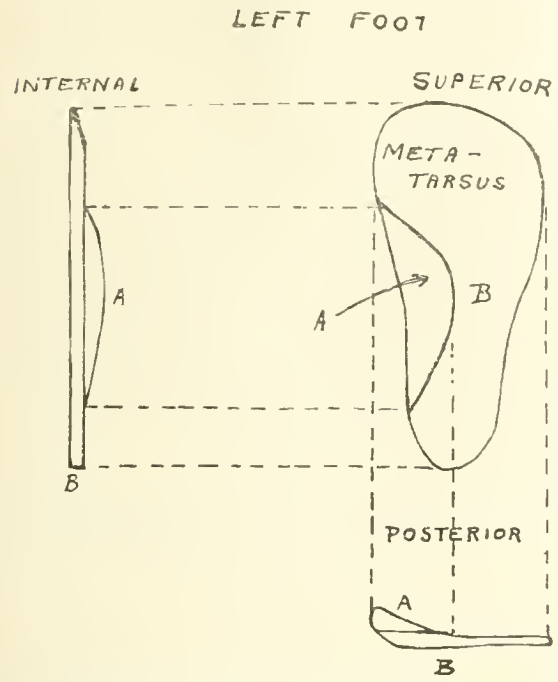

FIG. 1.—Pattern of cork insole and porous rubber pad. A, longitudinal pad of porous rubber; B, insole of cork, ⅜ in. thick internally, 1/32 in. thick externally.

Longitudinal Arch. See internal and posterior views at A. The pad can be either sewn or riveted to the cork insole. If the foot is only pronated, the insole should be used without the longitudinal rubber pad. By reason of the constant pressure of the body weight, this insole will in a few days become moulded to the exact form and shape that the foot requires. No irritation will result.

The foot is not a passive structure of support but an active one. The contour and shape of the foot change a dozen times during each step. A metal or leather arch support, or one made from a plaster-of-paris impression of the foot has but one rigid shape. It cannot change its shape so as to correspond to and accommodate the many changes in shape that the foot makes during the act of locomotion. Hence, severe irritation results

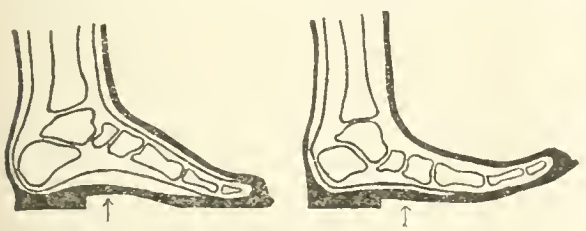

FIG. 2.—A, longitudinal arch normal; B, collapsed shank and longitudinal arch.

at the points of highest elevation and where the momentary downward pressure of the body weight is the greatest. This irritation occurs on most of the internal and plantar surfaces.

Furthermore, rigid supports make a weak foot still weaker, because free play of the plantar muscles is eliminated. Hence, destruction of the plantar-dorsal muscular tension occurs.

Flexible Shank Shoes: Another fallacy in the treatment of mechanical foot ailments is the use of the extensively advertised flexible shank shoes. These shoes are built contrary to the most elementary principles of mechanical support. Taking the human foot-print as a guide, the body weight, roughly speaking, is borne by the os calcis, cuboid with fifth metatarsal, the heads of the five metatarsals, and the five toes. Therefore there are four major weight-carrying areas. Figure 2A, illustrates an anatomically constructed shoe. The arrow indicates the rigid shank where the cuboid and fifth metatarsal receive sufficient support. The rigid shank is really a prolongation of the heel to the ball of the shoe. The body weight is, therefore, distributed normally the same as when the subject walks barefooted.

Figure 2B, illustrates a flexible shank shoe. Note how the shank collapses under the pressure of the cuboid and fifth metatarsal which are literally suspended in midair. The soft structures in this vicinity primarily contract and after a period of time collapse, causing an elongation of the plantar muscles and fascia. The dorsal muscles shorten, causing the toes to claw up which in time results in prolapse of one or more of the metatarsal heads.

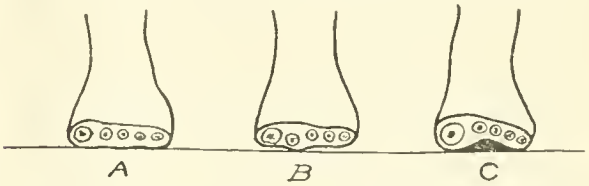

FIG. 3.—A, normal anterior arch; B, prolapse of second metatarsal; C, application of anterior rigid arch support.

In addition, the downward and outward displacement of the cuboid and fifth metatarsal causes disorganization of the scaphoid and cuneiforms which results in pronation and gradual collapse of the longitudinal arch.

Prolapse of the Anterior Arch.—The causes are many and varied, some having been already described. They are: wearing short shoes or short-vamp shoes, wearing flexible-shank shoes, wearing rigid arch-supports, etc.

The anterior arch is not a true arch, as all its parts touch the ground when bearing the body weight. The ligaments and muscles make possible a transverse and outward spreading of the metatarsal heads with their corresponding phalanges which is equivalent to a spring-tension. Figure 3 illustrates a transverse section of the foot at the heads of the metatarsals and shows the incorrect method of treatment. This method is not corrective but only palliative. Any method that destroys the flat and parallel alignment of the metatarsals heads, as illustrated at A, is unscientific.

Furthermore, if, as at C, the second metatarsal is elevated by the support it will still be in abnormal relation with the first, third, fourth, and fifth because they will have become prolapsed in their relation to the second which is now elevated. In addition, the transverse ligaments will become unduly strained, thus eliminating the lateral spring

tension in which all the metatarsals play an equal part.

It has already been demonstrated that if the equal tension of the plantar and dorsal muscles is destroyed, prolapse of the anterior arch results.

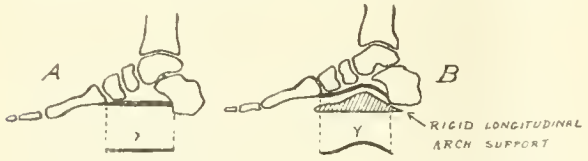

FIG. 4.—Showing the effect of a rigid longitudinal arch support upon the longitudinal ligaments.

In Figure 4, A denotes the plantar ligaments, X, and the straight line in which they lie. B illustrates the change that takes place when a rigid support is placed under the longitudinal arch. Note in Y how the plantar soft structures are forced upward against the bones causing the foot to become elongated. The unequal tension of the plantar and dorsal muscles causes contraction of the dorsal muscles which results in upward displacement of the phalanges and downward displacement of their corresponding metatarsal heads.

Correct Treatment.—A prolapse of one or more of the metatarsal heads, even if complicated with severe spasm of the dorsal muscles, can be corrected as illustrated in Figure 5. A represents prolapsed the metatarsal heads with upturned phalanges accompanied by an upward curling of the vamp of the shoe; and the position of the anterior rubber cleat on the sole of the shoe behind the heads of the metatarsals.

B. When the foot strikes the ground this rubber cleat is the major point of impact which causes an upward pressure to be exerted thus raising the metatarsals heads. (See arrow X). The toes really are suspended over a precipice. When the metatarsal heads are forced upward they in turn force their corresponding phalanges downward. (See arrow Y). Hence at each step this cleat automatically manipulates the metatarso-phalangeal articulations, thus breaking the dorsal muscular spasm.

This anterior cleat is made of hard sole rubber, $\frac{3}{8}$ inch thick and one inch wide, attached to the sole of the shoe by clinch nails. Rubber is used to soften the harshness of impact.

Conclusion.—The author during the year of 1920 treated the following cases of members of the New York Police Department: 399 cases of anterior

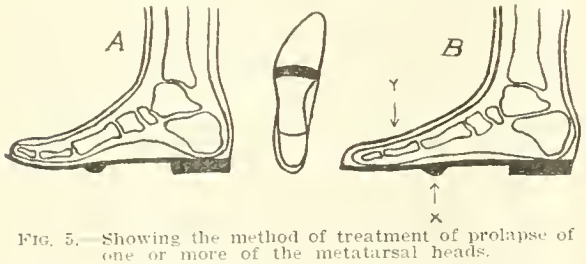

FIG. 5.—Showing the method of treatment of prolapse of one or more of the metatarsal heads.

arch prolapse of which 396 were spastic feet; 331 cases of longitudinal arch prolapse and pronated feet of which 286 were spastic feet.

Even though spastic feet are much more difficult to correct than weak feet, all of the above cases were permanently corrected with the exception of five cases. These did not respond, because of extreme chronicity, true ankylosis, systemic infections, senility, etc. However, corrective shoes as described in the foregoing had to be used in every case.

The author also examined and treated children of the child-caring institutions of the Catholic Charities of the Archdiocese of New York:

Total number children examined	4,487
Pronated feet and long-arch prolapse	207
Number corrected without the use of corrective shoes	16
Number which did not respond until corrective shoes were used	191
Number of cases of anterior arch prolapse	42
Number corrected without the use of corrective shoes	0
Number corrected after corrective shoes were used	42

It can be seen by the foregoing, that the foot should always be considered in its entirety. If a mechanical ailment exists it should be corrected so as not to disturb normal relations and areas. Only by correct diagnosis, persistent manipulation, exercise, and painstaking care in footgear, can permanent correction be achieved.

128 WEST SEVENTY-EIGHTH STREET.

THE PLACE OF THE MODERN MEDICAL LABORATORY IN THE DIAGNOSIS OF DISEASE.

BY LUCIEN ACHARD, M.D.,

NEW YORK

DIRECTOR OF THE GOOD SAMARITAN DISPENSARY'S LABORATORY.

THE modern medical laboratory is a very complex organization, which deals with diagnosis, treatment and prevention of diseases. Of these three functions the most developed at the present time is the diagnostic one. There is hardly a disease of which the diagnosis or the progress toward the desired or the undesired end can not be determined or controlled by some laboratory procedure, chemical, biological or bacteriological; on the other hand there are many diagnoses which depend solely on laboratory findings.

The general belief is that the laboratory is only the complement to the physical examination. That is, the patient will first have a physical examination, and after that the examining physician will request from the laboratory the tests he thinks necessary. This method of procedure presents several drawbacks. The examining physician may feel so sure of his physical findings that he considers laboratory tests unnecessary; we know how this reliance on our imperfect senses may be misleading. Again, busy principally in some other direction, he may not know the most recent or reliable tests for the special case. Others, in the rush of their work, forget some of those tests. Still others may feel that, to make a diagnosis without laboratory help speaks well for the natural diagnostic ability of the clinician. It is unnecessary for me to point out how many mistakes such practices will lead to.

Furthermore, the conscientious clinician, who knows that he cannot make a proper diagnosis without some laboratory findings, will, after the first physical examination, refer the patient or his specimens to a laboratory. After that perhaps he has to examine the patient again, either because in the lapse of time he has forgotten some physical signs,

or because he has to correct or make more definite some of his impressions. It is very evident that much valuable time is lost in this way, and that sometimes the result of the first physical examination may prove unsatisfactory.

To my mind the medical laboratory in our modern medical era should be something more and better than a mere help; it is the place where the scientific preparation for the correct clinical examination and the right diagnosis is made.

Many of us must have seen some of those engravings, where the physician is represented looking at a flask of urine, and many times those physicians were asked to make a diagnosis by the appearance of the urine alone. These were the first attempts to analyze a specimen, being the most easily obtainable, and at the same time the most useful indicator of internal conditions. These were the first steps in the way leading to a medical laboratory.

Since that time our laboratory methods and our pathological knowledge have gone on improving, and to-day we have already reached methods, which allow us to make with certainty the diagnosis of a good many diseases without the necessity of seeing the patient. But to diagnose a disease is not to diagnose the diseased condition, which shows variations in location, form, and amount with each patient; the clinician is called to recognize these differences and to direct his conduct accordingly. The first step under all circumstances is the diagnosis of the nature of the disease, and in our day this cannot be properly done without laboratory findings.

The laboratory findings are positive knowledge, while the physical examination gives only personal impressions, which, depending on our not always reliable senses, may be erroneous. The proper way to learn something is to start from known facts. The positive knowledge acquired through laboratory examinations are known facts. These can fix our ideas and sometimes give the diagnosis immediately, or when they cannot do that, they are the best guide for our further examination, and the best means for a proper interpretation of our physical impressions. If the patient comes to the examining physician with all the necessary laboratory tests already made, his ailments will be correctly recognized without loss of time. I here recall my medical student days, when one of our professors of clinical medicine always had his pupils go through the laboratory on their way to the wards, saying that "The way to the patient's bed is through the laboratory."

We have in the laboratory findings the thread which will guide us in our way in many clinical labyrinths. Would it not be wiser and more expedient to take this leading thread at the entrance of the labyrinth, and let us be guided by it without wasting a precious time? In other words, the laboratory findings should not be used to prove or disprove the clinical diagnosis, but should be the first step to put the clinician on the right road. In fact, the recourse the clinician has to the laboratory findings to make sure a diagnosis, giving to them the last word, the word of the judge, is an acknowledgment of the great importance of the laboratory for the right diagnosis. But it is not the last word he should give, he should give the first, the leading word. Every modern medical man is conscious of this fact, but the acknowledgment of it is not made in the plain and sincere way it should be, giving the proper place to the laboratory in the diagnosis of the diseases.

I have said that all the necessary tests would be made if the patients would go first to the laboratory. Therefore, it is necessary to have some one there who could establish which are the necessary tests. To my mind, this person should be no other than the pathologist, who necessarily has to have a perfect knowledge of the best methods the laboratory can offer in every special case.

To some it would seem that I am arguing for things which are already done in all the well-organized hospitals, as in them one of the duties of the house physician is to have the preliminary laboratory examinations made before the examining physician sees the patient. That is true, but to my mind it is not done as it should be, the pathologist being more or less looked upon as taking a secondary part in the establishment of the diagnosis. I wish to emphasize the importance which the laboratory has already attained today in the diagnosis of diseases, because there should be in every hospital a proper admitting department which, working independently from the clinicians, should be under the direct control of the pathologist of the institution. Here the patient should be thoroughly, and without loss of time, prepared for the examination by the clinician. The same thing could be done in dispensaries.

But what about patients who cannot be treated in institutions? This subject will be discussed in a subsequent article.

To conclude, it seems to me that the modern medical laboratory has a primary value in the diagnosis of the diseases, and that this fact should be more plainly acknowledged and accepted. If, then, we look at the laboratory in a comprehensive way as a diagnostic, therapeutic, and preventive agency, we see that in medicine today it should hold the first place, and it is going to hold such in the future.

Medical science can not be a mathematical science, as we always have to do with some variable and unknown quantities, but it is self-evident that the laboratory, in trying (and in many instances has already succeeded) to establish unquestionable facts and fixed rules based on these, is making, in every possible way, an exact science of it, independent from our clinical opinions or impressions. To use a mathematical comparison, I like to imagine the practice of medicine as a triangle whose base is made by the pathological science, from one end of which arises clinical skill, from the other therapeutic ability, which join together at the apex, where we find meeting the proper diagnosis and the correct therapy.

Surgery and the Constitution.—As in the old prescientific days surgeons now study the influence of the constitutional type on operative risk. Thus Payr states that in the status hypoplasticus there is an increased tendency to new formation of connective tissue, as shown in one locality by keloidal formation and in another by adhesion formation.—*Wiener klinische Wochenschrift.*

IS REJUVENATION AFTER PROSTATECTOMY A "STEINACH EFFECT"?

As a sort of by-product of the Steinach doctrine of regeneration is the theory that the improved general health which follows the operation of excision of the prostate may be due to possible section of the vasa deferentia incidental to the intervention. Such a view will be sure of some opposition from other progressive doctrines. Thus the upholder of the existence of "hyperprostatism" will conclude that the benefit following prostatectomy is the result of cutting off the supply of prostatic hormone which, like excess of thyroidin, can set up a morbid syndrome. If there are bacteria in the prostatic secretions the partisan of prostatic focal infection may ascribe the improved health to the cutting off of toxic products which have been poisoning the organism. The question which constitutes the title of this article is asked by Professor A. Blum of Vienna in the *Wiener klinische Wochenschrift* for Jan. 6, 1922, xxxv, 1. He regards the enlarged prostate as a true neoplasm and the socalled capsule is the remains of the atrophied organ. Incidentally the ejaculatory ducts are compressed and immobilized. This interpretation of the finds would at first sight tend to eliminate the possibility of such a condition as hyperprostatism, while in the advanced stages there could hardly be a possibility of latent microbism. But another factor which affects the general health—the removal of back pressure through removal of the urinary obstruction—would have to be awarded more or less credit for the improved general health and in cases in which the kidneys have been structurally compromised, it is conceivable that no marked general benefit could result.

Blum cites the belief in some quarters that removal of the prostate is followed by impotence and mental and physical decay, reasons often given by relatively young prostatics for refusing operation. This teaching once obtained to some extent among medical men. At present everyday experience is teaching us the contrary. In a majority of cases the broken down old man becomes truly rejuvenated. He looks younger, becomes springy and active, and in short has the actions and reactions of a young man. In a majority of cases sexual potency returns.

Authorities have been interested chiefly in the return of sexual potency as an isolated phenomenon. It is conceivable that with this renewal the rest might follow as a psychic reaction. Impotence is followed by intense mental depression, so that return of potence conceivably would have the opposite effect. It was only after the publication of Steinach's work on animals that the possibility of rejuvenescence from dividing the vasa was introduced into the speculations. The vital point then is the fate of these ducts as a result of prostatic hypertrophy and prostatectomy. Do they persist intact or are they damaged, and if the latter to what degree? The subject has been expertly investigated, and the conclusion is that with proper technique the ducts remain quite intact. Another question is much less easily answered. Does the typical prostactic resume sexual relations after operation and is he able to perform coitus physiologically and impregnate women? Blum finds that the sexuality of the individual after operation is commensurate with his years and that any abnormal increase of sexual power is not in evidence.

Blum has made intensive examinations of the prostatic remains, vesicles, and semen in some of his cases and found an approximation of a prostatic body, with vesicles normal and viable spermatozoids. Hence in this type of successful case no theory can be erected which is founded on the destruction of the ejaculatory ducts and interruption of continuity of the vasa deferentia.

Having eliminated this theory, Blum seeks the reason for the picture of rejuvenescence which undoubtedly follows the operation. Removal of back pressure with restoration of renal activity is a powerful factor in any case in which it has developed, and the condition known as urotoxemia which has long depressed the subject's vitality, spontaneously vanishes. In addition the author alludes to the subject, as discussed principally by French urologists, of hyperprostatism. One may go as far as to state that the prostatic adenoma secretes a toxic substance which affects the blood picture, the change in the latter again becoming normal after enucleation (eosinophilia, etc.). But it may be doubted whether this toxic principle is an excess of prostatic hormone, although apparently the normal prostate contains the same principle as the prostatic adenoma. Still another view is possible—that the normal prostatic hormone is necessary to health, that the atrophy due to compression of the neoplasm shuts off this supply, and that after prostatectomy there is a certain amount of recrudescence of prostatic tissue with reappearance of the hormone in the blood. Be this as it may, our next problem is the study of the prostatic hormone in health and disease. Blum does not mention the indirect psychic reaction following return of potency, nor does he allude to the possibility of a microbic factor;

but when severe general symptoms have been attributed to a few colon bacilli in the expressed secretion of the prostate, it would appear that the urologist should at least be certain that in all prostatics the secretions are quite sterile.

THE CLINICAL EVOLUTION OF PULMONARY GANGRENE IN CHILDREN.

THE symptomatic picture of pulmonary gangrene in children is difficult to outline. Primary gangrene and the secondary form due to pneumonia represent the two typical forms of the process. Their onset is sometimes preceded by some indefinite condition for several days or weeks, consisting of malaise, fatigue, anorexia, fever, and persistent cough. Following these prodromes, or even suddenly, chills occur, the temperature goes up, and the child complains of a pain in the side, extremely violent in character, a hard distressing cough, and quite severe dyspnea. The physical signs are slight and about all that can be found is a slight dullness of limited extent coinciding with a diminution of the vesicular murmur. Therefore, the onset of pulmonary gangrene is striking from the disproportion existing between the general symptoms and the small extent of the pulmonary physical signs. The child becomes extremely prostrated and distressed. The color is earthy, yellowish, or livid. The skin is dry, the temperature often 104° to 106° F. of the remittent type of hectic fever; the pulse is small, irregular, and soft; the tongue is dry, thirst is extreme, and there are complete anorexia, vomiting, and diarrhea. Sometimes the cough may be absent, but usually it is troublesome and prevents sleep. The dyspnea becomes more marked, especially should the lesions extend or if bronchopneumonia or pyopneumothorax develops. Fetid breath is wanting in 66 per cent. of the cases. In children under the age of five years expectoration is usually absent, but in older children a true vomicus may occur and that several times a day. Hemoptysis is met with in 25 per cent. of the cases and consists at first of pure blood without odor, then of black and horribly fetid blood, and this may be so profuse that death has been known to ensue. The physical signs are usually those of pneumonia, bronchopneumonia, or a pulmonary cavity. If a point of pulmonary softening occurs, resulting signs of pulmonary cavity are detected, and this may lead to the diagnosis of pulmonary gangrene. But often very few physical signs are present, although there are hectic fever, an earthy or leaden color, and a rapid weak pulse, all indicating a profound organic process. The gangrene may be latent and discovered only at autopsy.

In the pleuritic form of the process the onset is less sudden, although the pain in the side is violent. The physical signs are those of a pleural collection. About the end of the first week the general condition becomes bad, the temperature assumes the hectic type and exploratory puncture withdraws a very fetid purulent fluid containing particles of sloughing pleuropulmonary tissue. Neither the breath nor sputum is fetid. If the pleurisy be not surgically treated a pyopneumothorax will suddenly develop.

The embolic form of pulmonary gangrene usually follows otitis or mastoiditis. The child is suddenly seized with alarming symptoms beginning with headache, chills, sometimes vomiting, followed by a marked rise in temperature. The general signs of acute systemic infection then develop. Erratic pains arise in the limbs, the spleen and liver are tumefied, and the temperature remains between 102.5° and 106° F. Sometimes severe chills occur. The pulse is small, soft, and rapid, about one hundred and thirty to the minute. The pulmonary signs are of secondary importance and may sometimes be completely wanting. However, they usually exist, but are either overlooked or are not given their true value. The expectoration is not fetid because the foci of gangrene do not usually communicate with the bronchi, but the breath on the contrary is frequently foul. But it is the thoracic pain that claims attention; it is so violent that in itself it may lead to the diagnosis of pulmonary gangrene. Percussion gives few data; auscultation reveals diffuse signs which mean little, such as a slight decrease in the vesicular murmur, a sibilant respiration, sometimes friction sounds, fine subcrepitant rales, disseminated throughout the lungs, rarely large rales. Of the last two forms—the pleuritic and embolic—the former is particularly painful, the second especially serious.

LARGE DOSES OF ALCHOHOL IN THE TREATMENT OF ACUTE NEPHRITIS.

THE art of therapeutics is filled with paradoxes and inconsistencies and to paraphrase another proverb "what is one man's poison may exceptionally be another's cure." Ever since chronic interstitial nephritis became known in England as "spirit drinker's kidney" it has been taken for granted that alcohol is eminently a nephrotoxic substance. About a score of years ago a German whose name escapes us allowed subjects with chronic parenchymatous nephritis a ration of alcohol and announced that the percentage of albumin was not increased by one ounce daily of this substance, corresponding to two ounces of spirits. However, as he observed at the time, the drug served no useful indication in Bright's disease, so that the only interest to the practitioner was academic. According to the late Egbert Lefevre a spree by a subject with this affection is apt to precipitate a crisis of uremia which may prove fatal. So far as we know there has been nothing in medical literature with the exceptions to be noted later which would justify the drinking of alcohol by a nephritic subject. But very recently Dr. Barnardino Masci, a practitioner of Rome, has placed on record the singular fact that a victim of acute hemorrhagic nephritis who became intoxicated, so far from suffering an aggravation of the malady actually recovered. This patient was not a man but a thirteen year old girl, who had developed a nephritis from exposure, which is described in detail. Being dissatisfied with the meager amount

of food allowed her she surreptitiously drank from a bottle of brandy enough to intoxicate her. About thirty hours later she was seen to improve, began to void urine freely, the edema cleared up, and a report by a pathologist some hours later told that neither albumin nor formed elements were present. The report appears in the *Revista Ospedaleria* for December 15, 1921, xi, 23.

Ordinarily such an experience at the hands of a practitioner would not be taken too seriously. It may be that this girl would have recovered spontaneously. Alcohol of course possesses notable diuretic action in health but is hardly equal to overcoming a condition of persistent oliguria. It was only the occurrence of another case in the practice of the author that attracted his serious attention to the remedial use of alcohol in early nephritis. In another case the patient had suffered from this affection for four months, and was on a meagre salt-poor diet with wine practically cut off. The hopeless outlook of the case suggested allowing an indulgence of wine and the patient took advantage of this up to the point of intoxication. This was not repeated, but the subject began to improve and within a week oliguria had been replaced by normal passage of urine. The pathological report showed that the urine had become normal.

In the course of a perusal of the *Muenchener medizinische Wochenschrift* for August 15, 1919, Masci was startled to find an article by Bischoff which was based on some animal experiments. The latter appear to have suggested that alcohol, so far from being a bugbear to the nephritic, might actually be indicated in the treatment of acute glomerulonephritis. Such a change of front recalls the treatment of typhoid in which the fasting regimen was eventually succeeded by various degrees of feeding which culminated in the high calory diet of Coleman. Further one may recall the former prohibition of opiates in uremia until Loomis showed that morphine injections did not aggravate the condition, but on the contrary diminished the severity of the convulsions. The second case of the author given above was reported at the time in *Il Policlinico*, 1920, number 29. To sum up his position salt-poor diet and the balance of the modern treatment does not save these patients, so that we are justified in making use of anything which holds out hope of cure, and alcohol might be fairly tested, in countries where pure whiskey or brandy is obtainable, in acute and subacute nephritis which has proved refractory to other management.

EMOTION AS A FACTOR OF HYPERTHYROID STATES.

ALTHOUGH in exophthalmic goiter hyperfunction of the thyroid glands is the essential factor—and upon this point there seems now to be no question—Maranon (*Annales de Médecine*, 1921) considers that our theories in respect to the pathogenesis do not attribute sufficient importance to emotion as a causative factor. Only the most recent works—especially A. Kocher's article in Kraus und Brugsch's "Spezielle Pathologie und Therapie"—expressly mention violent emotional shock and prolonged emotional states, besides physical traumata, as factors. In a study of 159 cases of Graves' disease, Maranon has attempted to discover the determining cause of the affection, and he has found that in forty-eight cases an intense emotion coincided with the outset of the morbid disturbances. This observer, however, is categorical in his statement that emotion only was not the causative factor, but was the cause of the outburst of a preexisting latent hyperthyroid state, because he expressly states that in the vast majority of the cases (forty-one) the patients presented a marked predisposition, viz., emaciation without any manifest cause with exaggerated affective and neurotic tendencies, paroxysms of gastric hypersecretion, etc. The emotional factor is hence not in itself sufficient other than in a small proportion of cases; in the others a constitutional element is in play.

As to the mechanism of the relationship between emotion and the hyperthroid state the action of the endocrine glands must be admitted, and Maranon refers to Cannon's experiments and his own in which a glycosuria or hyperglycemia was noted following an emotion. Upon injecting small doses of adrenaline—¼ to ½ milligram—exaggerated reactions ensue and it may be supposed that the hyperthyroid state produces a condition of sensibilization of the vegetative nervous system which at least partially constitutes the emotive predisposition, and the adrenaline suddenly secreted on account of the emotive outburst, gives rise to the appearance of the characteristic changes depending upon the emotion. It is probably because of this that patients with Graves' disease are so sensitive to emotions and why a latent hyperthyroid state may become converted into a serious condition from an intense emotive attack, while less frequently a violent emotion or a series of emotions may transform a normal individual into a hyperthyroid subject.

Prolonged depressing influences, far more than a single violent psychic shock, are the cause and this fact may explain why the recent war did not give rise to as many cases of exophthalmic goiter as might have been anticipated. On the other hand the frequency of these depressing causes increases after the age of forty years, especially in women, and the so-called "climacteric hyperthyroid state" is, in reality an argument in favor of the importance that should be attributed to emotions in the genesis of exophthalmic goiter.

DIAGNOSTIC INSUFFLATION OF AIR INTO THE SPINAL CANAL.

THE insufflation of air into the spinal canal after extensive tapping to replace the withdrawn fluid is a comparatively old resource. The question of diagnostic possibilities came up considerably later, although at first rather for intracranial than intra-

spinal affections. Jacobaeus used the therapeutic insufflation of air as far back as 1909, and ten years later tried out the diagnostic possibilities on a case of spinal tumor. In an article which appears in the *Acta Medica Scandinavica* for December 5, 1921, lv., 6, he reports in great detail three cases including the preceding. Another Scandinavian, Josefson, reports a single personal case and apparently these four make up our knowledge of the successful cases. The points of vital importance are the shadow of the air column and the outlines of the tumor emphasized by the same. The author sums up his three cases in stating that in cases two and three the upper limit of the air column corresponded with the lower limit of the tumor as found later by operation; while in the first case the air column stopped somewhat short of the tumor, which may have been due to adhesions or to underinjection of air. In Josefson's case the air column also extended up to the tumor. The method therefore has a certain value in diagnosis, although the chances for error are great. It is certain that air cannot enter the entire canal save where a tumor is absent.

Furuncle of the Upper Lip.

This condition belongs among those which call for the greatest exercise of judgment on the part of the surgeon. A tragic death may follow under the let-alone plan and equally after an attempt to extirpate the focus in the interest of prophylaxis. The danger of general sepsis or of metastasis to a vital organ may not be so marked as that of phlebitis propagated to the cerebral sinuses. In the *Archivos de Medicina, Cirugia y Especialidades* for January 14, 1922, vi. 2, 32, Dr. Olivares reports a series of five cases of these lesions which well illustrates their redoubtable character. The first patient exhibited an intense edema involving the entire head. Seen on the fifth day the boil was treated with a crucial incision and an attempt was made to extirpate the necrotic tissue. Death took place forty-eight hours later without relief to the edema or temperature. The second patient was an elderly glycosuric. The edema which extended to the throat was intense, causing asphyctic symptoms. An attempt was made to rescue the patient by extirpating the necrotic focus but, although the asphyxia improved, death resulted within forty-eight hours. The third patient showed the same high degree of edema and the presence of exophthalmus might have suggested thrombosis of the cavernous sinuses; nevertheless radical operation appears to have saved the life of the patient, although convalescence was tedious. The fourth patient, aged fifteen, had a carbuncle and did well after operation on the fifth day by crucial incision. The lesion presented by the fifth patient was so severe as to suggest a malignant pustule. Extirpation was in vain and the patient succumbed several days later.

Diphtheria Antitoxin in Mumps.

The do-nothing treatment of epidemic parotitis is largely taken for granted, and it occurs to hardly and practitioner to seek new resources. In 1917 the chance improvement following injections of antidiphtheritic serum led to the systematic use of the latter in certain Italian and French clinics, with especial reference to warding off complications, notably orchitis. During 1921 an epidemic of mumps in a French garrison led to a trial of the serum and in the *Journal de médecine de Bordeaux* for January 10, 1922, xciv, 1, Mallié, a regimental surgeon stationed at Angouleme, reports his experience in the same field. The exhibition of the serum was limited to patients threatened with orchitis, who numbered 10, and in every case but one the orchitis seems to have been aborted. The question of routine administration in mumps naturally makes it necessary to fix the frequency of testicular complications; and as this shows considerable fluctuation it would be difficult to gauge the prophylactic powers of the serum. The incidence may be anywhere between 3 and 30 per cent., so that to be certain that wholesale prophylaxis has been successful an extremely low figure must be adduced in a large material. Salvaneschi, the originator of the treatment, injected 26 cases of mumps without a single development of orchitis, and the 3 times in 60 secured by Bonnamour and Bardin which equals 5 per cent. of failures is lower than the average incidence which seems to run about 7 or 8 per cent. for large material. Two sets of figures by des Cilleuls give an average incidence of complications, so that the prophylaxis of orchitis can hardly be said to have been achieved.

News of the Week.

Laboratory Workers Contract Tularemia.—All six of the laboratory workers of the U. S. Public Health Service who have been studying tularemia, a disabling sickness of man which has been known, particularly in Utah, for the last five years, have contracted the disease, two of them being infected in the laboratory in Utah and the other four in the Hygienic Laboratory in Washington. Such a record of morbidity among investigators of a disease is probably unique in the history of experimental medicine. In these workers the disease began with a high fever, lasting about three weeks, and was followed by two months of convalescence. The disease has few fatalities, its chief interest arising from the long period of illness which it causes in midsummer, when the farmers of Utah are busily engaged in cutting alfalfa and plowing sugar beets. The studies into the cause and transmission of the disease show it to be due to a germ, *Bacterium tularense*, which is conveyed by six different insects: the blood-sucking fly, *Chrysops distalis;* the stable fly, *Stomoxys calcitrans;* the debug, *Cimex lectularius;* the squirrel flea, *Ceratophyllus acutus;* the rabbit louse, *Hemodipsus ventricosus;* and the mouse louse, *Polyplax serratus*. Only the first four of these are known to bite man. It appears possible that the germ may also enter through unbroken skin; for instance, that of the hands.

A New Organism Akin to Botulinus. — The United States Public Health Service, in a recent report by Ida A. Benston, announces the demonstration of an anaerobic organism producing a soluble toxin which affects animals in a manner similar to that of the botulism organism but which fails to be neutralized by polyvalent botulinus antitoxin.

Study of the organism, as found in the larvæ of the green fly *Lucilia caesar* sent to the Service, indicates that it differs markedly from the botulinus isolated in the United States, and possibly is more nearly related to the European type described by von Ermengem in 1912, though it differs from this in important respects. Tests on laboratory animals by inoculation and by feeding caused death in from 5 to 71 hours. The most striking pathological result was, as in botulism, the congestion of the blood vessels of the brain and meninges. Efforts are being made to produce an antitoxin. The suggestion that the organism of the disease causes limberneck in chickens has not yet been demonstrated.

Child Welfare Bill.—The first child welfare legislation to be submitted by the State Child Welfare Commission was introduced on March 2. The measure is designed to include male children between the ages of 16 and 18 within the provisions of the present law, which forbids the employment of females of that age in a factory for more than forty-eight hours a week or more than eight hours a day or between the hours of 9 P. M. and 7 A. M.

Red Cross Aid to War Veterans.—According to the report of Judge Barton Payne, chairman of the organization, the American Red Cross expended $9,782.000 aiding disabled veterans of the World War during 1921. Of this amount $7,000,000 was disbursed by Red Cross chapters and the balance by the national organization. Including all forms of assistance the report shows that the chapters rendered services in more than 250,000 instances during each month of 1921.

Advocates Brief Loans of Radium.—In a recent address delivered in Quebec, Dr. C. Everett Field of the New York Radium Institute suggests that all radium hospitals, institutes, and public-spirited physicians possessing large amounts of radium be urged to loan to their community hospital centers an adequate supply for limited clinical use, such a project to cover possibly a ten-day loan four times each year. Dr. Field points out that there is a genuine need for such cooperation throughout Canada and the United States.

No Equity Remedy for Medical Board.—The State Board of Medical Examiners has no authority to bring an equitable petition to enjoin a physician from practising without a license, according to a decision rendered recently by the state supreme court of Georgia. The State Board presented in the superior court of Murray county a petition for an injunction to restrain Dr. Franklin C. Bentley from practising medicine. Bentley set up the fact that a jury in Murray superior court had previously acquitted him on an indictment charging him with practising without a license. He contended that the offense with which the State Board charged him in its petition was a criminal offense, and therefore outside of the jurisdiction of a court of equity. He claimed that the sole and exclusive remedy of the State Board consisted in criminal prosecution, and that the board was without authority to institute equitable proceedings. The court supported Bentley's contention.

Tulane University Plans New Medical Buildings.—Carrying out its original purposes for which an up-town tract was purchased thirty years ago, the Trustees of Tulane University have decided to begin moving the remainder of the medical school to the up-town site. This involves rebuilding the medical school plant with the addition of a university hospital. As the plan carries with it the expenditure of large sums of money it will require a number of years to complete the project. The new medical buildings and hospital will be located on the Tulane campus, facing Claiborne Avenue. The new hospital is designed simply to supplement the work of the Charity Hospital which will still be used, as heretofore, for the chief clinical work of the medical school.

Doctor Indicted for Violation of Harrison Act Acquitted.—Dr. John M. Manning, Mayor of Durham, N. C., was recently indicted in the Federal court at Raleigh for violation of the Harrison narcotic law, and was unanimously acquitted by the jury and judge. In this case the deputy demanded the payment of a penalty of $500, and upon Dr. Manning's refusal, issued a warrant against him and demanded that he be placed under a bond of $10,000, which was given. Judge H. G. Connor who tried the case declared this act on the part of the government inspector a "violation of both the letter and the spirit of the constitution." In charging the jury he said: "Why should a deputy revenue collector, who feels that some regulation of the department has been violated, demand of an honest citizen a penalty of $500, and on refusal, be authorized to have such citizen placed under a $10,000 bond with an implied threat of the Atlanta penitentiary, in order to collect the penalty which no process of law has fixed as being due by the citizen? The public will not stand for such treatment, and it is time to speak out for our protection. Judge Connor pointed out that had the defendant been less prominent he would not have stood upon his rights and the outcome might have been less fortunate.

Physicians Form Protective Association.—Physicians of Bartow county, Georgia, have perfected their plans for the formation of the Bartow County Physicians' Credit Association. They say they have found it necessary to form such an organization for their mutual protection, as physicians have done in other sections of the State.

Rockefeller Foundation Endows School of Hygiene.—The Rockefeller Foundation has given six million dollars to Johns Hopkins University, Baltimore, for endowment and buildings of the School of Hygiene and Public Health. Since this School was opened in 1918 the Foundation has furnished the funds required for its maintenance from year to year. With the acceptance of the present gift the trustees of the University assume full responsibility for the future needs of the School as they develop. The regular courses of study lead to the degrees of Doctor of Public Health, Doctor of Science in Hygiene, and Bachelor of Science in Hygiene. A certificate in public health is given to those completing certain special courses. Short courses or institutes are provided for health workers in service who cannot be absent from their positions for more than a few weeks at a time.

Physicians' Contribution to the Jewish War Sufferers.—Responding to an appeal Jewish physicians of Manhattan and Bronx have contributed over $40,000 to the New York Campaign for Jewish War Sufferers. The original quota assigned

to the medical profession was $25,000, but it is confidently expected that more than double this amount will have been raised before the campaign is closed. The committee in charge gratefully announces that a gratifying number of non-Jewish physicians have contributed to the fund.

Fox Hills Hospital to Be Abandoned.—It is reported from Washington that the sick and disabled ex-service men are to be removed soon from the Fox Hills Hospital on Staten Island. There are over 800 patients now in the hospital, some 500 of whom are suffering from tuberculosis. A number of the patients will be transferred to the Naval Hospital in Brooklyn.

Class Reunion.—The Class of 1892 of the Medical Department of the University of the City of New York, will hold an informal reunion and banquet at the Hotel Commodore, on Wednesday evening, March 29, 1922. All members of the class are invited to attend. The committee in charge includes Dr. Robert Emmet Coughlin, President; Dr. John F. Hagerty, Secretary, and Drs. J. Emmet Tower, William Meddaugh Dunning, and Frederick C. Holden.

Hospital Notes.—Plans have been filed for the proposed new home of the Hospital for Joint Diseases, which is to occupy the block front on the east side of Madison Avenue, between 123d and 124th Streets. There will be two buildings, a seven-story hospital to cost $650,000 and a six-story service building the estimated cost of which is $250,000.

Bids for the construction of the Shriners' Hospital for Crippled Children on Nineteenth Avenue between Lawton and Moraga Streets, San Francisco, have been opened. This is one of the series of hospitals which the Shriners are establishing in large cities throughout the country. It is planned to get the work on this hospital well under way this spring.

The contract has been awarded for the construction of an addition to the Woodlawn Hospital, Dallas, Tex. The new ward is to be used for the care of tuberculous negro patients.

Construction work has been begun on a new hospital at Ozark, Ark. The hospital will contain all modern surgical facilities.

The Soldiers' and Sailors' Memorial Hospital, erected by the Masons of New York State as a memorial to the 16,000 Masons in the state who took part in the World War, is nearing completion and will be dedicated on April 22. The hospital building containing 225 beds is located on the grounds of the Masonic Home at Utica and was erected at a cost of over $1,000,000.

The formal opening of the Conemaugh Valley Memorial Hospital and the twenty-eighth anniversary of the Women's Memorial Hospital Association were observed on February 22 with a reception in the Chamber of Commerce Rooms at Johnstown, Pa.

The International Health Board of the Rockefeller Foundation has selected the Shreveport (La.) Charity Hospital as one of the hospitals to be used in the training of men and women in hospital administration.

The Morrow Hospital, Liberal, Kan., has been purchased by the Roman Catholic Church and has been placed in charge of Catholic sisters.

The Lee Homeopathic Hospital, Johnstown, Pa., will soon open a free dispensary for the treatment of the poor.

The Commissioners' Court of Brownsville, Tex., has gone on record as favoring the plan to build a large county-city hospital at Brownwood that will cost approximately $75,000.

The Board of Health of Indianapolis has tentatively agreed upon plans for the construction of a new ward, administration building and nurses' home at the city hospital. The cost of these additions to the existing plant will be about $600,000.

The New York Skin and Cancer Hospital is making an appeal for funds with which to defray a deficiency of $35,000.

Dr. Hubert Work of Colorado, president of the American Medical Association, recently nominated as Postmaster General by President Harding, has been confirmed by the Senate. He took over the portfolio on March 4, when the resignation of Will H. Hays became effective.

Commander William Seaman Bainbridge sailed from New York Feb. 7 on the *Aquitania* to attend a meeting of the permanent committee of the Congrès International de Médecine et de Pharmacie Militaires, held in Brussels Feb. 20.

Dr. Benjamin Schwartz has been appointed visiting physician to Gouverneur Hospital, New York.

Dr. E. A. Gunderson of Chicago has been appointed to the staff of the Jacksonville (Ill.) Hospital, and will enter upon the duties of his new position immediately.

Dr. Herman A. Gailey has been appointed to the medical staff of the York Hospital, York, Pa.

Dr. Jesse Howell has been named physician to the Toledo (Ohio) Workhouse, to succeed Dr. Phillip Schreiber.

Dr. John D. Spelman of Cincinnati has been appointed superintendent of the Toura Hospital, New Orleans.

Dr. George Burton Stull and **Dr. Carson Coover** of Harrisburg have been named as associated railroad physicians and surgeons of the Pennsylvania Railroad.

Dr. R. J. Hutchinson has been appointed chief-of-staff of the Butterworth Hospital, Grand Rapids, Mich.

Dr. Alfred F. Hess of New York delivered the Cutter Lectures on Preventive Medicine at the Medical School of Harvard University on February 15 and 16.

Gifts and Bequests.—The American Society for the Control of Cancer, at its annual Meeting held at the Hotel McAlpin, New York City, February 23, announced a gift of $29,750 from the Commonwealth Fund of New York City for establishing a field service throughout the United States and Canada.

The will of the late Alfred S. Heidelbach provides for a bequest of $150,000 to Mount Sinai Hospital, New York, and bequests of $5,000 each to the Hebrew Orphan Asylum, the Sanatorium for Poor Children and the Lenox Hill Hospital.

Medical Society Elections. — THE EASTERN HAMPDEN (MASS.) MEDICAL ASSOCIATION, at its annual meeting held in Springfield, Feb. 9, 1922, elected the following officers for the ensuing year: *President*, Dr. R. E. Dickinson, Holyoke;

Vice-President, Dr. J. F. Gaylord, Springfield; *Secretary and Treasurer*, Dr. Elizabeth Young Sullivan Myers, Springfield.

The Southwest Texas District Medical Society, at its annual meeting held at San Antonio, Feb. 16, 1922, elected the following officers for the ensuing year: *President*, Dr. Houston Neely, Beeville; *Vice-President*, Dr. C. E. Scull, San Antonio; *Secretary-Treasurer*, Dr. William H. Cade, San Antonio.

The Texas Public Health Association, at its annual meeting held at Austin on Feb. 16, 1922, elected the following officers for the ensuing year: *President*, Dr. Z. T. Scott, Austin; *First Vice-President*, Dr. Elva A. Wright, Houston; *Second Vice-President*, Dr. J. B. McKnight, Sanatorium; *Secretary*, Dr. W. J. Butler, Galveston.

Obituary Notes.—Dr. Frank Byrnes of Chicago, professor of anatomy in Rush Medical College, and professor of surgery in the Illinois and Loyola Medical Colleges, died in the Memorial Hospital, following an operation performed last November, on March 1, at the age of fifty-eight years. He was graduated from Rush Medical College in 1894, and was an associate of the late Dr. John B. Murphy.

Dr. James William Flow of Kannapolis, N. C., a graduate of the North Carolina Medical College, Charlotte, in 1898, died of Bright's disease after a lingering illness, on February 9, at the age of fifty years.

Dr. John James M. Neville of Wortendyke, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1876, died on February 12, at the age of seventy-three years.

Dr. Darwin Crawford Smith, a graduate of Hahnemann Medical College, Philadelphia, in 1869, died at his home in Lewistown, Pa., on February 13, at the age of seventy-five years.

Dr. Otto Augustus Wall of St. Louis, Mo., died of heart disease on February 13, at the age of seventy-six years. He was graduated from Bellevue Hospital Medical College in 1871. He later taught at the Missouri Medical College and the St. Louis College of Pharmacy. He was a former president of the St. Louis Medical Society. He was the author of several works on pharmacology and materia medica.

Dr. William Carson of Shelbyville, Mo., a graduate of Washington University, St. Louis, Mo., in 1868, died on February 10, at the age of seventy-five years.

Dr. James Woods Babcock of Columbia, S. C., died at his home on March 3, at the age of sixty-six years. He was graduated from Harvard Medical School in 1886. He was a former superintendent of the State Hospital for the Insane at Columbia and later professor of psychiatry at the University of South Carolina. Dr. Babcock was one of the first physicians in the South to recognize pellagra and was coauthor with Dr. C. H. Lavinder of the United States Public Health Service of the first treatise in the English language on pellagra. Dr. Babcock was secretary of the National Association for the Study of Pellagra and its former president.

Dr. Albert Le Roy Shelton, the first Christian missionary allowed to enter Thibet, was assassinated by robbers at Batang, near Thibet, on February 17. Dr. Shelton was born in Indianapolis in 1875 and was graduated from the Medical Department of the University of Kentucky.

Dr. Martin M. Kittell of Jamaica, N. Y., a graduate of New York University Medical School in 1891, died of pneumonia on March 31, at the age of fifty-six years. He was a fellow of the American Medical Association and visiting physician to the Queensboro, St. Mary's and Flushing Hospitals.

Dr. Joseph W. Battershall of Attleboro, Mass., died following an illness of several months on February 24, at the age of seventy-nine years. He was graduated from the College of Physicians and Surgeons, New York City, in 1874, and formerly served on the Attleboro Board of Health.

Dr. James D. Nye, formerly a practising physician of Fond du Lac, Wis., died at his home in Denver, Colo., on February 21, at the age of 72 years. He was graduated from Hahnemann Medical College and Hospital, Chicago, in 1883.

Obituary.

HARRIS GRAHAM, M.D.

BEIRUT, SYRIA.

Dr. Harris Graham, professor of pathology and practice of medicine in the American University of Beirut, died on Feb. 27 in his sixtieth year at Beirut, Syria. Doctor Graham was born at Ottawa, Canada, took his A.B. at Toronto University and his M.D. at Michigan University in 1885, in which year he was commissioned by the American Board as a missionary to Turkey. He served four years as a professor in the medical school of the Central Turkey College, a missionary college at Aintab, until the Turks closed the school. He was called to the vacant chair of pathology at Beirut and occupied it with rare distinction for thirty-three years. He was the senior professor on the active list of the university faculty. He also served for nearly a quarter of a century on the executive committee of the Lebanon Hospital for the Insane, situated near Bierut. Dr. Graham studied bacteriology in Koch's laboratory in 1892, and subsequently worked in Berlin and Vienna. He first demonstrated that the culex carries the germ of dengue fever and claimed that he had discovered its microbe. His findings were corroborated by some and denied by others.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

CONCERNING "A VERY GRAVE CHARGE."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—My attention has been called to a letter in the MEDICAL RECORD of Feb. 18, headed "Denial by Proxy of a Very Grave Charge," and signed by Dr. J. Milton Mabbott of New York City. I should pay no attention to this letter if it were not for the fact that it might be read by people not familiar with the facts of the narcotic situation and the history of its development, and who may not have read my resolutions and speech in Congress. The widespread recognition of the need for the inquiry asked for by me and the conditions outlined in my speech upon which the demand was predicated, is shown by the countrywide support and indorsement of my action, and it makes me hesitate to trouble to answer this letter. However, since, to quote Dr. Mabbott, it may "convey an entirely erroneous impression to persons unfamiliar with the facts," I will simply make an observation or two, and let the matter rest there.

It is regrettable that the letter signed by Prentice and Harris and Hubbard and Greenfield, appearing in the *Brooklyn Eagle*, and which Dr. Mabbott seems to think contains so much valuable information, was not published in full in his letter. However, I do not blame him for not including it, because it answers itself to anyone who knows the facts outlined in my speech. There is no parallel to it in history outside of the case of the "Poo Bah" in "The Mikado," who could quote himself under the "proxy" of his various positions to prove anything he might say. Please add this *Eagle* letter to the following incomplete list of their interlocking activities and committees, etc., which I printed in my speech in Congress on Jan. 12, and which I have had mailed to most of the physicians of New York. The letter in the *Eagle* makes an interesting addition to the list of activities and "proxies" of the "Poo Bahs," and relieves me of any further necessity of discussing this interesting bit of epistolatory evidence in which they further involve themselves.

The letter in the *Eagle* and the letter in your journal prove how wise it is for this group not to come out into the open themselves and say much, but to do their "denial by proxy."

The following list is taken from the *Congressional Record*, Jan. 12, 1922, page 1336, and might be headed:

SOME OF THE ACTIVITIES AND PROXIES OF THE POO BAHS.

It is interesting to pause for a moment and scan the lists of so-called important medical committees from which have come announcements whose influence has more or less dominated the narcotic question for the past two years. For example:

1. Committee on narcotics, Council of Health and Education, American Medical Association. There we find Harris and Prentice.

2. Committee on narcotics, New York County Medical Society: Harris, Prentice, Hubbard, and Healy.

3. New York State Department of Drug Control, stated to have been operated under the influence of Harris, Prentice, Hubbard, and Lambert.

4. New York City Department of Health. Narcotic administration directed largely by Hubbard and Copeland.

5. Legislative committee, New York County Medical Society: Harris, Prentice, and Healy.

6. Health committee of Greater New York, whose report was printed in the *New York State Medical Journal*, May, 1920, as an argument in favor of the Cotillo bill: Harris, chairman; Hubbard, Prentice, and Healy reputed to be members of influence.

7. Cotillo and Fearon-Smith bills (New York), stated in print to have been written by Harris and Greenfield.

8. Report of narcotic committee of New York County Medical Society, read by Prentice. Committee: Harris, Prentice, Hubbard, and Healy.

9. Appeared at Albany in support of the above bills: Harris, Hubbard, Prentice, Healy, and Greenfield.

10. Appeared at board of health to advocate municipal code to conform with these bills: Hubbard, Prentice, Healy, Greenfield, etc.

11. Editor of bulletin of department of health, New York City: Hubbard.

12. Said to have been referred to from heads of administration at Washington as men to talk to for narcotic information and rumored to exert great influence with local offices of prohibition and Department of Justice: Harris, Hubbard, Prentice, and Greenfield.

We might go on with this at considerable length, but the above are sufficient examples of the concentrated influence of these few men in important places of authority and announcement. It would be interesting to discuss the actual qualifications and connections of this interlocking directorate, but time and space would be better utilized in outlining the general subject and leaving these matters of detail to a future investigation.

So if you will add to this list an "unlucky thirteen," in which they still further "put their foot in it" by quoting themselves, in Nos. 1, 2, 5, and 12, it will make another interesting exhibit. If you could find space for the original letter mentioned by Mabbott, I shall be very glad to try to get a copy of it and send it to you. It shows clearly why it is necessary for these people to use "proxies," and needs no answer other than the exposures of the above list.

My resolutions asking for investigation are simply the reiteration of requests that have come from all over the country and from many places. They and my speech are simply the collecting of a small part of the often recorded facts and exposures to which administration, medical and lay, has paid no attention, and whose neglect has permitted the narcotic situation to come upon this country and develop. My work is in the open, and is built upon the records and past experience. I need no "proxies." The record speaks for itself. All I have done is to present part of it where it can be no longer ignored; and the response and support from all over the country shows how badly it is needed and that this matter be taken out of the hands of "proxies" and brought out into the open. As to Dr. Mabbott's quotation of Congressman Mill's speech, I simply ask my fellow member in Congress to look up the evidence and record and see if he would not reverse his position and join in the growing demand for an investigation in a place where it cannot be controlled by any clique or interest.

Since making this speech and resolutions, I have been in receipt of communications from all over the country. They strengthen my position, and I want to say that if I had had the information ther that has come to me since, my speech would have had, if possible, more direct statements than I have used.

Apparently since the rise to power and influence

of these interlocking activities and interests and their influence over administration, these things and this situation have become inconceivably worse, and not to be longer tolerated by a self-respecting medical profession and a free people. If the medical profession's own committees and officers will do nothing to correct this state of affairs or to help the profession, it certainly was time to bring it before Congress. Let us eliminate the "proxies" and the secret conferences and committees, etc., and expose this whole medical farce-tragedy and get the whole thing out into the open.

LESTER D. VOLK.

HOUSE OF REPRESENTATIVES.
WASHINGTON, D. C.

DEEDS *VERSUS* WORDS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a recent letter to the Editor of the MEDICAL RECORD, Dr. J. Milton Mabbott says, "After a preamble relating to the defense of members of the Society who were awaiting trial for indictment by a Federal Grand Jury for alleged misconduct under the Harrison law, in advocating that our counsel should aid in their defense, if preliminary investigation seemed to warrant such procedure, I put myself on record as follows: 'In other words, I believe your action and the Society's position should be determined in every case on its merits, but giving the benefit of the doubt (if there be elements of doubt) to our accused fellow-member, be he great or small, be he accused of a great or small offense, and without undue deference to the rating of the interests arrayed against him.' "

Fine words, but "fine words butter no parsnips." What has actually been done? Take one example. A "fellow member" Dr. Christian F. J. Laase was accused, tried, acquitted, and died as a result of what he went through. What was done in the New York County Medical Society about his case?

Dr. Mabbott is distressed that those mentioned in Congressman Volk's speech should be asked to vindicate themselves, "and at their own expense." How about Dr. Laase? Was Dr. Mabbott perturbed because that member had to vindicate himself at his own expense and undergo prosecution and persecution, at a final cost which included his life? Dr. Mabbott should be heard from on these points. What has ever been done to find out the truth about the cases of Dr. Laase and of Dr. Bishop? Never mind any more evasions and "proxies" and words. What have he and his fellows on the inside of the officialdom of the Medical Society of the County of New York ever done to find out the truth about these two "accused fellow-members"? I would ask Dr. Mabbott to come out into the open and tell the facts. Never mind what he said, what has he done? What has the New York County Medical Society done to find out the truth about Dr. Laase and about Dr. Bishop?

If his friends are innocent they ought to be glad to have the investigation that Congressman Volk has asked for. What is there to get nervous about? If Dr. Mabbott knows anything he should tell it. It might help solve the drug problem.

JOHN P. DAVIN, M. D.

117 WEST SEVENTY-SIXTH STREET,
NEW YORK.

OUR LONDON LETTER

(From Our Regular Correspondent.)

LONDON, February 14, 1922.

Cancer Research. — Sir William Veno has consented to alter the conditions governing his offer of £10,000 for the discovery of a cure for cancer, and will give £1,000 a year for ten years for the purpose of cancer research. Lord Atholstan holds to his original offer of $100,000 prize for a cure, but will devote an equivalent sum to research purposes in addition. Sir William Veno is one of the most successful of the owners of proprietary medicines and an American. Lord Atholstan is the owner of the Montreal *Star*.

Physique and Fitness.—Another Industrial Fatigue Research report has just been issued in which it is stated that boys from Essex, mainly an agricultural county, are of definitely superior physique to those of Manchester. From these statistics, the authors of the report draw the inference that the country youths excel in stamina and general fitness which, according to Dr. Ritchie, medical officer of health of the English Education Department, is fallacious or, at any rate, misleading. In his opinion, the inferior height and weight standard of a big city's young men, so long as the disparity is a normal one and is not the effect of debility, warrants no such inference. Here are two points with which people of any big city may solace themselves: (1) Bulk is no criterion of fitness; (2) statistics relating to size, weight, and strength, unless interpreted by people competent to judge their relative meaning and value, may lead to quite fallacious deductions. Of course, a city youth is usually smaller than the countryside product, but the test comes when both of these are fully trained to a standard of fitness, not while they follow their ordinary daily calling. It is time that the present comparison was very justly made between Manchester boys following a calling in which they might be expected to develop a standard of strength and Essex boys engaged in work which might be calculated to do likewise; but this does not supply us with the requirements for a decision upon fitness, which is something quite other than bulk. As to a mental comparison, Ritchie agrees with the report that it would, indeed, be interesting to learn what difference, if any, exists between boys of the two communities. The history of the late war appears to bear out this view. The men from the big cities, although not so bulky as the country bred ones, showed themselves to be of equal staying powers, and, what is an important point, of equal courage as compared with those from rural districts. So far as mental powers are concerned, generally speaking, it may be said that the youth born and brought up in a town possesses a more agile brain, thinks more quickly than his country brother; but this does not mean that he is superior in brain power. Is not also the town-reared youth more immune to disease? Do not his heredity and environment tend to render him so?

Meeting of the British Medical Association in Glasgow, July, 1922.—The deliberations of the representative body will begin on July 21 and will continue daily, Sunday excepted, up to the afternoon of July 25. The annual general meeting will

be held on July 25, in the Bute Hall of Glasgow University, and in the evening the president will receive the foreign guests and the representatives of the oversea branches and will deliver his address. Professor J. Graham Kerr has agreed to deliver the Popular Lecture on the evening of July 25. The sections will meet for discussion on the forenoons of July 26, 27 and 28 in the various class rooms of the university, while a series of demonstrations will also be arranged for these days, Mr. R. H. Parry having been appointed director of demonstrations. The social program arranged is a varied one. The Glasgow Corporation will give a civic reception. A university reception will be given on the evening of July 26 in the Bute Hall and Hunterian Museum, and the Royal Faculty of Physicians and Surgeons has also undertaken to entertain the members on one evening. The annual dinner of the association will be held in the St. Andrew's Halls on the evening of July 27. Afterwards, there will be a dance in the ballroom suite of the halls. The Publishing Committee has well in hand the preparation of the Book of Glasgow, which is being specially written for the meeting.

Primitive Instincts.—Reference was made in a former letter to the discussion on psychology and especially to that part of it which deals with instinct in human beings which has been going on in the *Medical Press and Circular* for some little time past. The contention of the writer was that human actions are largely guided by instinct. Dr. Bernard Hart, lecturing at the Royal Society of Arts, London, a few days ago, said that his first business was to shatter the illusion that only animals were guided by instinct, and that man was guided by pure reason and intelligence. Man was a creature driven by instinctive forces, and reason and intelligence were merely guides or weapons in the hands of these forces. The sex instinct was one of the most powerful in the human mind, and was responsible unquestionably for much of our behavior and mental activity. Another great instinct was the herd instinct, by which the thoughts and actions of the individual became consonant to the community in which he lived. It was the mainspring of convention. Conflict between great instinctive forces was inevitable and the ideal solution of those conflicts was to be found in conscious control. It was imperative that education should take account of those instinctive forces, and the real task of education should not be solely the acquiring of knowledge but the cultivation and coordination of those instinctive forces in the light of reason and intelligence.

University of London.—Several new chairs have been instituted at the University of London.

Post-Graduate Work in Gynecology.—The staff of the Hospital for Women, Soho Square, has organized a scheme of post-graduate work in gynecology. Three sessions are to be held in the year, in January, March, and October, each of six weeks' duration. The hospital contains sixty-eight beds and over 14,000 out-patients attend in the course of the year. There is a well equipped laboratory and museum and an installation of the most modern *x*-ray apparatus for the treatment of carcinoma of the uterus.

Progress of Medical Science.

Boston Medical and Surgical Journal.

February 23, 1922, clxxxvi, 8.

1. Typhus Fever at the Boston City Hospital. George C. Shattuck.
2. The Surgical Management of Toxic Goiters. John de J Pemberton.

1. Typhus Fever at the Boston City Hospital.—George C. Shattuck began this work at a time when cases of typhus fever were being found among immigrants recently arrived in New York with the object of learning the number of cases recorded at the Boston City Hospital in recent years, to ascertain whether cases of typhus had been overlooked, and to determine the principal diagnostic difficulties relating to typhus in this locality. It was found that the records of the Boston City Hospital for the past ten years show that during that period four cases have been diagnosed as typhus fever. In a few cases diagnosed otherwise, a diagnosis of typhus fever would have been justified. The signs in another small group of cases are highly suggestive of typhus. Numerous cases, probably not typhus, had eruptions suggestive of typhus. There would seem to be a possible danger of mistaking for typhus an eruption in typhoid fever, paratyphoid fever, pneumonia, influenza, measles, cerebrospinal fever, eruptions in septic conditions, in alcoholism, and drug eruptions. Rashes strongly suggestive of that of typhus have been caused by arsphenamine. The diagnosis of typhus in atypical cases may be difficult or impossible by the use of known clinical methods, even when supplemented by the ordinary diagnostic procedures of the laboratory. Two of the newer methods of diagnosis are especially valuable, namely, (a) the proteus reaction of Wilson, Weil, and Felix, and (b) microscopic examination of bits of skin excised during life, which in typhus fever have a characteristic pathology.

2. The Surgical Management of Toxic Goiters.—John de J. Pemberton bases this paper on 1,224 operations for exophthalmic goiter performed on 677 patients from July 1, 1920, to July 1, 1921. Of these twenty-three died, a mortality of 1.87 per cent. by operations and 3.39 per cent. by patients. From July 1, 1920, to July 1, 1921, 1,954 patients with goiter were operated on in the clinic. Of these 101 had ligations only; 1,853 patients had partial thyroidectomies, in 465 of whom the thyroidectomy was preceded by one or more ligations. Thirty-five patients died, a mortality of 1.78 per cent. Eight of 996 patients with simple goiter, unassociated with hyperthyroidism, died, a mortality of 0.8 per cent. Four of 281 patients with hyperfunctioning adenomatous goiter died, a mortality of 1.4 per cent. Five, or 22 per cent., of the patients who died had recurrent goiter; they represent 8.9 per cent. of the fifty-six patients in whom the disease recurred. The deaths were due to three main causes: (1) Accidental causes, three patients; (2) intense hyperthyroidism, seven patients; and (3) moderate hyperthyroidism plus pulmonary complications due to the patient's lowered resistance, or some intercurrent cause as hemorrhage or infection, twelve patients. The deaths due to severe hyperthyroidism are preventable to a large extent; either an error is made in selecting the patient for operation or in selecting the operation for the patient. The basal metabolic rate as an index to the operability of a patient with exophthalmic goiter is valuable only when considered with the clinical history and findings. The high operative risk clearly contraindicates operation for exophthalmic goiter in three phases of the disease; that is, during an impending crisis (evidenced by a steady rise in the metabolic rate and loss of weight), during a crisis, and immediately after a crisis. Added risk is obviously encountered in patients with low grade infections, lowered resistance, dilated hearts, visceral degeneration, etc. Primary thyroidectomy unless contraindicated by some of the factors enumerated is indicated in patients with mild or moderate hyperthyroidism, whose basal metabolic rate is not more than +55 per cent., provided they are carrying the increased load well. In a second group of cases with a higher basal metabolism about whom doubt exists as to the advisability of recommending thyroidectomy, ligation of the superior thyroid is advised as a test. A

third class of patients are obviously in need of preliminary medical and surgical treatment before major surgery can be attempted. After the ligation of both superior thyroid vessels and a period of rest (three months), the patients, with but few exceptions, show a really remarkable improvement, but operation for resection of the thyroid gland should be insisted upon, or a "recurrence" will most likely follow.

9. Actinomycosis of the Urinary Organs: Report of a Case of Pyelonephritis in Which Actinomyces Bovis Was Found. H. L. Cecil and J. H. Hill.

1. The Relation of Labyrinthine Tonus to Muscle Tonus.—J. Gordon Wilson summarizes this study as follows: (1) Tonus is a plastic state of the muscle associated with the maintenance of normal attitude. (2) This state is under the control of reflex nerve impulses, which automatically produce a modification of the muscle to maintain a particular attitude. (3) One source from which these reflex nerve impulses arise is the labyrinth. (4) These reflex nerve impulses, determining the amount of muscle lengthening and shortening, together with the degree of fixation, depend upon antigravity impulses arising in the labyrinth. (5) The labyrinth is chiefly concerned with the maintenance of the head in space. As a corollary, the labyrinth influences secondarily the muscles of the trunk and limbs. (6) The muscle proprioceptors are concerned with segmental posture. The labyrinth is concerned with total posture. So far as trunk and limbs are concerned, the labyrinth may be regarded as a mechanism superimposed on the segmental. (7) In unilateral destruction of the labyrinth the deviation of the eyes and neck is due to tonic activity of the other labyrinth. (8) The stimulation of the nerves in the labyrinth is due to mass movements of the otoliths and fluids in the canals.

6. Quantitative Bacteriology of the Tonsils.—H. D. Caylor and George F. Dick present a study of a series of tonsils in respect to bacterial count, size, weight, and pathological change in the tonsils, and to the presence of disease in other parts of the body. In this series the tonsils from patients who complained of recurring sore throats or who had at the time of operation enlarged cervical glands, contained from two to twenty times as many bacteria per gram as did the tonsils from patients who did not complain of sore throat or have enlarged cervical glands. The results of this work indicate that tonsils should not be regarded as harmless because they are small. It is often not possible to express pus from the smaller tonsils because drainage of the crypts is prevented by fibrous tissue. The total bacterial content, as well as the number of bacteria per gram, may be much greater than that of large tonsils. Quantitative bacteriology is of more aid than is qualitative bacteriology in determining the condition of tonsils that have been removed, and in determining their possible relation to disease elsewhere in the body.

7. Definition of Experimental Typhus Fever in Guinea Pigs.—Peter K. Olitsky draws attention to the conditions necessary to establish experimental typhus fever in guinea pigs, indicates the nonspecific or pseudoreactions which should be considered as possibilities in the determination of each of these criteria, and finally shows that no interpretation of an experiment can be made unless all the requirements are met and the nonspecific or pseudoreactions are considered. Experimental typhus fever presents constantly and regularly certain manifestations, which stamp it unmistakably as a typical disease. These manifestations consist of a characteristic febrile reaction, of indefinite transmissibility from animal to animal, particular histological changes in various organs, but mainly in the brain, absence of bacteria cultivatable in any aerobic or anaerobic medium whatever, and, finally, immunity, determined by cross-immunity tests, to materials carrying known typhus virus. Nonspecific or pseudoreactions can be produced with a variety of substances such as various infective bacteria, and the failure to realize this fact may lead, and, indeed, has already led, to erroneous interpretations of inoculation experiments in guinea pigs in the course of studies on the etiology of typhus fever.

9. Actinomycosis of the Urinary Organs.—H. L. Cecil and J. H. Hill report this case, which occurred in a healthy, robust man thirty-five years of age. He had an infection of both kidneys with an organism rarely found, *Pseudomonas pyocyanea*, complicated with the presence of *Actinomycos bovis*. He had been treated for two years with practically all drugs, both old and proved, and new and experimental, without the slightest benefit. The writers are able to find only ten similar cases in the literature, which they summarize.

4. An Attempt to Procure Immunity to Malignant Disease in Man.—Thomas H. Kellock, Helen Chambers, and S. Russ in a previous paper have recorded that immunity to transplanted malignant disease can be produced in animals by inoculating them with tumor tissue which has been exposed to a suitable dose of radiation, and that this can be done without risk of a tumor forming at the site of injection. With these results it has seemed to these investigators worth while to test the process in the human body. In all thirty cases of cancer have been treated. The time is too short to permit of definite statements as to the value of the treatment to be made. All that the writers claim at present is that, with efficient technical precautions, the treatment can be carried out without causing tumor formation or serious effects. The cases treated were those in which the disease was at such a stage that complete surgical removal was not considered possible, but not so far advanced as to preclude the prospect of life for some months. At operation only enough tumor need be removed to provide sufficient material for subsequent injection. In cases in which glands have been involved no attempt is made to remove all the growth. The wound is closed and dressed. Two pockets are then prepared in the abdominal wall, on either side of the midline, in the following manner: An incision about an inch long is made down to the deep fascia, and a strong pair of sinus forceps thrust along between the subcutaneous tissues and muscles and then opened out. The pockets thus formed are fan-shaped with the narrow end upwards, so that injected materials tend to be retained. The pockets are made large in order to increase the area of contact between the patient's tissues and the injected material. If this precaution is not taken much of the tissue injected undergoes autolysis and is discharged. A large sized drainage tube is put into each of the openings, nearly to the bottom. With aseptic technique the specimen removed is put through a mincing machine into a shallow dish, and spread into a layer of uniform thickness. The rim of the dish is smeared with sterile vaseline, covered with a sheet of mica, placed in a larger dish, covered with a sterile towel, and exposed to *x*-rays. After a radiation dose of two rads the minced tumor is sucked up into an all-glass syringe, fitted with a wide aperture. It is taken

to the ward and injected in equal quantities into each drainage tube. The tubes are then withdrawn, previously placed ligatures are tied, and the wound sealed with gauze and collodion. It is very essential that a lethal dose of *x*-rays be given. As far as is known at present the addition of antiseptics to the irradiated material weakens its immunizing properties; there is also some indication that the tumor tissue is of no value if infected with septic organisms sufficient to cause an abscess to form at the site of injection. A number of cases are cited which show encouraging results following this procedure.

6. The Serological Test in Typhus.—W. James Wilson summarizes his serological observations in typhus fever as follows: Proteus X 19 when rapidly dried in vacuo can preserve its agglutinability as regards typhus serum for months at room or body temperature. When emulsions are made of such desiccated bacilli they can be for some weeks preserved with 0.1 per cent. formalin without their sensitiveness being impaired. These facts make it possible to prepare a stable sensitive diagnosticum and to dispense with living cultures, the advantage being obvious in military service in the field and also in enabling one to use an emulsion of known sensitiveness. It is well known that proteus X 19 in the living state is apt to vary as regards its agglutinability. Desiccation of bacilli renders them less agglutinable by specific serums, and to this rule proteus X 19 is no exception. It would therefore seem that the typhus serum agglutinins for X 19 are different from those produced in the blood of an animal by inoculation. Coliform, non-lactose fermenting bacilli are occasionally found in typhus urine and are agglutinated by the serums not only of the individual patient but of other patients. On one occasion a strain of *B. pyocyaneus* was isolated which was agglutinated by a few of the typhus serums.

7. The Earliest Sign of Senile Cataract.—Henry Smith ventures the hope that the general practitioner will learn to recognize that failing distance vision in people over forty is the first sign of cataract, and that he would do well to send the patient to an ophthalmologist for investigation. If this is done it will be found that the early stage of cataract is more frequent in people over fifty than has been supposed. The writer recommends the subconjunctival injection of iodide of potassium and finds that from 15 to 18 grs. to the ounce gives an efficient hyperemia. He advances the theory that iodide of potassium or cyanide of mercury act by producing hyperemia, which affects the nutrition of the lens, or the elimination of its waste, or both. He thinks more attention should be given to the nutrition of the lens and vitreous than has been given in the past.

2. Fats in Relation to the Genesis of Goiter.—Robert McCarrison reports feeding experiments carried out on pigeons in the Nilgiri Hills of Madras, 6,000 feet above sea level, where goiter is practically unknown. The incidence of goiter in pigeons fed on mixed grains and butter, but without onions, was 65 per cent.; in the remaining 35 per cent. there was no goiter. The cases that did not develop thyroid hyperplasia have a significance second only in importance to those that did. They suggest that the excess of butter was not in itself the cause of goiter, but that it was made a potent contributing or determining cause by the operation of some other factor or factors. In other animals under similar conditions oleic acid and cod-liver oil were substituted for the butter. The outstanding results of the experiments were: (1) The potency of the conditions of close confinement, want of exercise, overfeeding, and fecal contamination in the causation of goiter. (2) The completeness of the protection against goiter afforded by cod-liver oil. (3) The influence of butter in favoring the development of the thyroid swelling, and the still greater influence of oleic acid in so favoring it. (4) The pronounced individual idiosyncrasy to the disease as evidenced by size of the goiter. The latter fact suggests the possible influence of individual variations in metabolic rate in determining the size of the goiter, the greater need of some individuals for iodine than of others, and the more potent operation in some cases than in others of bacterial agencies in the digestive tract in hampering the absorption or utilization of iodine.

The fact that the free oleic acid appears to be the more potent in favoring thyroid production than butter suggests that it may be by means of the free unsaturated fatty acid derived from the butter in the digestive tract that the latter exerts its harmful action on the digestive tract. Experiments on tadpoles showed that an excess of the several fats in the food caused remarkable retardation in their rate of growth. Iodine in amounts of 0.5 to 1.0 mg. per gram of food mixture tended to prevent the retardation of growth induced by butter and oleic acid, but not that induced by cod-liver oil. So far from iodine exercising any compensating action on the retardation of growth induced by cod-liver oil, the retardation was increased by the iodine. The retardation of growth induced by the fats was associated by delayed development of the thyroid gland; it appeared to cause a diminution of the colloid content of the gland out of proportion to its retardation in development. It would seem that oleic acid has a special tendency to prevent the storage of iodine-containing colloid in the thyroid gland. The writer points to the possibility that abnormal conditions may arise in connection with the "fat-thyroid-iodine balance" in consequence of bacterial action which would render by one means or another the small amount of iodine available in the food relatively deficient, or free oleic acid relatively excessive. He is glad that this latter aspect of the problem is at length receiving attention.

3. The Recognition of Aortic Incompetence.—E. M. Brockbank asserts that on many occasions in recent years he has found incompetence of the aortic valve which had not been previously recognized or suspected. Aortic incompetence is most likely to be overlooked when it occurs, as it not uncommonly does, without any accompanying obstruction or stenosis to attract attention to the diseased aortic valve by its definite, easily recognized systolic murmur heard over the second right costal cartilage. When a heart is enlarged and beating regularly, and at a moderate rate, and there is no increase in blood pressure, aortic valvular disease must be suspected and auscultatory evidence sought for, not only over the aortic cartilage but also down the left border of the sternum, and especially over the tricuspid region of the precordia, where the earliest evidence of aortic incompetence, Dr. Brockbank maintains, is most likely to be found.

6. Serological Investigation of Oriental Sore.—W. H. McKinstry has examined the blood of twenty-eight cases of oriental sore in all stages of the disease, according to the Wassermann technique used at Military Hospital at Rochester Row. In twenty-seven of the cases the diagnosis was established by the microscopic finding of Leishman-Donovan bodies. In the one case in which Leishman-Donovan bodies were not found there was no doubt from the clinical history and position of many old cicatrices that the case was one of oriental sore. Of the twenty-eight cases only one gave a positive Wassermann reaction. This case had points of clinical interest which helped to establish the fact that a positive Wassermann reaction is practically never found in oriental sore without concomitant syphilis. While admitting that eighteen cases is a small number upon which to dogmatize, McKinstry is confident that in the absence of concomitant syphilis, the Wassermann test never gives a positive reaction in cases of oriental sore.

3. The Practical Value of the Slide Diagnosis of Gonorrhea.—A. Mattes presents this paper not to open up a new field of endeavor but to more forcibly impress, if possible, the feasibility, the importance, and, above all, the diagnostic value of the slide diagnosis of gonorrhea. It should be remembered that a case need not necessarily be considered gonorrheal or so diagnosed upon finding intracellular diplococci in a simple stain. The organisms with which gonococci are often confused are colon bacilli, staphylococci, and *Micrococcus catarrhalis*. Gram's stain aids greatly in the differentiation and should be employed in all cases to avoid confusion and error. Making a diagnosis on history alone is not justified in these days of modern practice. Non-specific infections of the genitourinary tract occur very frequently. The symptoms are practically the same as those of gonorrhea. However, the prognosis and the treatment are entirely different. The practice of medicine has outgrown quinine administration for the diagnosis of malaria, and now awaits a laboratory diagnosis before treatment is begun. Should not the same apply to the diagnosis of gonorrhea as well?

8. Diagnosis and Susceptibility in Hay-Fever.—William Scheppegrell reviews the symptoms and describes the tests employed to verify the diagnosis of hay-fever. He points out that an attack of hay-fever not only does not develop immunity but hypersensitiveness due to decreased resistance, resembling in this respect the infection with such organisms as the influenza bacillus, pneumococcus, streptococcus, and staphylococcus. The susceptibility of hay-fever patients varies within considerable limits, not only in the degree of the reaction, but also in their reaction to different pollens. In order to determine the influence of heredity in hay-fever, Scheppegrell has analyzed a series of 1,000 cases treated in the hay-fever clinic of the Charity Hospital, New Orleans, and in private practice. This shows that over one-third of the cases (37 per cent.) had relatives of the first degree (father, mother, sister, or brother) who suffered from hay-fever. The exact proportion is probably higher than this, as specific susceptibility may exist indefinitely without developing hay-fever, by reason of insufficient exposure to hay-fever pollens. In this series of 1,000 cases of hay-fever 53 per cent. suffered from asthma during some portion of the season. Although this is a higher ratio than has heretofore been recognized in hay-fever, the probability is that the proportion is still higher. There are many cases in which the nasal symptoms of hay-fever are so mild and of such short duration that the patient recognizes only the asthma from which he is suffering. In addition to this there are also cases of asthma, due to pollen sensitization, in which the nasal symptoms are apparently entirely absent, and therefore its relation to hay-fever is unrecognized. In view of this all cases of asthma, especially those occurring during the usual hay-fever season, should be tested with extracts of the atmospheric pollens to which the patient is exposed. The writer's experience has shown that the number of asthmatic patients giving positive reactions to the pollens, especially the grasses and ragweed, is quite high. This diagnostic test is therefore important, especially in view of the experience that these cases not only respond favorably to the immunizing hay-fever therapy, but that the number of seasonal cures and improvements equals those of the uncomplicated form of hay-fever. In this series of 1,000 cases there were only seven atypical forms of hay-fever and asthma due to the inhalation of dandruff protein of horses and other animals, or to the protein of coffee, flour, and similar materials. However, the possibility of this form of reaction should be borne in mind.

4. The Polypoid Posterior Tip of the Inferior Turbinate as a Causative Factor in Progressive Deafness. Harold Hays.
5. Ohio's Opinion of the Nurse Anesthetist. Gainor Jennings.
6. Against the Reporting of Venereal Diseases. J. Van Bacalaere.

2. Bacterial Vaccines Are Good Antigens in the Treatment of Bacterins.—G. H. Sherman submits the following argument: That either an acute, subacute, or chronic infection of an organ will impair or suspend its function is perfectly apparent. If the infection is very severe, the function of the organ may be permanently destroyed within a short time, and if life can be sustained without the crippled organ the infection may subside without restoring the function of the organ. A less severe infection may suspend the function of an organ, leaving the organ in such a condition that its function will be restored after the infection is eliminated. If, on the other hand, the infection continues for a long time, the function of the organ may eventually be permanently destroyed, even if the infection is eventually eliminated. From these considerations it is apparent that an infection of the pancreas would suspend its function of secreting the ferment that controls sugar metabolism and thereby establish a diabetic condition, and if this infection continues until this function of the pancreas is destroyed, the diabetes would continue even if the infection should be eliminated. Considering diabetes as due to infection, immune therapy is the most rational procedure. Since the streptococcus and colon bacillus are the most common organisms responsible for infections of the abdominal viscera, with a large percentage of cases in which the staphylococcus and pneumococcus are also present, and since the pancreas, especially that portion which contains the islands of Langerhaus, is inaccessible for bacterial examination, the most rational procedure is to institute immunization against all of these organisms by giving a mixed vaccine which contains these various organs. The writer claims to have demonstrated the correctness of this contention by clinical tests in patients suffering from diabetes. If the vaccine treatment is instituted during the earlier stages of the disease before destructive processes have had time to develop, it is found that sugar rapidly disappears from the urine. The vaccine treatment is harmless and may be employed in conjunction with the routine dietetic treatment of diabetes.

Finska Läkaresällskapets Handlingar.

November-December, 1921, lxiii, 11-12.

Radiation of the Viscera to Hasten the Coagulation of Blood.—Elving has studied the hemostatic action of the *x*-ray on the spleen, liver, and heart. The coagulation time is dated from the appearance of the first shreds of fibrin and the silent interval is calculated by Bürker's method. The daily variations in the healthy are first determined. In some of the cases the spleen was subjected to the *x*-rays, one-third of a skin-unit dose. Of twelve individuals studied, but one showed absence of an accelerating action on coagulation. The maximum acceleration was noted about four hours later, and after eight hours, although still pronounced, it had begun to recede. In a number of cases there was evidence of acceleration as late as twenty-four hours after raying the spleen. The maximum acceleration was about 67 per cent., and in individual cases the time ran from 25 to 40 per cent. The liver was rayed in six cases and the optimum acceleration was seen eight hours later; the maximum acceleration was 43 per cent. and in general about 20 per cent. Raying of the heart produced accelerations as high as 31 per cent., with a mean of 16 per cent. From the therapeutic angle the spleen was rayed during actual hemorrhages but with inconstant results. A much more decisive action followed prophylactic raying before operation. Of numerous other hemostatics tested in connection with their action on the coagulation time of blood the best results were obtained with calcium chloride in intravenous injection.

Book Reviews.

VETERINARY HYGIENE. By R. G. LINTON, M.Q.C.V.S., Professor of Hygiene, Royal (Dick) Veterinary College, Edinburgh. The Edinburgh Veterinary Series. Price, $6. New York: William Wood & Company, 1921.

THE seven sections of this volume are devoted successively to water supply, meteorology, sanitation, air and ventilation, building construction, preventive medicine, and sanitary law. The animals under consideration are cattle, pigs, horses, sheep, dogs, cats, rabbits, and poultry. The specific and transmissible diseases and insect transmitters naturally receive due attention. A work like this, which parallels the subject of human hygiene and often overlaps it should prove of value for the medical practitioner as well as the veterinarian.

ARTERIAL SCLEROSIS, A Consideration of the Prolongation of Life and Efficiency after Forty. By LOUIS FAUGÈRES BISHOP, M.A., M.D., Sc.D., F.A.C.P., Professor of the Heart and Circulatory Diseases, Fordham University School of Medicine, New York City; President of the Good Samaritan Dispensary; Physician to the Lincoln Hospital; Chairman of the Section of Historical Medicine of the New York Academy of Medicine; Member of the American Medical Association, of the Medical Veterans of the World War, of the American Therapeutic Society, of the New York Pathological Society, of the Society for the Prevention and Relief of Heart Disease, and of the Alumni Association, St. Luke's Hospital; Author of "Heart Troubles; Their Prevention and Relief." New York: The Oxford University Press, American Branch, 1921.

IT is gratifying to find that a new issue of this excellent work is called for. Dr. Bishop was, we believe, the first to recognize the influence of protein idiosyncrasy in the causation of cardiovascular disease. Since the first edition of this book was printed, the method of testing for protein idiosyncrasy has been developed but it is practically impossible to test every protein that enters into man's diet, so that the author's injunction to cut out all meat and eggs, and even fish, remains sound, and should be followed if one would be on the safe side. The book is most readable and is full of practical suggestions; especially useful are the chapters on The Riddle of Arteriosclerosis, The Treatment of Arteriosclerosis, and The Prevention of Arteriosclerosis, but the whole book is valuable and will well repay study.

AIDS TO MEDICINE. By BERNHARD HUDSON, M.D., Camb., M.R.C.P., Lond., Swiss Federal Diploma; Physician in Charge of the English Sanatorium at Montana, Switzerland; Visiting Physician to the Queen Alexandra Sanatorium at Davos; formerly Assistant Physician to the City Road Chest Hospital, and Pathologist and Registrar to the East London Children's Hospital. Third Edition. Price, $2.00. New York: William Wood & Co., 1921.

THE writer makes it clear in the preface that it is not his intention that this book shall serve as a substitute for the many excellent textbooks on medicine. His object is to supply the student with a book for revision purposes of a convenient size to carry about. In this he has succeeded admirably, for in the space of 360 odd pages he gives a succinct outline of the practice of medicine which the student will find most helpful in crystallizing his knowledge. In this edition the subject matter has been brought up to date, affections brought into prominence during the late war are briefly described, and a new chapter on the more common skin diseases has been added.

BACTERIOLOGY. For Students in General and Household Science. By ESTELLE D. BUCHANAN, M.S., recently Assistant Professor of Botany, Iowa State College, and ROBERT EARLE BUCHANAN, Ph.D., Professor of Bacteriology, Iowa State College, and Bacteriologist of the Iowa Agricultural Experiment Station. Revised Edition. New York: The Macmillan Company, 1921.

THIS text-book, first published in 1912, for students in general and household science, has been revised and portions have been completely rewritten to bring it in line with the revised scheme of classification of the names of bacteria recently formulated by the Committee on Nomenclature of the Society of American Bacteriologists. In the present edition the topic of food preservation has been elaborated and increased emphasis has been put upon panary and acid fermentations. The text meets in a fair way the needs of students in non-technical courses. It does not supply the detail of laboratory technique required by the medical student.

THE LIFE AND TIMES OF AMBROISE PARÉ, with a New Translation of His Apology and an Account of His Journeys in Divers Places. By FRANCIS R. PACKARD, Editor of the Annals of Medical History. Price, $7.50. New York: Paul B. Hoeber.

THIS is a most attractive volume both from the literary standpoint and from that of the printer's art. There are among the 22 text illustrations and 27 full page plates, many excellent reproductions of illustrations from Paré's original text and from portraits of his times. In addition there are two folded maps of the 16th and 17th centuries. The first part of the volume is concerned with the historical setting in which Paré passed his life. This was a most interesting period in the history of France, one of cruel civil and religious wars and expensive foreign wars. These conditions furnished the opportunity for the development of one of the most remarkable figures in the history of medicine, and a man who also played no mean part in the social, military and political life of his country. He was surgeon successively to Henri II, François II, Charles IX, and Henri III. He was held in such high esteem that though he was probably a Protestant in his sympathies, his life was spared during the Massacre of St. Bartholomew, when the order was sent forth to spare no Protestant.

The second part of the book consists in a translation of "The Apology and Treatise containing Voyages into Divers Places." In this the author has made an effort to translate as literally as possible the old French in which Paré wrote, the French of Rabelais and Montaigne, with whom Paré was probably acquainted. While we may smile at many of the strange concoctions upon which the therapeutic faith of those days was pinned, there were many matters upon which Paré displayed a most remarkable insight. For instance, after describing the horrors of a battlefield, he writes that swarms of flies procreated in the dead bodies and expresses the belief that where they settled they carried plague and caused pestilence. This is undoubtedly the most readable translation of Paré's Apology that has yet been printed. The book is one that will delight anyone interested in the history of medicine or in this period of French history.

DISEASES OF THE NERVOUS SYSTEM. By H. CAMPBELL THOMSON, M.D., (Lond.), F.R.C.P., Physician to the Department for Diseases of the Nervous System, and Lecturer on Neurology, Middlesex Hospital; Physician to the Hospital for Epilepsy and Paralysis, Maida Vale; formerly Dean of the Middlesex Hospital Medical School. Third Edition, Revised. With 11 Color and 12 Black-and-White Plates and 120 Figures in the Text. Price, $5.00. New York: Paul B. Hoeber, 1921.

THE student of medicine and the young practitioner are apt to find that diseases of the nervous system present unusual difficulties. Writers of textbooks are likely to overlook or to underrate these difficulties, with the inevitable result that the recent graduate generally knows less of nervous diseases than he does of (say) diseases of the digestive or circulatory system. The present volume is a useful introduction, with ample explanation of the anatomical relations, and with due attention to the difficulties ordinarily met with in this branch of medicine. In this new edition there is a chapter on Encephalitis lethargica; the relation between the neuroses and the internal secretions has been emphasized, and new material has been inserted in the sections on injuries to the spinal cord, aphasia, and the autonomic nervous system. The book is clearly written and well printed; it is very readable, is unusually well illustrated, and should prove popular with the class of reader for whom it is intended.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 5, 1922.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Radiograph in the Diagnosis of Brain Conditions. Ventriculography.—Dr. WALTER DANDY of Baltimore gave this presentation, which consisted in a lantern slide demonstration. He said that, as was well known, the only shadows shown in a radiograph were those due to differences in tissue density. In an *x*-ray of the head the only shadows were those of the bones of the skull. If, however, the cerebrospinal fluid was removed from the cranial channels and air was introduced into the lateral ventricles, the entire ventricular system could be filled with air and one could get well-defined shadows on an *x*-ray plate showing the conformation of the ventricular system. By this means deviations from the normal shadow of the size, shape, or position of any or all of the ventricles and of the subarachnoid space could be demonstrated. This procedure had proved itself useful in the localization of brain tumors, the demonstration of all types of hydrocephalus, and the detection of abnormalities that might be the cause of epilepsy. By far the greatest field of usefulness of ventriculography was in the localization of brain tumors. The limitations of neurological signs in the localization of brain tumors was well known. Up to the present time it had been impossible to localize more than one-half of all brain tumors by the neurological signs, whereas with experience in the technique of this procedure and care in the interpretation of *x*-ray plates few tumors would escape accurate localization. There was only one form of treatment for brain tumors, namely, operative extirpation. To obtain the best results brain tumors must be diagnosed and localized in the earliest stages. Gliomata arising very deeply in the brain or in vital parts of the brain must still be looked upon as hopeless, but the vast silent areas harbored most of the incipient brain tumors and from these regions could be removed with impunity. The operative approach would be dictated by the precise location. Decompressions, routinely performed, were among the most harmful and indefensible operations in surgery. They should never be performed for unlocalizable tumors. They were the exact equivalent of giving morphine for abdominal pain; the symptoms were masked until it was too late. Decompressions should be performed only as a last resort—when the tumor could not be removed; and then only after the localization of the tumor was known. Exploratory craniotomies for brain tumors were now scarcely ever indicated. Early and accurate localization and thorough operative treatment would eliminate all unnecessary and harmful operations. Ventriculography would differentiate between cerebral and cerebellar lesions, which was frequently one of the most difficult tasks in intracranial localization. Many useless and harmful operations would be spared the patient by a judicious use of ventriculography. A number of slides were shown with entirely different findings which served to demonstrate the range of usefulness of this procedure when tumors of the cerebral hemisphere were suspected. Ventriculography would also serve to exclude a cerebral tumor when the lesion was situated elsewhere. The physician should learn to detect early symptoms and signs of intracranial pressure, as well as the local manifestations. It was due the patient that headaches or pains in the head, unexplainable vomiting, unusual malaise, visual disturbances—dimness of vision, hemianopsia, diplopia, transient amblyopia—any focal, motor, or sensory disturbances and all unusual epileptic attacks, disturbances in the gait, etc., should be thoroughly investigated by one of adequate experience to pass on the intracranial possibilities in a decisive manner.

Biological Determination of X-Ray Dosage.—Dr. FRANCIS CARTER WOOD made this contribution. (See page 399.)

Effects of X-Rays on Inherited Characteristics.—JAMES W. MAVOR, Ph.D., Professor of Biology of Union College, made this presentation, which was illustrated by lantern slides. He stated that the experiments he would describe were carried out on certain varieties of fruit lice and on red-eyed and white-eyed flies to determine the effect on inherited characteristics of exposure to *x*-rays for varying periods of time. In these experiments a 50 milliampere current passed through a water-cooled tube was employed; no filter was interposed, the whole spectrum being allowed to act. They had first determined the lethal dose of *x*-rays for flies in the various stages of their existence—egg, pupa, larva—and the quantity of *x*-ray required to sterilize a fly. In order to study the effect of the *x*-ray on chromosomes they had selected red-eyed and white-eyed flies. They first studied the inheritance of red eyes and white eyes in numerous matings of red-eyed and white-eyed flies and found that the transmission of this characteristic followed the Mendelian law. They then studied the genealogies of red-eyed and white-eyed flies that had been exposed to the *x*-rays for various periods of time. The study brought out the fact that the *x*-ray used in a particular way on certain germ cells exerted a definite influence on the behavior of the chromosomes.

An Appraisal of the Newer Methods of Deep Roentgen Therapy.—Dr. JAMES T. CASE of Battle Creek, Mich., made this contribution to the program. He said he was neither a physiologist nor a biologist, but a clinical man recognizing the need of somethng to aid surgery in dealing with various pathological conditions, particularly malignancy. His remarks would deal chiefly with the use of the *x*-ray in deep-seated disease. For the treatment of deep-seated lesions one needed first a generating apparatus that would send 200,000 volts or more through the vacuum tube. With this apparatus, long distance radiation and the employment of larger fields more could be accomplished in the treatment of deep-seated lesions than had heretofore been possible. There was little to be gained by the use of copper or zinc filters less than ½ to 1 mm. in thickness; heavy filters were essential for the delivery of these highly penetrating rays to the parts to be treated. After describing the Dessauer apparatus and the work being done by Opitz and Friedrich and by Seitz and Wintz, Dr. Case stated that the results thus far obtained with the new high power *x*-ray machines warranted a certain amount of enthusiasm and in fact were decidedly optimistic. The value of single massive doses had been demonstrated. It was now an axiom that the harder the ray the more intense the radiation and the less danger of skin damage. No changes in the blood had been noticed as a result of treatment with these large doses of *x*-ray. There was sometimes a drop in the hemoglobin, but it soon returned to normal. Occasionally temporary intestinal disturbances might occur. It was generally believed that excision of small pieces of tumors encouraged metastases, but it had been shown that *x*-ray in efficient dosage did not increase metastasis. Insufficient dosage might actually stimulate disease. The German investigators had calculated the dosage for different types of growth with a fair degree of accuracy. Carcinoma required from 100 to 120 per cent. of the erythema skin dose; sarcoma did not require as large a dose of *x*-ray as carcinoma, about 60 per cent. of the skin dose. Large myomas required 50 to 60 per cent. of the skin dose. Statistics published by the foreign workers seemed to be very encouraging. Seitz no longer operated on uterine sarcoma, no matter how early, but cervical growths were still operated on with carefully planned pre- and postoperative radiation. Personally, the position he took was that operable growths should have the advantage of surgery supplemented by suitable pre- and postoperative radiation. Perhaps one had no right to talk of the results of intensive radiation as yet, but one certainly was justified in feeling encouraged. If the good results were not permanent they were much superior in a palliative way to any measures we had hitherto had at our disposal.

Dr. JOHN S. SHEARER, Professor of Physics, Cornell University, discussed the *x*-ray from the physical standpoint. He said he was interested in Dr. Wood's remarks, especially in regard to the physics of the *x*-ray, which reflected views that he largely could not accept. In the first place, no well-informed physicist would now assert that the quantity of radiation was

fixed by the current through the tube. That idea had been exploded, but the report of the changed views had not yet permeated all quarters, and we still noted dosages published in milliampere minutes, a terminology entirely meaningless unless the tube voltage was specified. As one increased the voltage with the same current there was an increase in the *amount* of radiation at least in proportion to the square of the voltage. For instance, if one were using 5 milliamperes at 50 kilovolts and increased the kilovolts to 100, the result would be four times as much *x*-ray. The voltage completely determined the quality of radiation. Hull had shown the difference between the amount of radiation with the sine wave and with a constant voltage of 70 kilovolts. It required 3 milliamperes with the sine wave to deliver the same amount of radiation as given 2 milliamperes with the continuous voltage. The measurement of the output and of its quality in electrical terms was quite possible and would be much more reliable than methods now in use. There had been a great deal of discussion of physical laws by people who had had inadequate experience in those laws. For example, the inverse square law has been called in question. It has been stated that the inverse square law did not apply to filtered radiation. There was every reason to believe that the inverse square law held rigidly and was not to be cast aside by any superficial biological observations. Dr. Shearer said he did not know anything about standardized tumor reactions, nor did he know how the biologists determined just when a tumor died, therefore he did not know just how accurately biological cells could be standardized with respect to radiation, though he thought a great deal might depend on the nature of the tumor and upon the previous condition of the patient. Another point to which attention was called was the erythema dose. Personally he believed that the erythema dose produced by one wave length was not equivalent to one produced by another wave length. One could use a ray so soft that 90 per cent. would be absorbed in one millimeter of skin and the effect would be quite different from that resulting from the use of more penetrating radiation. If one took a series of "erythema doses," so-called, not only would the time of appearance vary, but in the subsequent history there would be a great deal of variation because the distribution of absorption and action on deep tissues would be entirely different. Without asserting that the physicists would solve all the problems of radiotherapy, Professor Shearer said he would emphasize that the advances made by the German and French roentgenologists had been made on the basis of sound and rational physics. Their work showed a knowledge of physics of high order. They had moved the target further from the skin in order to get better distribution, and had taken account of scattering in utilizing larger ports of entry. The limit of radiation was the limit of skin tolerance, so as much must pass through the skin as possible. If you increased the portal of entry of the radiation you increased the amount of radiation absorbed because more was delivered. If you delivered the radiation through a 1-inch opening and doubled the linear size of the opening, you increased the amount of radiation fourfold, and the total absorption had been increased thereby. He was inclined to think that the introduction of ionization methods as a routine in laboratories would not greatly improve results. For the past fifteen or eighteen years he had been trying to teach others to use the ionization apparatus and had found that there were many uncertain factors that must be taken into consideration. He therefore believed that the time would come when the apparatus delivering the radiation would be standardized. Then it would not be necessary to worry about the variation in wave form. He thought the time would come when it would not be necessary to carry out complicated measurements of radiation any more than it was necessary now to carry a photometer in order to see if one had the correct amount of light to read by. The time was probably not far off when we should know the quality and quantity of radiation, how it was distributed and dosage might be determined from a simple chart. Dr. Shearer said he had been asked to say a word or two on the subject of apparatus. His impression today was that we did not need to import apparatus for deep therapy unless one wished to do it because it was fashionable to have the imported equipment. He felt confident that apparatus could be built in this country superior to anything he had seen in connection with the German apparatus. Furthermore, he felt that by modification and simplification of apparatus floor space might be economized and more efficiently used than was being done at the present time. It would be extremely desirable if apparatus could be made which would take care of more patients in a given time than is being done at present. Professor Shearer said he had no arguments in favor of measuring the dosage exclusively by means of biological, physical, or chemical action, but he did not like to have the physical methods cast aside until they were properly understood and applied, because he thought that by the application of physical principles the apparatus could be rendered safe and sane. He favored simplification of the apparatus, for if the apparatus was complicated the roentgenologist had to spend too much time in the study of technique which could be more advantageously spent in the study of the patient. In the clinics abroad they had devoted a great deal of time to careful physical diagnosis.

Dr. L. T. Le Wald said that as the hour was late he would omit all detailed discussion, interesting as each of the subjects had been. A number of men had asked him to ask Dr. Dandy to give them more information with reference to the technique of ventriculography, to say something about the amount of air injected and whether the injection was followed by shock or other untoward results, and whether with air injection he had been enabled always to obtain accurate information of diagnostic value. Dr. Wood had made his tests very accurate as to the effect of the *x*-rays on animal tumors. He would like to know whether they were applicable to human beings and whether the dosage of various types of human tumors had been worked out to his satisfaction. He hoped Professor Mayor would tell them whether his observations might lead to some practical application to human beings. As to the question of the necessity of importing apparatus, that had been asked again and again. He was glad Dr. Shearer had answered it so definitely that there was no necessity of importing apparatus. Dr. Case had answered the question in the affirmative as to the use of the *x*-ray in operable cases. The question as to the adequate protection of those who gave the treatments had also been asked, and how this problem had been met. In closing Dr. Le Wald said the audience owed a great debt of gratitude to the speakers, some of whom had come long distances to give their personal experiences on these subjects.

Dr. Walter Dandy, in reply to the questions propounded by Dr. Le Wald, said that the amount of air injected into the brain was exactly equivalent to the amount of fluid removed; any more than that was very dangerous. The entire procedure was very dangerous and should be employed only when something worth while was to be determined. The danger came not only at once, but during the twenty-four hours following the injection. The intracranial pressure caused by the air acted as an irritant and excited an increased secretion of cerebrospinal fluid which it was sometimes necessary to remove in order to avoid serious consequences.

Dr. Wood, replying to Dr. Le Wald's question as to whether the *x*-ray dosage in animal tumors was applicable to human beings, stated that these animal tumors on the average required about the same amount of *x*-ray as a primary human tumor, say of the breast. Dr. Wood said he was much obliged to Professor Shearer for pointing out that his knowledge of physics was about as deficient as was Dr. Shearer's knowledge of biology. However, Dr. Shearer had misunderstood him. He had not said that he thought the quantity of *x*-ray was necessarily wholly determined by the voltage and the current through the tube, but had, on the contrary, pointed out that this conception was incorrect.

Dr. Mayor said he understood Dr. Le Wald's question as to whether his investigations had an application to the human inheritance as a joke. The importance of the finding lay in the discovery that the chromosomes were affected by the *x*-ray; that the *x*-ray affected the cell in a very delicate way and yet the cell lived indefinitely. The dosage of *x*-ray was probably very dif-

ferent in insects from that in the human being. Insects were extremely resistant to the action of the *x*-rays. It required hours of exposure to the *x*-ray at the closest distance to kill certain insects.

Dr. CASE, in closing the discussion, said his views coincided entirely with those expressed by Dr. Shearer in regard to the relative value of the domestic and foreign *x*-ray apparatus. Personally, he was equipped with a superior American *x*-ray apparatus and liked it. The Germans were very skeptical about our apparatus, and doubted that we could do all we claimed to do. Dr. Shearer's remarks about the size of the apparatus and the amount of floor space it occupied were quite true. It was to be hoped that the apparatus would be modified so that it could be used to better advantage. As to protection against the *x*-rays, the patients were thoroughly protected as the tube was enclosed in lead except for the aperture in the top permitting local application. A very good quality of leaded rubber was now being made which afforded additional protection to the patient. However, occasional accidents occurred. It was necessary to be very careful to protect the patient against *x*-ray burns, inasmuch as the compensation laws held the physician to account for them. As to the protection of the person who administered the *x*-ray treatment, he was in an adjoining room, separated from the treatment room by a leaded wall.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 10, 1921.

DR. MARSHALL C. PEASE IN THE CHAIR.

X-Ray Demonstration of Rudimentary Development of Both Arms, with Lacking Elbow Joints.—Dr. CHARLES WINFIELD PERKINS gave this demonstration. He stated that the first illustrations were from a case that came to the Seaside Hospital, a young boy about 12 years of age, with rudimentary arms. He was otherwise perfectly developed and his mental condition was bright. With these two rudimentary arms the boy was able to dress himself, put on his shoes and with the right hand he was able to write his name. The radiographs showed that there were no elbows and only a rudimentary radius and ulna on the left side and rudimentary fingers. The left arm was smaller than the right. From the shoulder to the wrist there was but one bone with the effort at the development of a radius and ulna. On the right side there was but one bone from the shoulder to the wrist. An operation was undertaken at one time with the object of making an artificial elbow joint, and although there was no joint there was a little bend to the arm which gave the boy better function than though the bone was perfectly straight. On the right side there was fusion between two of the metacarpal bones, and on the right side two rudimentary metacarpal and phalangeal bones.

X-Ray Demonstration of Congenital Malformation of the Heart in an Infant of Three Months.—Dr. CHARLES WINFIELD PERKINS presented illustrations of the chests of children from nine years of age down, showing the normal position and size of the heart at different ages. These were taken at a distance of six feet from the tube. He also presented a diagram superimposed over a roentgenograph of a normal heart and chest of 9 years, showing the size of the heart, its position and the location of the valves. He stated that in the young children under 4 years the heart was more globular in shape and its base wider than in older children. In making radiographs of the chests and hearts of children it was essential that the child be absolutely parallel with the plate or there would be an enlargement at the base of the heart due to the oblique position of patient which would mislead one into suspecting a thymic condition. The radiograph of the congenital malformation of the heart which Dr. Perkins exhibited was that of a case referred to him by Dr. Graves, who had been called in on the case when the child was two months old. The child gave a history of choking and dyspnea from the age of two weeks continuously onward. A number of men of ability who saw the case were of the opinion that it was very suspicious of thymic enlargement. At first no signs could be elicited of any abnormality of the heart by auscultation or percussion. The child, however, was cyanosed and blue. Two days before the radiograph was taken there were signs of beginning bronchopneumonia in the right upper lobe. The *x*-ray plate showed enlarged right auricle and enlarged left ventricle and a globular heart. The thymus was not enlarged as suspected. The infant died three days after the radiograph was taken of suffocation more or less gradual in culmination probably associated with bronchopneumonia. No autopsy could be obtained. The diagnosis was congenital malformation of heart associated with probable bronchopneumonia. Dr. Perkins showed another radiograph of the chest of a child two days old suspected of having thymic enlargement. There was an enlarged heart but no abnormal thymic condition. This baby also died on the following day.

Dr. GAYLORD W. GRAVES stated that the infant with the normal heart had had a crowing type of respiration for a number of weeks. It was thought the case was one of congenital stridor, socalled Thomson's Disease. That child was doing well. The other patient with the globular heart showing dilatation had presented no ordinary physical signs of congenital heart disease. It had been the consensus of opinion of three physicians that this case was one of enlarged thymus gland. The respiration reminded one of that of a child suffering with laryngeal obstruction, as in laryngeal diphtheria, and was characterized by retraction of the intercostal spaces. The respirations which were ordinarily about fifty, at times became more rapid. There were repeated attacks of impending suffocation and seizures a little like convulsions. Several times the mother found the baby in a state of almost complete asphyxia and applied mechanical measures to effect restoration. The auscultatory signs were those of bronchitis; there was no cardiac murmur. The *x*-ray revealed the congenital cardiac malformation which would hardly have been detected by percussion and was not suggested on listening with stethoscope even after the *x*-ray examination. Unfortunately there had been no autopsy. Congenital malformation of the heart without murmur was a comparatively common condition. Absence of congenital murmur had been explained at times by complete pulmonary atresia. In view of the fact that symptoms of congenital malformation of the heart and those of the thymic enlargement were thus sometimes similar, it would be wise to take more *x*-rays of infants in both the antero-posterior and lateral positions. Especially in cases of urgent dyspnea and asphyxia, if there were malformations of the heart, the *x*-ray might afford the explanation of the condition. Dr. Graves said it was a revelation to him that a congenital heart case could give such a clear clinical picture of thymus enlargement.

The Diagnosis of Peritonitis and Peritoneal Exudates by Means of Abdominal Puncture with Capillary Tube.—Dr. BERNARD S. DENZER presented this communication, in which he stated that the difficulties surrounding the diagnosis of peritonitis in infants had been universally recognized. The signs of peritonitis so striking in the adult were vague and misleading in the infant: pain, localized distension and paralytic ileus were either absent or difficult to elicit, and even when present might be ascribed to some gastrointestinal disturbance of which they were also characteristic. Finally, the fact that peritonitis in infancy occurred so often without an intraabdominal focus, was part of a general infection, or was of so-called primary type, rendered its diagnosis particularly uncertain. The perfection of the usual methods of clinical examination of the abdomen held out little hope of more accurate diagnosis and the effort was therefore made to find some objective or instrumental procedure that would demonstrate minute amounts of peritoneal fluid. The technique for obtaining samples of peritoneal fluid from laboratory animals by inserting a capillary tube into the abdominal cavity suggested the procedure finally adopted. A metal trocar cannula was made ½ inch long and about 17 gauge bore. Glass tubing was drawn out, inserted through the shaft of the cannula and cut off so as to protrude 1 or 2 mm. from the tip of the cannula. The purpose of this technique was to prevent the breaking of the capillary tube within the peritoneal cavity. The capillary tube impinged on the wall of the cannula at such a point that after the tubing was safely inserted into the cannula, a break, if it occurred

at all, would take place at or above this point, and the lower fragment fixed in the shaft would be withdrawn with the cannula. The performance of the puncture was simple. The trocar cannula was inserted through the abdominal wall and the sudden release of pressure indicated that the peritoneal cavity had been entered. The trocar was removed and the capillary tube inserted as far as it would go. It was advisable to wait a few moments and to turn the tube in various directions before concluding that there was no fluid. Any place in the abdomen except the parts covered by a solid viscus or one attached by a short mesentery might be used. Over 100 taps had been done and no untoward incident had occurred. This method would demonstrate fluid in the peritoneal cavity not only when there was a large ascites but would also demonstrate small amounts. One interesting phase of the subject was illustrated by the case of a marantic infant with no signs of peritonitis. An abdominal tap was done merely because this procedure had been adopted in all acutely ill cases in which the diagnosis had been in doubt. The abdominal puncture in this case revealed a milky fluid. This showed on smear gram positive cocci in chains. The baby died the following day and autopsy revealed a diffuse purulent peritonitis. No focus of infection or portal of entry could be found. This case typified peritonitis in infancy. Such infants showed the signs of marasmus only, and there was nothing in either the history or examination to direct attention to the abdomen. Two other cases were cited to illustrate the initial reaction of the peritoneum to inflammation and that abdominal puncture demonstrated an extremely small amount of fluid. The therapy of peritonitis in these young and delicate infants would probably remain far from satisfactory; however, adequate therapy depended upon prompt recognition of the disease and the procedure described raised the hope of early diagnosis. In marasmus and rickets abdominal puncture had developed unexpected results. Twelve marantic infants were tapped and in seven of them ascites was demonstrated. As a rule the fluid was clear and at most contained 1700 cells. The cellular elements were chiefly lymphocytic. There was every reason to believe that the amount of fluid was small and speculation as to the rôle that this ascites played in the picture of marasmus would lead him too far afield. For the moment he would content himself with recording the fact that in a certain percentage of marantic infants free fluid might be found in the peritoneal cavity. In five of twelve cases of rickets a fluid was demonstrated similar in appearance and cellular content to that found in marasmus. Here, too, the ascites was probably small. The occurrence of pot-belly in most of the cases that showed free fluid suggested that the mechanical and circulatory derangements incident to the large abdomen were probably responsible for the ascites. However, this was merely an impression and would need confirmation. Dr. Denzer also referred to some work of Dr. Anderson and himself on the absorption of fluid injected into the peritoneal cavity, the striking feature of which was that they could now follow with ease and safety and accuracy the response of the peritoneum to a foreign substance. To illustrate this the following case was cited. In a malnourished, dehydrated infant, three weeks of age, an intraperitoneal injection was indicated. The preliminary tap before the injection of saline was dry. Then 150 c.c. of Ringer's solution was injected. The abdomen was tapped, 3, 6, 12, and 24 hours after the injection. At the first tap the fluid was sticky, thick and mucoid like in the early cases of peritonitis described. In some of the smears from similar cases made within six hours of the injection, Dr. Anderson found large endothelial cells with ameboid movement, probably the macrophages of Metchnikoff, which Adami considered characteristic of early inflammatory reaction. In this way the course of this sterile chemical inflammation was traced just as one followed by serial blood counts the reaction of the blood to infection. The results presented in this paper merely represented the essential proposition and emphasized the way in which a new method revealed new problems or new avenues of approach to old ones. The peritoneal response to injury could now be followed with safety and with a degree of faith in the significance of the findings similar to that we had learned to place in lumbar puncture. Of course, it would be necessary to establish the limitations of this procedure, and to arrive at its final evaluation would require the experience of many men and varied material.

Dr. Harold Neuhof said the question of abdominal puncture, as Dr. Denzer had pointed out, was not new. A number of years ago it had been shown that the abdominal cavity could be punctured for diagnostic purposes. Dr. Denzer, however, had shown in a brilliant way some of the possibilities of abdominal puncture. The method he employed was one which was entirely satisfactory in his hands. Personally, Dr. Neuhof said he had had no experience with Dr. Denzer's technique, but during the past two years he had been employing abdominal aspiration, in conjunction with Dr. Ira Cohen, more frequently in adults than in children, for diagnostic purposes. They had been using a lumbar puncture needle and withdrawing with an aspirating syringe any peritoneal fluid that might exist. This method had proved safe in their hands. Various points on the abdominal wall might be chosen for puncture, all but that over the course of the epigastric vessels being safe. By making a minute incision through the skin the sense of touch, which was the guide to the entrance into the peritoneal cavity, was best preserved. Further technical details would be out of place. The point was that there was no danger of injury to a loop of intestine unless the gut was fixed. In one case in which it was necessary to introduce fluids into the jejunum at a laparotomy he found that it was impossible to pass a lumbar puncture needle into the lumen unless the gut was fixed. If the method he was using was entirely safe certainly the one employed by Dr. Denzer should prove free from danger. Dr. Denzer mentioned that the diagnosis of tuberculosis peritonitis might be established at a relatively early stage before ascites had become marked. It was in just such conditions as peritonitis that there might be contraindications to puncture as there was more likely to be fixation of a loop of intestine and under those circumstances one might enter a loop of intestine; the same was true in the presence of a mass in the abdomen, unless one made the puncture far away from the mass. As to the value of abdominal puncture in the diagnosis of peritonitis they had had some very remarkable results, and had learned that even small quantities of fluid might be withdrawn by aspiration. The observations were substantiated by his operative findings. In his experience with the aspiration method in some 40 cases only one was negative by this method, in which fluid was found at operation, and he believed that if Dr. Denzer's method had been employed fluid would have been found in that case as well. It seemed to him that Dr. Denzer's method was applicable to adults as well as to infants and children. One group of cases in which the diagnosis was established and operation avoided by abdominal puncture was that of pneumococcus peritonitis. In several cases they had been able to diagnose pneumococcus infection; one was then enabled to determine the type of pneumococcus and to employ serum therapy. In a number of cases in which peritonitis was merely suspected it was definitely revealed by aspiration. In traumatic cases they had found aspiration of considerable value. In one child, for instance, a condition was revealed by aspiration which had scarcely been suspected. The child was struck by an automobile in the left lower chest and was in slight shock. There was slight rigidity of the left upper abdominal wall, and some acceleration of the pulse. A diagnosis of an abdominal condition was entertained but the actual lesion was not suspected. By aspiration fresh blood was withdrawn, and at operation a ruptured spleen was found. Unquestionably Dr. Denzer's method, as he had presented it, was a real contribution to the study of peritonitis in childhood.

Dr. Henry Heiman stated that this method of abdominal puncture had been adopted during the war. Dr. Lilienthal, after his return to Mt. Sinai Hospital, advised the use of this method. They had had occasion to use the method on four of their cases, and in every one they had been able to establish the diagnosis of pneumococcus peritonitis. However, they had not employed the capillary method but had simply employed the smallest caliber hypodermic needle attached to the

aspirating syringe. The point of entrance advocated by Dr. Lilienthal was one inch below and one inch to the left of the umbilicus. This avoided the attachments of the liver and it avoided puncturing the small intestines. The danger of puncturing the intestine was small, but it had occurred in one case not yet published. In the smear were found a number of bacteria, but the child made a good recovery. It was not a pneumococcus case and there was no ruptured appendix. It was interesting to be able to type the pneumococcus in nine cases. It was type I in five cases, type II in but one case, type III in no cases, and type IV in three cases. The method employed by Dr. Denzer was a distinct advance, and he saw no reason why it should not be employed instead of the needle and aspirator.

Dr. Leon T. LeWald asked if this device could not be employed to introduce air or carbon dioxide into the peritoneal cavity if it became necessary to clear up a question of adhesions or of a mass. By the introduction of gas and an *x*-ray examination Dr. Denzer's device might be a diagnostic help from the *x*-ray standpoint as well as in the extraction of fluid from the peritoneal cavity. It seemed to him that *x*-ray examination might be combined with the removal of fluid while the tube was in place.

Dr. Denzer, in closing the discussion, said he wished to show the type of needle Dr. Anderson and he had used in infants requiring intra-peritoneal injections. This needle had an attachment in its shoulder permitting the insertion of a Luer syringe or a Luer adapter. They first tapped the mid-line of the abdomen, inserted the capillary tube and after seeing that the peritoneal cavity was dry, attached a Luer adapter and proceeded with the injection of saline. This would permit a comparison of the method with the capillary tube and that of aspiration, which Dr. Neuhof had suggested. At present Dr. Denzer did not feel capable of passing judgment on the comparative values of the two methods. At the Nursery and Childs Hospital, where the cases were obtained, the service was rich in medical material, but the surgical cases were scant, and it took almost two years to collect these six cases. Stimulated by Dr. Neuhof's experience, aspiration was tried in several cases. In two blood was obtained and the method was discontinued. This should not militate against the method, particularly as one of the cases belonged to the group in which the transudate had been produced artificially. The needle presented would permit the introduction of air or carbon dioxide at the same time that the test with the capillary tube was being made. Dr. Heiman had brought up the question of the needle entering the peritoneal cavity. If a needle of a wide bore was used this would not happen. At the autopsy table the effort had been made to enter the intestine, and in order to do so, it was found necessary to hold the gut firmly and to use considerable force. It was difficult to imagine the free gut permitting the entrance of the needle, providing the needle was of sufficiently large bore. Dr. Denzer said that he did not wish to give the impression that abdominal puncture was a new method, but that the use of a capillary tube was a new modification of it. They had used the capillary tube because they felt that aspiration must have been tried and to a certain extent discarded and because the capillary tube seemed safer. However, it would require a great deal more work before the real worth of the method was established.

The Late Treatment of Chorea as a Problem of Convalescence.—Dr. George R. Irving read this paper, which was based on records of 123 of the younger patients treated for chorea at the Burke Foundation. After reviewing the characteristics of this ailment he stated that recently there was a decided tendency to stress the details of the treatment other than by medicine. Most authors agreed that rest was one of the prime factors in the management, some insisting that this be carried out under conditions of absolute isolation, while others allowed mild physical activities with restricted attendance in the matter of visitors. There was, however, increasing importance being attached to a type of restriction, brought about by country or seashore convalescence, avoiding only the more violent exercises, and at the same time instituting such general strengthening measures as might tend to lessen recurrence or minimize the danger due to existent or possible cardiac and rheumatic conditions. This had stimulated considerable discussion as to the advisability of a somewhat more active regime for the choreic patient, particularly in the convalescent stage, and had prompted the present review of the Burke Foundation's policy in the matter. Only the accepted straight types of chorea were admitted, and the only characteristics insisted upon were that the children should be able to walk fairly well and should be able to feed themselves at the table, although often with considerable difficulty. The age of the 123 patients ranged from 9 to 16 years. There were almost four times as many boys as girls, a reversal of the accepted sex incidence in chorea, due to the Foundation having made special provision for the much-needed accommodation of the generally neglected boys at the Sunny Brae branch. The tables showed that there were almost again as many children admitted from May until November as from November until May. Among this group of patients 39.8 per cent. presented cardiac complications of various types and grades. There were only two children in the group who had rheumatism as a complication. This might be explained by the high degree of care given these patients before their admission to the Foundation—the early and acute stage treatment and the efforts made to eliminate possible foci of infection. The average residence in the institution was 33.8 days, varying with the condition on admission, a satisfactory improvement at the end of a given period of time, the ability to resume school, and the anticipated co-operation of patient, parent and the referring agency in the matter of follow-up. Almost no drugs were used excepting in incidental conditions requiring medication. The diet was one with low protein content, but well balanced, satisfying in amount and in the manner of service. Talks were given by the resident physician from time to time to explain the methods of, and to urge the entrance into the routine. Dr. Irving outlined the detail of this routine and stated that under it 115 of the 123 children gained an average of 3.86 pounds per child. Only eight children failed to gain. The following conclusions were drawn: (1) Supervised activity in the later treatment of chorea, in this series, did not lengthen the course of the attack, as compared with the standard figures on the duration of the ailment. (2) Little difference had been found in the progress of cardiac and noncardiac patients convalescing from chorea; the weight gains would slightly favor the noncardiacs. (3) Chorea patients were not hindered in their convalescence by the presence of other patients or by the nursing methods—a point of great importance in mental therapy. (4) This more active method in caring for the chorea patient was in line with the latest advanced ideas of convalescence in other diseases. (5) By better "conditioning" in the open air, during this stage of chorea, the patient was found to be stronger in every way at the termination of the attack; physically improved; morally encouraged as to the outcome and the effect of this disease upon his ultimate well being; mentally given an interest in out of doors and in play as a valuable means of upbuilding. These things, Dr. Irving believed, tended toward a lessened recurrence of chorea.

Dr. Frederic Brush stated that he had very little to add to Dr. Irving's paper except to note that the point might be lost unless one understood that before the Burke Foundation began its work there was almost no convalescent place for older boys with chorea, and they had been advised not to attempt them; also that it was not best to treat chorea along with other conditions, because the others would ridicule and irritate the choreics. As a matter of fact, the other boys did not badger the boys with chorea, but let them alone, and thus induced normalizing more rapidly. It was nerve and mental therapy of the best kind. Separation of the children with chorea in some severer cases was tried but they always got better results if they were allowed to mingle in with other children. In convalescing in chorea there seemed to be a distinct turning point, occurring toward the end of the second or in the third week, after which came rapid improvement. One learned to wait for this turn, and not be discouraged. The figures gave less than five weeks as average stay, but that was because some came late in the course of convalescence or left for various reasons before con-

valescence was completed. The right stay was from five to eight weeks, the same as had proven best for the cardiacs. Heart complications were present more often than was given by the senders' diagnoses, and probably more than stated in the paper. Another impression which could not be expressed in figures was that a heart complication was nearly always a distinct disadvantage, lengthening the period of convalescence not so much as to nervous symptoms as by a slower restoration of good "general condition," which was the main aim. No claim to a more rapid elimination of choreic nerve symptoms was here made, but rather the plea for speedier general setting-up and normalizing through this active method.

Observations on Cerebrospinal Fluids in Infants and Children.—Dr. STAFFORD MCLEAN presented this paper, which consisted in the analysis of the findings in 250 specimens of cerebrospinal fluid obtained from the records of the Babies' Hospital during the past four years. All bloody fluids were discarded, as well as fluids from all types of meningitis and poliomyelitis. The records of the fluids were grouped according to clinical diagnosis, many of which diagnoses were controlled by autopsy. There were 35 cases in which the discharge diagnosis indicated some intestinal disturbance. In four of these fluids the cell count showed over 20 cells per cubic millimeter. There were five counts of 20 or more cells; one of these was 90; another 70; a third 62, and a fourth 60. While it was true, as shown by this table, that the usual cerebrospinal fluid in active respiratory infections was clear and colorless with a cell count of 10 or less, with a positive Fehling's test and a negative globulin, it was not uncommon to withdraw a clear fluid which contained over 50 cells per cubic millimeter. Among 21 cases of defective cerebral development the fluids were all clear and colorless and in only one instance did the cells number more than 12. In 16 cases of hydrocephalus two fluids showed xanthochromia; the others were clear. In one case with 91 cells the autopsy demonstrated hemorrhagic staining of the dura, flattening of the spinal cord and hydrocephalus. In four cases of status lymphaticus proved by autopsy there was nothing of special interest in the spinal fluids. Among four neuropathic children the number of cells in the spinal fluid was 2, 10, 15, 30, respectively. In 26 cases of tetany the spinal fluid was clear and colorless in every instance. The highest cell count was 30 cells per cubic millimeter. In seven cases of primary otitis media the highest cell count was 10 cells per cubic millimeter. Lumbar punctures were done in six cases presenting symptoms commonly expressed as meningisms, although Dr. McLean did not consider this term acceptable. In all six cases the spinal fluid was clear and colorless. In five instances it was under increased pressure, and in these fluids the cell count numbered 15, 20, and 70 cells, respectively. Among 11 cases of congenital lues, five of which were autopsied, the fluid was clear and colorless in every instance and the highest cell count noted was 48. Many other cases classified in groups were reported, which Dr. McLean said would be reported in detail later.

The Value of the Colloidal Gold Reaction in the Diagnosis and Treatment of Epidemic Poliomyelitis.—Dr. JOSEPH C. REGAN read this paper, which consisted in a study of 21 cases of poliomyelitis which were admitted to the Kingston Avenue Hospital during the autumn of 1920. A total of 74 special fluids were examined, the fluids being taken at intervals varying from the fourth to the one-hundred and twenty-third day of the disease. The curves thus obtained were classified according to the week of the disease in which the spinal fluids were taken. On this basis an average curve was constructed for each week from the first to the eighth; likewise an average curve for the fatal cases. The following conclusions were drawn from the study: There was always a reaction with colloidal gold solution in every poliomyelitis fluid examined during the acute stage of the disease. This reaction was constantly in the same zone with that of luetics. The average curves for the first and second weeks were very similar, and consisted in a gradually rising curve representing a graduated increase in reduction in ascending dilutions of the spinal fluid starting in the reddish-blue zone in 1-10 dilutions and extending into the lilac or purple zone in 1-40 to 1-80 dilutions, and then descending somewhat more abruptly into the reddish-blue zone in 1-160 and reaching the non-reducing or red zone in 1-640. In the latter weeks of the disease the average curve gradually subsided, reaching normal in a minor proportion of the cases (3 out of 10), by the eighth to the ninth week, while in the remaining 7 (70 per cent.) the curve was still elevated at the ninth week. In two cases examined later than the eleventh week, one being in the fourteenth and the other in the eighteenth, the curve was still elevated in both. The earliest subsidence of the curve to normal was the 28th day. Cases presenting a persistence of the very acute curve of the first few weeks up to the ninth week or beyond commonly presented at this time either considerable residual paralysis with slight, moderate or marked polyneuritis, or else slight paralysis with a neuritis which was still pronounced. The writers were inclined to believe that there was a relationship between the duration of the positive colloidal gold curve and the acute inflammatory stage of the malady, so that when the gold chloride reaction became normal the acute period of the disease was over. If this was so the reaction should therefore be of value in determining when the rest of the acute stage might be terminated. The gold chloride test had clearly differentiated in this series of cases the various forms of meningism, tuberculous meningitis, and epidemic meningitis. The only curves with which that obtained in poliomyelitis was apt to be confused were those obtained in cerebrospinal lues and in a minor proportion of cases of epidemic encephalitis. From the former the clinical symptoms, history and Wassermann reaction would afford an absolute means of differentiation, so that no mistakes could thus arise. Most cases of epidemic encephalitis gave a paretic, mild luetic or negative reaction. It was only those which presented a mild luetic curve which would, by means of the gold chloride reaction, be indistinguishable from poliomyelitis. No close relationship was found between the cytology and chemistry of the spinal fluid and the colloidal gold reaction except in a general way. The reactions obtained in the fatal cases although showing a tendency to produce greater reduction, did not differ sufficiently from those obtained in the non-fatal cases to make the test of value in prognosis. It must be realized that the gold chloride reaction was the most valuable laboratory test we possessed at the present time for the recognition of Heine Médin's disease. To realize its full value it must be taken into consideration with the history, physical findings, and other laboratory data in the individual case.

Dr. MARTHA WOLLSTEIN showed how comparatively rare abnormal spinal fluids were in the various diseases of infancy, excluding meningitis in its various forms, as Dr. McLeans had done. She thought, however, that we must concede that the normal cerebrospinal fluid in infants differed from the normal cerebrospinal fluid in adults in that it contained more cells, the average in infants being 20 or even 25. In normal cerebrospinal fluid there was an absence of demonstrable globulin. In some cases of pneumonia and other acute infections there was comparatively often an increase of normal fluid from which inflammatory elements were absent. That kind of fluid was found in cases which for the want of a better name were still called meningismus. In other cases cerebrospinal fluid containing more cells of the polymorphonuclear variety with a slightly increased amount of globulin were present, and those cases were examples of serous meningitis, which was rather rare, but did occur. In their experience this type of cases usually ended in recovery.

Dr. W. W. HERRICK stated that he considered Dr. McLean's paper important in that it was the first paper in which a collection of spinal fluids in a variety of acute diseases in young children had been placed on record. He was interested because he had published the results of a study of the spinal fluids of about eighty adults suffering from various acute infections. About one-third of these showed abnormal findings in the way of an increase in the number of cells or globulin in the cerebrospinal fluid. These were cases of pneumonia, bronchopneumonia, influenza, tonsillitis, scarlet fever, smallpox, and other infections. In the clinical study of the early phases of acute disease one

saw almost constantly severe headache, hyperesthesia, exaggerated reflexes and not infrequently vomiting, and their significance was perhaps that they were related to irritation in the meninges. Possibly this was evidence of a protective reaction consolidating the defenses of the meninges against infection. It was interesting to speculate that in the exanthemata it might be part of an allergic reaction on the part of the ectodermic tissue, since in the exanthemata there were frequently changes which we recognized as serous meningitis. In smallpox there was severe headache, tremendous lumbar pain and vomiting. In the one case examined there was increased globulin and an increase in the number of cells in the cerebrospinal fluid. A great deal had been said as to the danger of lumbar puncture. Those who had had the largest experience were not convinced of the danger of a clean puncture with a small needle and the withdrawal of 3 to 5 c.c. of cerebrospinal fluid; this could do no harm in competent hands. It was important that the practitioner should recognize this and also that he should recognize that a slight increase in the cell count and globulin did not necessarily mean meningitis, poliomyelitis, or one of the group of diseases characteristically involving the central nervous system or its coverings.

Pernicious Anemia with Special Reference to the Spleen and the Large Intestine.—William J. Mayo states that a comparison of fifty patients in whom splenectomy was performed for definitely established pernicious anemia with a similar series of non-splenectomized shows that 21.3 per cent. of the patients with pernicious anemia survived the operation three years or more, living two and one-half times as long as the average in a similar group of non-splenectomized patients at the same stage of the disease, and that 10.6 per cent. are alive after more than five years. The course of pernicious anemia, generally speaking, is ameliorated, the relapses are less severe, and the cord changes less rapid than after transfusion or any other type of treatment with which we are acquainted. If we assume that the removal of the spleen has a beneficial effect, as appears from the evidence at hand, are we to assume also that the spleen is the cause of the changes in the bone marrow? A study of the literature and of the cases observed by the writer does not give this impression. It would be more reasonable to assume that the same agents which destroy the bone marrow injure the spinal cord, produce the achlorhydria and the glossitis, affect the spleen, and that by removal of the spleen a vicious circle is interrupted. Many observers have expressed the opinion that toxic materials from the gastrointestinal canal are the cause of pernicious anemia, and if this is true the probable location of this absorption would be in the proximal half of the large intestine. There is a mystery concerning this portion of the human anatomy which conceals some queer metabolic disturbances. Carcinoma or tuberculosis of the proximal half of the large intestine produces an anemia, unexplained by hemorrhage, much more severe than the anemia of carcinoma or tuberculosis in any other part of the body. Tumors in the right half of the colon which are curable by operation may cause a reduction of the hemoglobin to below 25 per cent., edema of the lower extremities, and a general physical condition which would apparently place the patient beyond surgical interference. Experience with a large number of resections for the relief of such patients in wretched general condition has shown a comparatively low mortality and a high percentage of permanent cures. However, there is too little evidence to show that the etiological agents of pernicious anemia arise in the large intestine. It behooves us to study carefully the blood conditions of all patients who have disease of the large intestine to try to ascertain whether anemia, achlorhydria, glossitis, or some other abnormal condition exists.—*Annals of Surgery.*

Number of Ovariotomized.—When Zola was about to write his book entitled "Fecundity," he asked of Pozzi the probable number of French women who had up to that period been sterilized by removal of the ovaries. The estimate of the latter was half a million. This number is difficult to visualize even now.—*Le Progrès Médical.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE TREATMENT OF ARTERIAL HYPERTENSION WITH LOW SODIUM CHLORIDE DIETARY.

BY HARRIS A. HOUGHTON, A.B., M.D.,

NEW YORK.

CONSULTANT IN METABOLISM, MANHATTAN EYE, EAR AND THROAT HOSPITAL.

WE are indebted to French clinicians for knowledge of the part played by sodium chloride in causing certain forms of edema, and again, latterly, to the suggestion that this salt is largely responsible for arterial hypertension. Little has appeared in American literature concerning the latter relationship. F. M. Allen of Morristown published a short note about one year ago (*Journal of the American Medical Association*, 1920, lxxiv, 652) in which he called attention to the association of high plasma chlorides and high blood pressure and suggested that they stood to each other as cause and effect. This was followed last winter by an article by John H. Musser of Philadelphia (*New York Medical Journal*, 1920, cxii, 570), who presented some clinical data along the same line.

The immediate toxic cause of high blood pressure has naturally been of great interest to the clinician, for ignorance has precluded definite and satisfactory treatment. Search for a hypothetical pressor substance has been directed along diverse lines. Many expected that it would be found among the protein fragments of metabolism, the primary postulate usually being a damaged kidney. Endocrine disorders of toxic origin, bacterial toxins from focal infections, including especially those from the colon, have been studied, each in turn. Notwithstanding lack of definite results in treatment, these associations are recognized. The immediate cause, however, has eluded identification.

In an experience now large enough to warrant temporary conclusions, and especially in view of the publications of Allen and Musser, it has become increasingly evident that sodium chloride is the immediate and chief toxic agent, often associated, especially in those with higher pressures, with excessive retention of water and possibly uric acid. Kidney incapacity is again postulated and often high intake may be a causative factor. This conclusion has been made possible by two diagnostic refinements recently developed, viz., blood chemistry, whereby it is possible to determine quantitatively material in the blood plasma that should be excreted through the kidneys, and a better knowledge of the chemistry of food stuffs, whereby conditions discovered by blood examinations can be efficiently controlled by chemically correct dietary. The solution of no other problem in clinical medicine promises so rich a return in human happiness and longer life, as the solution of this problem of high blood pressure. It will throw a flood of light on many other deviations from normal health, both major and minor, which have proved most troublesome.

The Metabolism of Sodium Chloride—The presence of sodium chloride in the plasma and cells is essential to vital processes, but so far as is known, its metabolic chemistry is extremely meagre. Perhaps a small portion is split to assist in the formation of gastric hydrochloric acid, but even this portion tends to cyclic change and is again resecreted into the stomach. However, its usefulness is by no means negligible as it maintains, with magnesium, a base balance in the body fluids, as against potassium and calcium. The base intake, other than sodium, is very constant and therefore sodium as chloride is used largely by the organism to maintain the molecular concentration of the plasma at a constant level. Under normal conditions the sodium chloride concentration does not wander far from 0.565 grams per 100 c.c. Apparently the kidney plays a part in maintaining this concentration by removing water from the plasma, or, if conditions are the reverse, in delivering a urine of high concentration when water retention is necessary. Even under pathological conditions the balance is very closely determined. The daily intake of sodium chloride varies with the character of the food, the amount used in cooking and that used on the table. With an ordinary diet, an individual with fair taste for seasoning will consume from ten to fifteen grams of salt daily. With high proportion of meats, and high seasoning, the amount may reach twenty grams. Diffusion into the blood stream is rapid under normal conditions and an amount equivalent to the intake reappears in the urine in a few hours. In the meantime, nature is further assisted in maintaining the osmotic tension at normal by frequent water ingestion, and this also in turn stimulates excretion.

The Effect on the Kidney of Acute and Chronic Irritation and Overwork.—Patients having high arterial tension almost universally present a history of acute infectious disease—especially scarlet fever—and clinical examination will develop the presence of chronic infections as sequellæ. Apparently the clinical progress of the disorder may be summarized as follows. Those cells of the kidney concerned in the excretion of sodium chloride are the first to yield to these infectious processes and the "factor

of safety" is gradually lowered as the irritation continues. Oftentimes the irritation is reinforced in its action by gross dietary errors and high sodium chloride intake. The expression in the urine is the persisting trace of albumen, a sign of irritation found at the time that the examination is made. Nor is the process which is oftentimes so chronic necessarily constant. Long periods may elapse when the focal infections are quiescent. With a continuance of the irritation the blood picture, as revealed by those chemical methods now employed, gradually changes. As has been stated, the first cells to yield are those which have to do with the excretion of sodium chloride and with a constant or excessive intake its percentage in the plasma will rise. There is likewise apparently a voluntary retention of water to maintain the osmotic tension. The arterial tree gradually becomes distended. In the later stages the water retention becomes a condition *per se*, and is not a compensatory phenomenon. The arterial tension rises gradually to meet these changed conditions.

The second renal function to be curtailed is that of the elimination of uric acid, followed by a gradual rise in the plasma content. Urea and creatinine gradually follow and in the order named. As is well known, a creatinine content of the plasma over 2.5 milligrams per 100 c.c. is of grave prognostic import. This picture may not hold in every case, but on the whole it is fairly representative of the average high blood pressure patient. Each individual has his own peculiarities which must be taken into account in the dietetic treatment. Many details are of course lacking, but the above statement presents a working hypothesis which has the virtue of clinical substantiation.

The status of uric acid in the etiology of high blood pressure, particularly in those cases which show a pressure of 200 mm. or more, is unknown, but apparently it does play some part. Urea and creatinine do not. These statements are based on clinical evidence. Should an attempt be made to reduce a blood pressure of 235 mm. by withdrawal of salt and water from the dietary of an individual in whom the blood shows on analysis both salt and uric acid retention, it will be found that the pressure will fall slowly, perhaps to normal, but more often will "stick" in the neighborhood of 160 mm. On the other hand, if the purins also are eliminated from the dietary, the reaction on the part of the organism, assuming that the kidneys have not too far lost their function, will be prompt and the pressure will fall.

The Sodium Base and High Blood Pressure.—Again, from clinical experience, the thought has suggested itself that the primary cause of the trouble lies in the sodium base. The following experience is a constant one. There are many patients who, to ease digestive disturbances, take sodium bicarbonate. Blood pressures will not recede under such conditions. Therefore, laxative salts should be interdicted. With ordinary food intake, sodium in other forms than the chloride tends to remain at a low level and constant. Man is the only animal which has unlimited sodium chloride at his command and in civilized communities its use increases to satisfy jaded palates. If it shall be determined that the primary fault lies in the sodium base, it will be possible to arrange refinements of dietary which will give quicker and more certain results.

Blood Examinations.—It is always well to make the blood examinations as "complete" as possible, for other factors which vitally affect the life, health, and symptoms of the patient may thus be revealed. For instance, a plasma sugar over 150 milligrams per hundred c.c. of blood indicates pancreatic incapacity and potential diabetes, assuming the blood is drawn three or more hours after a meal. With this knowledge, a slight change in the diet may prolong a life for many years. If there is a high content of sodium chloride and the uric acid content is normal, many articles of food, such as meat and coffee, may be left in the diet of high blood pressure patients, and their comfort enhanced. If the carbon dioxide absorption capacity of the plasma is low, the cause of the acidosis must be immediately located and removed. If there is a high protein metabolism and high plasma sugar, in association with a high pulse rate, this is a clear indication of a potentianl or established hyperthyroidism. From the metabolic standpoint, each case presents a definite problem, the limitations of which should be clearly determined

Table Showing Effect of Low Sodium Chloride Diet on High Pressure

No. of Case	Initials of Patient.	Date of Examination.	Age	Weight in Kilos.	BLOOD							Urinary Albumen	Date Dietary Commencement.	Systolic Pressure.	Date Close of Observation Period.	Systolic Pressure.

Blood Examinations by Dr. Cyrus W. Field.—Abnormal figures are italicized. Patients were instructed to drink two glasses of water, one and one-half hours prior to the examination and to empty the bladder one-half hour later. At the time that the blood was drawn the one hour's collection of urine was used for the calculation of Van Slyke's formula,

$$\text{Coefficient} = \frac{D}{Bl.\sqrt{V.} \times Wt.}$$

in which D is the daily output of the substance (sodium chloride in this table) in grams as calculated from the output during the test period. *Bl.* is the concentration of the substance in the blood plasma, expressed as grams per liter. V is the volume of urine for 24 hours as calculated from the output during the test period. *Wt.* is the normal weight of the patient at maturity expressed in kilos.

prior to dietary treatment, and there are almost as many variations in diet as there are patients. It has been found that the calculation of Van Slyke's coefficient (modified from Ambard's) is a most useful procedure, giving a mathematical factor which is expressive at the time of kidney capacity for excretion. A second blood examination three or four weeks after beginning the diet with lowered pressure indicate by calculation of the Van Slyke coefficient a recovering renal function for the elimination of sodium chloride and a happier prognosis.

The Proper Handling of the Patient.—Patients fall naturally into two classes, *i.e.* those with pressures over 200 mm. and those whose pressures are below that figure. In dealing with the former class, it has appeared best not to reduce the pressure too suddenly, unless, for the sake of relieving myocardial insufficiency, rapid results are necessary. It has therefore become the habit to indicate a diet which contains not more than four or five hundred c.c. of water, as low a purin content as possible, and one which contains a maximum of four grams of sodium chloride by calculation. This assumes a blood examination as basis for the procedure. A diet of this nature will reduce the pressure gradually to 150 mm. or thereabouts. The sodium chloride content of the diet is again recalculated and the intake brought down to less than two grams daily. The pressure will then go to normal or below. Pressures falling to a subnormal are not unusual, and in such an event, sodium chloride should be added to the intake to bring the pressure back to the normal. If at the end of a four-day period, a twenty-four hour specimen of urine shows an output of more than two grams of sodium chloride, the diet is not sufficiently free from that substance. Consequently, the blood pressure will not be normal. The converse is also true.

If the urinary excretion for the twenty-four hours shows a sodium chloride content of less than two grams and the blood pressure has failed to reach the normal figure, there is only one answer. The kidney capacity for the elimination of salt is very low, and a persistence in the dietary restrictions lasting for weeks is necessary to achieve the desired result. The converse of this is also true. There is little to be said concerning the lesser tensions. Uncomplicated by uric acid hold-up, the dietary management is simple, always calculating on an intake of less than two grams of sodium chloride daily, though oftentimes a daily intake of four grams will produce the desired end. The water intake naturally lessens as the salt is reduced, but always the warning should be given not to overuse water. Many patients have been contrariwise instructed.

To patients of both types the subjective reactions to salt withdrawal are the same, and they should be carefully explained in advance. If this is not done the patient will feel that the diet is insufficient and be apt to break away in spite of advice. On the third day following the initiation of the new dietary regime, a feeling of lassitude begins which is overcome with great difficulty. It increases until the sixth or seventh day. Whether this is due to the withdrawal of the nervous stimulation of the sodium chloride or to the falling pressure, it is impossible to say. Perhaps both are factors. By the eighth day the patient, still following the diet, things begin to look a little brighter and strength begins to return. There is then built up a mental clearness and resiliency which earns much comment and gratitude from the patient. By the close of the second week, lassitude has entirely disappeared, and this is accompanied by a host of minor symptoms, insignificant from the physician's standpoint, but always troublesome to the subject.

Water as a Factor in High Blood Pressure.—Little has been said concerning water as a factor in the production of high blood pressure. In the higher pressures it is quite evident that failing capacity of the kidney to eliminate water is a decided factor. At the same time, the major reason why water is not eliminated in the lower pressures lies in the fact that there is retention to maintain osmotic tension in the presence of sodium chloride excess. Limiting the salt intake, therefore, serves as a partial corrective for the distended arterial tree. The reaction of the organism to water withdrawal is constant and interesting. Patient may lose as much as fifteen pounds in weight during the first week—all water. The accompanying weakness is due to the falling pressure and salt withdrawal. To this time no patient has yet been seen who did not concentrate urine successfully with water withdrawal, notwithstanding the fact that there may be a history of several years of inability to do so.

As will be seen in the table of cases, it often happens that the blood pressure will reach 100 mm. by the tenth day or sooner, and the patient may voluntarily go to bed. Two grams of salt should be added immediately to the daily intake and the pressure will promptly—sometimes within a few hours—return to normal. The whole chain of events is usually so striking to the patient that it serves as a valuable object lesson. On a diet containing less than two grams, symptoms of salt starvation will supervene in three or four weeks, namely, sleeplessness, headache and weakness, assuming a kidney capacity for excretion of more than two grams. At this point, or perhaps a little sooner, it is best to return to an intake of four grams daily. This amount can then usually be borne without return of a high tension. The final test is the blood pressure, for at normal, no matter what the intake, there is sufficient in the body to supply metabolic needs.

The Psychology of Diet.—It is always desirable to find out what the patient usually eats, and his daily dietary habits. From that list, a low salt diet usually can be arranged with a minimum of discomfort to the patient. It is surprising oftentimes how little change is necessary except to stop the use of salt in the kitchen and on the table. It has also been found inadvisable to leave the matter of food intake to a general statement of the foodstuffs available for use. Better technical results are obtained if a full menu of twenty-one meals for the week is furnished. The patient is thereby directed to a more intelligent cooperation. The habit of using salt on the food is purely artificial. Patients miss the taste during the first few days and complain vigorously. But several times, when, to hold a patient for future good, he has been advised to use a little salt with the food, it has been found that the taste for it has gone and there is a distinct dislike. Even children have refused to resume its use.

Some Sources of Error.—There is no department of medicine where attention to every detail is more necessary to achieve success. Lines of procedure as given above yield definite results, yet, in earlier experience, failure was common. It was felt that there was nothing incorrect in the principles involved but that the failures were due to lack of knowledge in applying the principles. Larger experience confirms that judgment. It was in tracing down the causes of failure and correcting them that an appreciation of the narrowness of the working pathway developed.

The examination of blood must be started within two hours after its withdrawal. The usual institutional procedure of allowing specimens to stand on the laboratory table over night will yield vicarious results in this work. The reasons for this must be left to chemists, but the fact remains. When estimations are made on whole blood, the results are inconstant and misleading; when made on plasma, the results are constant and consistent. Here again, the argument must be left to the chemists. The sodium chloride content of plasma is a constant within the limits to be defined later. Many errors arise in the laboratory during the course of blood examinations of which I am not qualified to write. Technically this work is of the highest type, and in the hands of one with highest training it has its limitations. In the hands of the unskilled the results are worse than useless because they are misleading. The common practice of taking a young woman from a nearby farm and attempting to evolve a laboratory technician will not suffice in this work. The question here comes up whether a technician with thorough theoretical and laboratory training can do blood chemistry satisfactorily without the added knowledge derived from a medical education. The clinician must be ever on guard against taking a narrow view of the patient's condition. The relationship between an excess of sodium salts in the blood and high arterial tension may be regarded as established, taking into account the other factors named. In probably 90 per cent. of high tension cases, even after the tension is lowered by the methods detailed above, the trace of albumen will persist in the urine and continue until the septic cause thereof is found, and removed. In this last point may be found the ultimate "cure" of the patient, and a recovery at least to some extent of the excretory power of the renal epithelium.

The Complications of High Arterial Tension.—The symptoms of high arterial tension are often masked by others of a more serious nature referable to the heart or other organs. This is well illustrated by Case No. 6. Here the patient was suffering from decompensating heart secondary to a mitral lesion and a high pressure. Bringing down the pressure was followed by immediate relief, as was to be expected. It is really startling to watch the general improvement and relief from symptoms which accompanies dechlorinization in patients who suffer from true angina pectoris. All have at least a little high tension. The principles herein laid down are applicable to the aged in whom there is high degree of arteriosclerosis, and in these I have seen nothing but good follow. The pathological blood pressures of pregnancy may be treated likewise, provided the process is not too acute, although the limitations in this field have not been carefully worked out.

A flood of questions naturally springs to mind. Occasionally a patient will be encountered whose blood will show on examination a high plasma percentage of sodium chloride and whose blood pressure is normal. This has been encountered in pulmonary tuberculosis and pernicious anemia. Apparently the pressor and depressor substances neutralize each other in their tension effects. Occasionally a patient will be found whose plasma contains normal salt percentage, and who has a moderately high arterial pressure. So far, such patients have presented a type of nephritis which is more acute and falls into that category known by the French as "azotemias." Plasma nitrogen is high and the outlook is very discouraging. Diabetics often show high blood pressure and high plasma salt content. Their condition is always benefited by attention to the salt content of their food. There have been a few patients presenting the association of high salt content of the plasma, and a high blood pressure in whom withdrawal of salt, purins and water have apparently failed to produce a lowering of pressure. I have not always been satisfied with the technical handling of these patients. I am inclined to think that these failures are due to faulty technique rather than any negation of the general principles. Some patients thought to fall into this category afterwards worked out satisfactorily, the difficulty apparently lying in the very low excretory power of the kidney for the elimination of salt.

The dietary for each patient should be made up separately on the basis of the blood examination. Every patient is an individual problem. It does not yet appear that standardization of diets is possible in this work, or that quantity production can be applied to this field of medicine. The common practice in hospital life of ordering a "salt-free" diet, may perhaps yield some results in patients who have edema of the legs, but it is essential that in lowering blood pressures the salt intake must be less than two grams daily. The best dietary results are achieved in the home with intelligent co-operation of the patient. Less efficiency is expected of patients who live in hotels, but even here the results have been satisfactory.

Case I.—Mrs. T. H. Lives in a hotel. Married and two children. Present symptoms headache, lassitude, early fatigue on exertion and slight dyspnea. Previous etiological infections: Scarlet fever in childhood and pneumonia at 23 years of age, with repeated attacks of acute tonsilitis during third and fourth decades. There is now present chronic tonsillitis, chronic gall-bladder disease and chronic enterogenic intoxication with moderate indicanuria. Complicating conditions: Subacute keratitis and potential diabetes. After institution of a low sugar, low salt (four grams), low purin diet, her systolic blood pressure promptly went down from 235 mm., until on the seventh day, it was 125 mm. On the fourth day of the diet she was taken suddenly ill and obliged to go to bed with severe pain in the left loin. High colon irrigations and the character of the fecal discharge clearly disclosed the nature of the trouble. Rapid dechlorinization was undoubtedly assisted by the irrigations.

Case II.—Mr. A. F. complained of left sided, frontal migraine, attacks averaging one day duration, every ten days and terminating in vomiting. These began after a typhoid fever at 12 years of age and have never been relieved. Previous etiological infections include scarlet fever and typhoid fever in childhood, and dis-

tinct history of attacks of colonic intoxication. There is now present chronic sphenoidal disease, and tonsils which give every indication of covering sepsis. The dietary régime was carried out in the home. On the fifth day following the beginning of the diet, his blood pressure had gone from 160 mm. to 105 mm., with the usual reactions of weakness from lowering pressure; he was nearly prostrated. Four grams salt daily was added to the dietary to bring back the pressure to normal. On this date, (July 30) the pressure is 125 mm. and while it is much too early to predict any premanent result, the headaches have disappeared.

Case III.—Mrs. E. T.—Symptoms: Feeling of lassitude and fullness in the head amounting at times to dizziness. At other times it took on that form of buzzing which is so characteristic of Mènier's disease. She also presented a right ulnar neuritis of two years' standing, which gave her much pain and loss of sleep. Previous etiological infections: Scarlet fever early in life. During mid-life, following years of tonsillar difficulty, she had an acute attack of diphtheria which left her with paralysis of a segment of the colon. This was followed by some years of sevére colonic intoxication, which was finally cured by abdominal massage, and instillation (rectal) of cultures of *B. coli.* Complicaing conditions included a low grade keratitis. The diet was carried out in her home, notwithstanding some difficulty in getting the patient to understand what was wanted. This was low sodium chloride, (under three grams) practically purin free, with water intake restricted. The tonsils were removed by Dr. F. N. Irwin. Subsequent to beginning of the diet, I did not see her for nine days as she lives at some distance. The systolic pressure at that time was 110 mm. and she was very weak. Four grams of salt were added to the daily intake and four days later the pressure was normal. In the meantime, the pressure symptoms disappeared, and the neuritis also cleared up. Last seen, May 20, when the systolic pressure was 125 mm.

Case IV.—Mrs. J. C. H.—Symptoms: Lassitude, moderate dyspnea, and frontal headache. Previous etiological infections: Scarlet fever and pneumonia in childhood. Latterly there has been occasional attacks of tonsillitis, pus appearing in the tonsils on examination. Complicating conditions: Acute keratitis. The dietary régime was carried out in the home, and there was some delay owing to the fact that perhaps I was not as specific as necessary in giving directions. Several visits to the office followed during which time the blood pressure slowly went to normal as the withdrawal of purins and sodium chloride became more perfect. On April 10 the systolic pressure was 120 mm. On May 26 the pressure was 130 mm. and she was still adhering to her diet because she felt so well.

Case V.—Mrs. R.—Symptoms: Slight dizziness, periodic frontal headache and slight dyspnea. Several times daily, for a period of from one to two minutes, she would have a feeling she described as "everything was sliding out from under." At times this seemed to amount to momentary loss of consciousness. This symptom had persisted for several years. The diet was carried out in her home, and the intake of sodium chloride and purins was placed at a low point. The pressure went from 210 mm. to 125 mm. in eleven days. The reaction of weakness was unusually severe. In the meantime, her pressure symptoms disappeared and she lost the feeling of dread which was the result of the periodic partial fainting. On May 26 the systolic pressure was normal.

Case VI.—Miss J. E. This case is included because it shows what can be done with patients with cardiac lesions as complicating factors in high arterial tension. The patient was in bed with edema of the legs and periodic attacks of severe dyspnea (several times daily lasting from ten minutes to half an hour) which were determined by myocardial degeneration, especially of the right heart. The attacks were distressing and dangerous. The mitral lesion was evidently of long standing. Twenty-four hours after being thoroughly established on a low salt and purin-free diet, with restricted water intake, the anginal attacks ceased and a week later her blood pressure had gone down from 190 mm. to 160 mm. Further instructions as to diet were given and in a few days more the systolic pressure was normal. The edema quickly disappeared. A rest in bed of some weeks followed, allowing plenty of time for the weakened heart muscle to recover. Miss J. E. was seen with Dr. R. R. Ryan.

Case VII.—Dr. R. No active symptoms, except perhaps a consciousness that his mental activity was below normal. Previous etiological infections: Scarlet fever, pneumonia, and what was diagnosed during young manhood as pulmonary tuberculosis. There was also a history of chronic appendicitis with operation. During the course of the dietary régime, Dr. R. missed his salt intake, and took it upon himself to do a little experimenting. Twice during the two months of observation, he presented himself with blood pressures of 160 mm. and 150 mm. respectively, confessing after examination that his yearning for sodium chloride on his food had overcome his judgment or stimulated his curiosity as to results. On December 15 the systolic pressure was 130 mm. It was again normal on January 20 after the two rises spoken of above. It was 125 mm. on June 15.

Case VIII.—Mr. C. D., in his twenty-fourth year had a moderately high blood pressure (160 mm.) coexistent with attacks of epilepsy, apparently dependent upon sphenoidal sinusitis. The diet prescribed during a brief stay at the Manhattan, Eye, Ear and Throat Hospital was approximately purin and salt free as shown by the chloride excretion of a twenty-four hour urine specimen indicating an intake of less than one gram (0.7 gram). This may be considered an excellent dietary result. The previous etiological infections included scarlet fever, measles, acute and chronic tonsillitis, colonic intoxication and early prolonged southern malaria. The systolic pressure was reduced to 120 mm. in two days.

Case IX.—Mrs. F. S. The symptoms were those of gout. Previous etiological infections: Scarlet fever, typhoid fever, and a coexisting gall-bladder disease. In four days after beginning the diet, the systolic pressure was reduced from 200 mm. to 130 mm. and two days later was 105 mm. There was much weakness, the patient spending much of her time in bed. Four grams of sodium chloride was added to the daily ration and four days later the pressure was again normal to the great relief of the patient. There was also a reduction in the sugar intake inasmuch as her blood sugar indicated a condition of potential diabetes. In the meantime the gouty symptoms disappeared. The patient had previously been operated for double cataract. Arteriosclerotic conditions were very marked.

Case X.—Miss L. This case came from the clinic of the Manhattan, Eye, Ear and Throat Hospital, and was chosen to illustrate what can be done with people of reasonable intelligence who live in the cheaper grades of New York restaurants. The obvious clinical symptom was chronic glaucoma, and there was a high degree of arteriosclerosis. Previous etiological infections: Scarlet fever, pneumonia and urinary cystitis of some years standing. There was also a chronic tonsillitis, as pus appeared on stripping the tonsil. The reduction in blood pressure was delayed owing to the fact that it seemed to be almost impossible to convince the patient that milk contained sodium chloride and to leave it alone. Finally, after the milk intake was stopped her pressure went from 180 mm. to 120 mm. and she felt much better for the change. She still sticks to her diet from choice and the blood pressure is still normal.

Summary.—1. Arterial hypertension is a tertiary condition. The immediate or determining cause is a larger intake of sodium chloride than the damaged kidney can excrete. Complicating causes are the presence of an excess of water in the blood and distension of the arterial tree, and possibly the retention of uric acid. Kidney limitations causing retentions of this type are undoubtedly determined by previous attacks of acute infectious disease, notably scarlet fever, and indefinite continuance of the irritation from the absorption of toxins in residual local septic foci. With the renal epithelium, all the highly specialized organs of the body suffer in the process, notably, the cells of the thyroid, pan-

creas, eye and perhaps the endothelium of the arterial wall. Our appreciation of the damage to the renal epithelium is more certain owing to the precision of blood chemistry. It is the failure to recognize the universality of these processes and their slow effects that determine a limited view of degenerative processes.

2. "Bright's disease" is a symptom and not a primary condition, unless the etiological infection develops in the kidney itself. Mental lassitude finds a resting point in the use of this term in much the same way that it finds expression in the use of the word "dropsy." Albuminuria of any degree which is of renal origin is a manifestation of irritation. Treatment, to be complete and of permanent benefit to the patient, should include elimination of septic foci, as well as the correction of the malmetabolism through dietary regime.

3. There is good reason for believing that the real toxic immediate cause of high arterial tension is the base sodium. To a more limited extent the other vital bases, potassium, magnesium and calcium may participate, although this is doubtful.

4. The blood plasma of a patient with arterial tension should regularly show an excess of sodium chloride content, and a high Ambard threshold. If this result is not obtained, pathological processes may usually be looked for in the laboratory technique as well as in the patient. If the hypertension does not become normal within a reasonable time, either the patient's diet is not below two grams in sodium chloride content, which may be determined by a twenty-four hour urinary examination, or advanced anatomic nephritis is present which prevents rapid dechlorinization and dehydration. Time and proper diet will usually produce the desired results.

5. Cardiac complications are immeasurably benefited by reduction of blood pressure, and this is the natural and rational method of giving relief. The low-salt diet furnishes the best therapeutic measure. Attention to these details should be given in the treatment of diabetes, toxic eye conditions, toxemias of pregnancy and in the post-operative care of surgical patients.

97 Riverside Drive.

SOME REMARKS CONCERNING COMPENSATION FOR OCULAR INJURIES.*

By FRANK ALLPORT, M.D.,

CHICAGO, ILL.

THIS paper is written partly in the hope of drawing attention to some of the difficulties that have been observed in eye and ear litigation in the prosecution of corporations by injured employees before State Industrial Commissions. It should be admitted at the start that such Commissions have amply demonstrated their usefulness and necessity, even under adverse conditions. Petty claims for damages can be speedily settled before such informal tribunals without the waste of time and money necessarily expended in trials before higher courts, where the dockets are already clogged by innumerable cases that can only be reached after a very long and indefinite period. But it must not be forgotten, that trials before the Industrial Commissions are not final in their outcome, for either side of the controversy can appeal to a higher court for a further decision if, for any reason, they desire to do so.

In order that the decisions of such Commissions shall be reasonably just and satisfactory, the Commissioners themselves should be men of high character and intelligence, possessed of fair, unprejudiced, and unbiased minds, and should not be composed largely of either the employer or employee class of men; there should be a fair division of both. Cases heard by Industrial Commissions are mostly instances of injured men, prosecuting their employers for physical disability. It is but natural that a Commissioner, who has been a laboring man, should have sympathy for those who labor and that a Commissioner, who has been an employer of labor, should sympathize with other employers of labor. Inasmuch as most men belong to either one class or the other, it is evident that Commissioners must largely be selected who are either employers or employees. It is merely contended that Commissions should not be practically composed of men in either one class or the other; there should be a fair intermingling of both. Commissions in some States are composed largely of ex-laboring men who have received such positions by gubernatorial preferment. Such men, although honest, will probably with the best intentions in the world, quite naturally, sometimes render decisions that seem to favor the laboring classes, thus giving the Commission the reputation of a class bias, prejudicial to its usefulness as a judicial body. Commissions should not lean either one way or the other in rendering decisions; they should be open minded and should decide cases on their merits without fear, sympathy or favor. Any other course if continued will detract from the reputation of Industrial Commissions in general and will ultimately necessitate their abandonment on the ground of unfairness and incompetency.

Commissioners should remember that if they desire a permanent continuation of such semi-judicial bodies, and if they do not desire the humiliation of a frequent reversal of their opinions by the higher courts, their decisions must be based on an absolutely impartial consideration of the cases that are tried before them. Sentimentalists and partisans may argue that the poor laborer should be given the advantage in such trials; that he has a family to support; that he has been injured while working for some wealthy corporation; that he is poor, needy and unfortunate, etc., etc. Other equally illogical but prejudiced individuals may say, on the other hand, that the man was well paid for his services; that he accepted the job voluntarily; that the employer has a hard time paying expenses and making a profit; that the law is hard on the employer, etc., etc. Both sides of the argument are wrong and pernicious. Cases should be decided on their merits and according to the law without regard to sentiment or class prejudice. No other course can produce permanently satisfactory results and unless this course is followed the useful and desirable Industrial Commissions will have to go and litigations, both large and small, will revert back to the higher courts or some other method of adjusting small claims will be devised.

*Read before the Chicago Ophthalmological Society in December, 1921.

The medical expert is sometimes discouraged at the lack of credence given his testimony. Assuming that the Commission believe in his honesty, skill, and intelligence, it is sometimes difficult to understand the verdict. For instance, a man suffers a comparatively slight blow on the head. In about a month he brings suit for a bad ear that he claims dated from the accident. Examination discloses a profuse foul discharge from the ear with polypi, necrosis, and deafness—conditions impossible to have occurred in so few weeks. Testimony is given accordingly, and yet a verdict in favor of the plaintiff is given. Another instance is that of a man claiming profound deafness in one ear, who by the malingering test is found to be grossly deceiving and yet he received a verdict. Another man claimed excessively poor vision in one eye and was proved to be a falsifier by malingering tests; he also was awarded damages. Other instances similar to these might be enumerated, but these are sufficient to show that something is wrong with the system when it is possible for proven and sinister liars to go into court and obtain damages for injuries that competent and honest medical testimony has proven to be non-existent. I will not attempt to analyze the source of defect. It may be class prejudice, or ignorance, or non-judicial temperament, or illogical conclusions, or something else; I do not know. But I am sure that this evil exists, whatever it is, and I am also certain that unless it is purged out of the system, the existence of these highly desirable, informal, semi-judicial courts, will be in extreme danger.

I trust that it will not be considered that I am asking for the appointment of supermen to the office of commissioners. Neither do I wish to be understood as believing that mistaken judgment is inconsistent with perfect honesty and intelligence. Commissioners are not trained lawyers and frequently not even well educated men and the only wonder is that they do so well and perform such satisfactory work. Personally, I have always been treated with the greatest courtesy and consideration by the Industrial Commission of my own State and I wish to make it plain that I am *not* criticizing the Illinois Commissioners, in fact, I have two other states in my mind in writing this article. As a matter of fact I do not wish to criticize any set of Commissioners in particular. I am simply reciting some of the errors in the system believing that Commissioners will be quite as anxious to receive suggestions and act upon them as honest observers are to advance them. Industrial Commissions are a new thing and, of course, open to much justifiable criticism. Imperfections will never be overcome without open and fair-minded discussion, instigated, *not* from captious and prejudiced criticism, but from an honest desire to improve the system and insure its perpetuity. May I be pardoned if I refer in passing to a law concerning visual losses that is most unfair and illogical to all parties concerned and has from time to time resulted in working much hardship to both employer and employee. It seems that if a man, who is already blind in one eye, loses the other eye while in employment, the employer is liable for the loss of *both* eyes. This seems almost incredible but it is true nevertheless. It is of course merely common sense to require an employer to be only responsible for the eye that is lost while the worker is employed by the employer and yet the law holds him liable for both. It has been suggested that an applicant for work, who possesses only one seeing eye may give the employer a writing exonerating him from liability for the loss of the blind eye, damaged perhaps years ago, but this cannot be legally accomplished, so tightly have the framers of the law constructed their senseless, unjust, and unfortunate enactment. It is not only unjust to the employer, but it is also unjust to the man seeking work, for who wants to employ a one-eyed man if he assumes a two-eyed responsibility? Thus many men are debarred from desirable occupation because unjust responsibilities are forced upon employers. It is well known that a man with only one eye is not so safe from accidents as a man with two eyes. He is more liable to be injured by collisions, flying objects, etc. on his blind side, and cannot obtain as good and comprehensive vision as a man possessed of two good eyes. Employers, you may be sure, realize the situation and know that they are taking chances when they employ a man with only one good eye and when they also must assume responsibility for an eye perhaps damaged years ago, they are not at all desirous of giving work to a man thus handicapped.

The subject of traumatic cataract is one of great interest and importance in the adjustment of personal injury cases. Let us suppose, for instance, that a man gets a piece of steel in his eye that is removed by a magnet, leaving him with an eye blinded from cataract. Let us further imagine that irritation and inflammation have all subsided but that the cataract remains and that the indications are that a removal of the cataract would result in the restoration of vision. The surgeon now asks the corporation whether he shall remove the cataract and perhaps restore vision or whether he shall cease his attendance and leave the case at this juncture. The corporation will naturally ask as to the probability of a successful result following the operation. This question cannot be positively answered, especially when it is remembered that intraocular steel invasions are apt to be followed by serious intraocular pathological changes, even in eyes that seem, for a time, to be doing well after the steel has been removed. Nevertheless there is frequently a good fighting chance for vision if the cataract is removed. Let us suppose that the employer decides to allow the surgeon to remove the cataract and that after this has been accomplished the vision is 10/200 without a glass and 20/20 with a glass; in other words, the result is perfect. In spite of this, however, the patient will probably not wear the glass, provided his other eye is good, because the discrepancy between the two eyes and the two glasses is so great that he is much more comfortable not to wear his cataract glass at all. He will merely realize that he has an eye upon which he can fall back in case of disease or accident occurring to the other eye. This is like laying up money in the savings bank for use upon "rainy days,"—of no use *now*, but a safeguard for the future. So that, while it is doubtless a satisfaction to the surgeon to know that he has restored vision and a satisfaction to the patient to know that he

has good vision and also a satisfaction to the employer to realize that he has been the financial motive behind the good result, after all where does it benefit the employer in the settlement of the case except through the consciousness of having performed a meritorious act. He has expended several hundred dollars that will serve him no useful purpose in the final adjustment of the claim; the reason being that Industrial Commissions, as a rule, insist upon estimating vision in such cases *without* glasses instead of *with* glasses. The argument being that the accident has destroyed industrial vision unless glasses are worn and that they have no authority to order the wearing of glasses in estimating visual losses. I have no desire to argue the justice or injustice of this claim. I am willing to admit that there are two sides to the question and I have no desire to impose any hardship or injustice on the laboring man; in fact, my sympathies are distinctly with a man who leaves his home in the morning safe and sound and who by night becomes maimed for life. I repeat that my sympathies are *with* him so long as his claims are truthful and honest and just and my experience with employers and accident companies is such that I am confident that in almost all instances they entertain the same sympathies and intend to act accordingly. It is this very sympathy with the injured man that makes me feel that the policy of ignoring the results of successful cataract operations in making settlements is a hardship to the injured man himself, who insists that claims for injury must be settled on a financial basis. There is no room in his scheme for sympathy for the employer or for the extension of benefits to him. He wants his money and he wants all he can get. Then why should the employer spend hundreds of dollars for cataract operations, attendance, hospital bills, etc., when no allowance will be made to him in the final settlement for vision obtained. He might as well, or even better (financially) order the cessation of surgical attendance after the steel has been removed and the eye has become quiet. He will have to pay for the total loss of the eye anyway, even if the cataract is removed and vision is restored to normal. Why, then, should he incur an extra expense of several hundred dollars for which the Industrial Commission will not give him credit? Inasmuch as these cases are to be settled on a financial basis, why should not the employer protect himself financially and allow the injured man to have his cataract removed if he desires and to pay for it himself? The alternative would be for Industrial Commissions, Legislatures, etc., to allow an employer some reasonable financial consideration if he undertakes the expense of a cataract operation. My experience with employers and accident companies is such that I know that almost all of them are not only willing but anxious to do all they possibly can for injured men when they are responsible for injuries and often do more than the law requires, but when it comes to spending several hundreds of dollars and getting absolutely no credit for it, they cannot be blamed if they positively refuse to submit to such injustice. My contention is, therefore, that in case an employee has a traumatic cataract and his employer pays to have it removed, the employee's vision should be estimated *with* glasses and that a reasonable financial concession should be made to the employer for assuming the expense and responsibility of operative procedures.*

Another point I wish to make is to urge employers and employees to insist upon eye and ear examinations before employment is given. This is only justice to the employer for, if he is to pay for eye and ear damages after injury in occupation, he should certainly be allowed the privilege of accurate knowledge concerning ocular and aural conditions before an employee is placed to work. I am well aware that some labor agitators resent such preliminary examinations, and it is certain that such objections can have but one motive and that a sinister one: viz., to prevent a knowledge of old physical defects in order to increase the financial liability of employers in case of accidental injury. A subterfuge of this character is not honest, is unworthy of any straightforward organization, and should not be countenanced. It must be the experience of all surgeons doing any amount of industrial surgery that many employees endeavor to represent that old pathological eye and ear conditions have never existed until some recent accident has occurred. They then claim that an old necrotic discharging putrid ear or perhaps a senile cataract is the result of some recent accident of greater or lesser degree of severity. Personally, I frequently see several such cases in my office in one day and it can be readily understood that deliberate efforts of this nature to deceive and obtain money under false pretenses almost shatters one's faith in human nature and in the existence of common honesty. Employers should, therefore, be allowed to require and should insist upon the careful physical examination of all applicants for work before employment is given. This is not only ordinary justice, but it will save thousands of dollars that would otherwise be paid in the liquidation of dishonest claims. There is no adequate honest reason why such preliminary examinations should not be made and I trust that before long this idea will be universally adopted. Such examinations would likewise be of enormous benefit to employees for it would disclose the existence of perhaps unsuspected diseases that could be benefitted or cured and would call the attention of employees to *known* diseases that could also be relieved by proper medical or surgical advice. The disclosing of diseases or defects would also exert a strong influence in enabling employers to assign to employees occupations harmonious with their physical condition, such as the improving of lighting conditions for workers with poor vision, the forbidding of work on emery wheels when one eye is very defective, keeping men away from dusty places who have sore or irritable eyes, etc.,

*In a decision of the Illinois Supreme Court that affirmed an award of the Illinois Industrial Commission and the Circuit Court in the case of Juergens Bros. Co. (plaintiff in error) vs. The Industrial Commission et al. (Fred Kaage, defendant in error), published in volume 290, page 420 Illinois C. S. reports. A decision was rendered in the kind of case just referred to under which the employer was obligated to pay for the complete loss of the use of the eye.

etc. It will thus be seen that these preliminary examinations, while beneficial to the employer, are also beneficial to the employee and as there can be no valid objections to them and as they are needed by both employer and employee, they should be adopted without further controversy.

One obstacle to the just and intelligent settlement of visual losses has been and for that matter is the absurd but, it must be confessed, natural interpretation of Snellen's Test Types in estimating defective vision. Doctors, and I regret to say, eye doctors, have in the past, with the best intentions in the world, endorsed the improper, misleading, and literal readings of Snellen's types for compensation purposes. For instance, they have testified that 20/40 indicated a half loss of vision or that 20/50 indicated 2/5 loss of vision. Some medical men, even at the present day, obstinately persist in such opinions when testifying as expert witnesses, although most ophthalmologists have come to recognize that it is absurd to say that a man's eyesight is half gone when his vision is 20/40, according to Snellen's types. Professor Snellen never intended to have his types and fractions used to indicate visual losses. They were devised merely as an international language to indicate visual conditions, chiefly as relating to refraction work. These views being correct, and it may be safely assumed that they are, it remains for us as ophthalmologists to correct erroneous views of the past and to guide industrial commissions, courts, lawyers, etc., to a rational and correct view of the situation. People of these classes fall back on the old and proverbial "quarrellings amongst doctors" to justify themselves in not abandoning the discarded opinion that 20/40 means a 1/2 visual loss, etc. In truth, it must be confessed, they occupy a defensible position, for in the first place *all* opthalmologists have not espoused the new views and not yet have ophthalmologists in general adopted any new scale for estimating visual losses. So the opposition says, "How can you expect *us* to participate in your 'New Thought' when you yourselves are still fighting? Get together, bring us something that is generally adopted and we will "join the procession. Until this occurs, however, we propose to do as we think best, or rather as *you* have taught us in the past." This is about what they think and, indeed, what they say and who, forsooth, can blame them. Let us then "get together," let us bury our own personal opinions and adopt some plan, some method, some scale that we can unitedly present as being to all intents and purposes a safe, equitable, and reasonably accurate plan to serve as a basis for the settlement of visual losses. It is, of course, understood that no cold table or scale can possibly entirely settle claims fairly or equitably, there are too many conditions to be taken into consideration. A person may have a vision of 20/40, 20/50, 20/30, or what not, and yet have an advancing optic atrophy or choroiditis or detachment of the retina or a cataract, etc., any of which must be taken into consideration in awarding damages. These are conditions which must be solved by the expert medical witness and the time will never come when his services can be dispensed with. A table for compensation is only valuable, therefore, as it provides a basis or foundation upon which to work and as voicing the opinion of the profession of the relationship of compensation to the varying degrees of visual losses. Any one who regards a compensation scale or table as an unbending, inelastic measure of settlement entirely misunderstands and misconceives the object of a table.

In order to construct a table certain initial points must be settled:

1. 20/20 must be admitted to constitute normal vision.

2. Some standard must be arbitrarily settled as constituting industrial blindness.

This latter is a mere matter of opinion. There is no law by which it can be settled. Personally, I believe that when a man's vision is worse than 20/200, he is industrially blind—not actually blind, but industrially blind; that is, unable to earn his living through ordinary means *by his eyes*, each eye being considered as an entity by itself. The question of shifting occupations will, of course, frequently present itself; that is, the necessity of changing vocations on account of visual deficiency, as for instance, from being a watchmaker on a high salary to a day laborer on a low salary. This is a problem that cannot be solved by a scale or a rule; it must be settled by expert evidence and by a judicial and equitable survey of the entire situation. Having, therefore, settled that 20/20 constitutes normal vision and that vision worse than 20/200 constitutes industrial blindness, it simply becomes necessary to graduate in percentages the varying losses of vision between the two extremes in order to frame a compensation table. The amount of damages to be awarded is something that we as table constructors have nothing to do with—it is taken out of our hands and is settled by the State. For instance, the Illinois law awards an applicant 100 weeks of compensation for 100 per cent. of visual loss of one eye with the following modifications. The Illinois law holds that the total loss of one eye entitles an applicant to 100 weeks of compensation with $12 a week as the maximum to be paid, the minimum being $7 a week. In case the maximum is paid, the amount is increased $1 a week for each child under 16 years of age up to and including three children. In case the minimum is to be paid, the amount is increased $1 a week for each child under 16 years of age up to and including three children. Of course no one thinks for a moment that an amount varying from $700 to $1,500 compensates a man for the loss of his eye, but it must be remembered that this compensation is being paid by the employer and not by the injured man himself and a more liberal policy in general would be ruinous to almost any business. Each man can take out all the accident insurance he wishes to or can pay for, but as long as his employer is paying all the damages including doctor's bills, hospital charges, etc., the injured man should be satisfied with reasonable returns.

The only thing to be done now in constructing a compensation table for monocular visual losses is to arrange a mathematically correct graduated scale of visual loss percentages between the two

extremes of the table, or, to be more specific, between normal vision and industrial blindness. This has been attempted by various observers, but the one most favorably considered was adopted by the Chicago Ophthalmological Society at a meeting held November 10, 1919. This is a very fair and reasonably accurate table, but unfortunately it presents certain mathematical discrepancies that will always render it open to criticism. These have been pointed out by Professor G. A. Bliss of the mathematical department of the University of Chicago and others.

THE CHICAGO OPHTHALMOLOGICAL SOCIETY TABLE.

20/20	indicates	100%	of visual efficiency and			no	loss of vision		
20/30	"	94.5%	"	"	"	5.5%	"	"	"
20/40	"	89.0%	"	"	"	11.0%	"	"	"
20/50	"	83.5%	"	"	"	16.5%	"	"	"
20/60	"	78.0%	"	"	"	22.0%	"	"	"
20/70	"	72.5%	"	"	"	27.5%	"	"	"
20/80	"	67.0%	"	"	"	33.0%	"	"	"
20/90	"	61.5%	"	"	"	38.5%	"	"	"
20/100	"	56.0%	"	"	"	44.0%	"	"	"
20/110	"	50.0%	"	"	"	50.0%	"	"	"
20/120	"	41.0%	"	"	"	59.0%	"	"	"
20/130	"	36.5%	"	"	"	63.5%	"	"	"
20/140	"	32.0%	"	"	"	68.0%	"	"	"
20/150	"	28.5%	"	"	"	71.5%	"	"	"
20/160	"	23.0%	"	"	"	77.0%	"	"	"
20/170	"	18.5%	"	"	"	81.5%	"	"	"
20/180	"	14.0%	"	"	"	86.0%	"	"	"
20/190	"	12.0%	"	"	"	88.0%	"	"	"
20/200	"	10.0%	"	"	"	90.0%	"	"	"

It will be noticed that the changes in percentages from line to line are not uniform and, therefore, incorrect and criticizable. For instance, in the last line it says that 20 200 indicates 10 per cent of visual efficiency. The line above says that 20 190 indicates 12 per cent. of visual efficiency. The line above says that 20/180 indicates 14 per cent. of visual efficiency. So far the differences in percentages are uniform; that is, there is 2 per cent, between each line. But the next line says 20 170 indicates 18.5 per cent. of visual efficiency, thus separating the two lines by 4.5 per cent. instead of 2 per cent. The next line is also separated by a difference of 4.5 per cent., for it says that 20 160 indicates 23 per cent. of visual efficiency. But the next line is even worse, for it says that 20 150 indicates 28.5 per cent. of visual efficiency, a difference of 5.5 per cent., and so on. Other discrepancies will be found on carefully analyzing the table. This table is meritorious and essentially correct and equitable. The compensation from its readings is about the same as that from other tables, but these discrepancies in percentages render it open to criticism and progress toward its general adoption is thereby considerably deterred. I know this is true from personal experience, as I will relate. The Industrial Commission of a neighboring state called me to testify in a certain case, but the real object was to have the Chicago Ophthalmological Society table explained to them. They were favorably inclined to it and really wanted to adopt it, as may be seen from the fact that they paid me $500 for the trip. Notwithstanding this, however, they refused to adopt it on account of the percentage discrepancies, believing that a more accurate mathematical table would soon be presented to which they could subscribe. I have, therefore, conferred with Professor Bliss of the University of Chicago, Dr. J. D. Whitaker of Indianapolis, Dr. W. N. Sharp and Dr. Joel Whitaker of Indianapolis, and Dr. V. A. Chapman of Milwaukee, and we have concluded that the essential features of the Chapman table are the most perfect of any table before the profession. To all intents and purposes it works out about the same amount of compensation as the Chicago Ophthalmological Society table; in fact, most of the tables do this. The only real advantage of the Chapman table is that it is more accurate mathematically and is free from discrepancies, thus rendering it impervious to just criticism and therefore more likely to be generally adopted.

I herewith submit the Chapman table and leave it to the profession to make what use they please of it.

I have changed the table somewhat, in order to clarify it, but the table as here appended is essentially the Chapman table. I have "cut out" Chapman's mention of 20/15 of vision, as being unessential and confusing and start out with 20/20 or normal vision. I also maintain that while the last two items, viz., 20/210 and 20/220 are desirable as completing the table, they are unessential from a compensation point of view, for in the judgment of most fair-minded men anything *less* than 20/200 constitutes "Industrial Blindness."

	20/20	indicates	100%	of visual efficiency and			no	loss of vision		
1	20/30	"	95%	"	"	"	5%	"	"	"
2	20/40	"	90%	"	"	"	10%	"	"	"
3	20/50	"	85%	"	"	"	15%	"	"	"
4	20/60	"	80%	"	"	"	20%	"	"	"
5	20/70	"	75%	"	"	"	25%	"	"	"
6	20/80	"	70%	"	"	"	30%	"	"	"
7	20/90	"	65%	"	"	"	35%	"	"	"
8	20/100	"	60%	"	"	"	40%	"	"	"
9	20/110	"	55%	"	"	"	45%	"	"	"
10	20/120	"	50%	"	"	"	50%	"	"	"
11	20/130	"	45%	"	"	"	55%	"	"	"
12	20/140	"	40%	"	"	"	60%	"	"	"
13	20/150	"	35%	"	"	"	65%	"	"	"
14	20/160	"	30%	"	"	"	70%	"	"	"
15	20/170	"	25%	"	"	"	75%	"	"	"
16	20/180	"	20%	"	"	"	80%	"	"	"
17	20/190	"	15%	"	"	"	85%	"	"	"
18	20/200	"	10%	"	"	"	90%	"	"	"
19	20/210	"	5%	"	"	"	95%	"	"	"
20	20/220	"	0%	"	"	"	100%	"	"	"

In conclusion, I desire to say, that if it is the intention of ophthalmological organizations to establish scales, tables, or rules for the purpose of awarding compensations to the injured, that shall, perhaps, be valuable from an academic standpoint, and comprehensive to educated ophthalmologists, and satisfactory as scientific productions, let them go on formulating abstruse, incomprehensible, impractical resolutions, that will doubtless be satisfactory to themselves, and to the highly scientific organizations, before which such papers are read. But, if they desire to produce something that shall reach the purpose at which such papers are aimed and receive the endorsement of business men, lawyers, courts, etc., they will have to get down to the medically uneducated level of such men, and give them something they can clearly and instantly understand without study. Nothing else will do, and nothing else will be accepted as a working basis for litigation. It must be remembered that eye injury cases are not tried before educated ophthalmologists, they are tried before medically uneducated industrial commissioners, judges, lawyers, and juries. *They* are the people to be reached and satisfied, and we must "cut our garment, according to our cloth." Questions of

an abstruse nature, must be settled by the expert witness on the witness stand. They cannot, and never will be settled by scales, tables or resolutions. Writers and committee men, endeavoring to settle this vexed problem, often make the mistake of thinking that because their literary productions are plain to *them*, they must be plain to everybody. Many of them, however, are not plain even to me and perhaps other ophthalmologists. How, then, can they expect them to be understood and adopted by laymen.

7 West Madison Street.

THE BACTERICIDAL VALUE OF THE ANTI-DIPHTHERITIC SERUM, WITH THERAPEUTIC DEDUCTIONS.

By FERDINAND HERB, M.D.,

CHICAGO

Handed down by Behring more than a score of years ago, the opinion still remains undisputed that the antidiphtheritic serum is an antitoxin, and that its efficiency rests solely upon the neutralization of poisons. This fact can no better be demonstrated than by quoting a recent statement made by Dr. Simon Flexner, of New York. In the first article of the series on "Biologic Therapy,"[1] initiated by the Council on Pharmacy and Chemistry to serve as a guide for physicians and published in the Journal of the American Medical Association, he says: "Diphtheria antitoxin is still the outstanding example of a therapeutically active serum, while tetanus antitoxin has a high protective but a low therapeutic value. These two antitoxic serums act not directly on the infecting bacilli, but on their liberated toxins which they neutralize, after which the body readily rids itself of the bacilli themselves."

It is the object of this paper to disprove the correctness of these views and to show that the antidiphtheritic serum does not neutralize liberated toxins, but does act directly on the infecting bacilli themselves.

In adducing the required proofs to uphold this assertion, it is not necessary to dwell at length upon the neutralization of toxins. Many have attempted to demonstrate this supposed neutralization experimentally, but not one has succeeded. Indeed, the conclusions to be drawn from these experiments point the other way.

A definite clinical proof against the neutralization of toxins is furnished by the accidental destruction of horses that, during immunization, died from a dose of diphtheritic poison which could, and would, be neutralized many times over by the large quantity of free antitoxin found in the blood after death, if antitoxin merely neutralizes toxins. Such accidents have been reported by the Pasteur Institute, Behring himself and many other observers.

A further clinical proof is furnished by the following phenomenon: After immunization, the amount of antitoxin remains for a while at its full height, then it gradually declines, if the inoculations of toxin are stopped. If a single dose of toxin is given before the decline begins, the amount of antitoxin which disappears from the blood is altogether out of proportion to the amount of the inoculated toxin, and would, for simple neutralization, require from two up to ten thousand times the inoculated dose.

Of the many further proofs against neutralization a third may be added. A dose of toxin, lethal to a guinea pig, can be rendered harmless by a definite quantity of the respective antitoxin. If we inject more and more lethal doses, all fully neutralized by the proper amount of antitoxin, the law of multiple proportion holds up to a certain point. If more than ten lethal doses are injected, the law does no longer hold and no amount of antitoxin will avert the fatal issue.

Each of the three clinical proofs submitted speaks absolutely against the antitoxin theory. They can, however, be readily explained on the basis that the specific germicidal antibodies are present in the serum, as we will see later.

Eliminating, therefore, the antitoxin theory, we must look for another cause of the acknowledged good results obtained from antidiphtheritic serum. In doing so, I wish to point to the fact that the inoculation of diphtheria toxins produces immunity in children. Though this fact is too well established to require further proof, the proper deductions from it have never been made.

If we attempt to make these deductions, a peculiar light is thrown, first of all, upon the diphtheritic toxin itself. Immunity is bactericidal. This means, the body of the immunized child has acquired the faculty to kill, and dispose of, diphtheria bacilli, should they invade the blood or tissues; it does not mean that the body of the immunized child has acquired the faculty to neutralize liberated toxins, but must depend upon some other mysterious force to kill, and dispose of, the bacilli themselves. On the other hand, we know that immunity is due to the presence of specific ferments, or antibodies, that kill and disintegrate the bacilli, or at least, upon a state of sensitization, that is, of preparedness of the cells of the body, so that specific antibodies are produced immediately when occasion demands. Specific antibodies, or specific sensitization, however, are not produced unless the body cells have been sensitized by coming in contact with specific diphtheritic antigen. Consequently, the resulting immunity proves positively that such specific diphtheritic antigen is contained in the diphtheritic toxin.

Specific diphtheritic antigen can consist of two substances only: either of the body substance of diphtheria bacilli or of their still specific intermediary split products. As the molecules of the undisrupted albuminous body substance of the bacilli are too large to pass through the porcelain filters used to filtrate the toxins, these specific toxins must be made up of the specific intermediary split products coming from bacilli that have died and disintegrated in the culture.

That such split products can display all the characteristics of the toxins has been demonstrated experimentally by Victor C. Vaughan[2] and his collaborators. They have shown that the intermediary split products of all albuminous substances are in part highly poisonous, but that they lose their poisonous character when broken down into simpler compounds. It has further been shown that the diphtheritic toxins closely resemble peptones, and that they are readily broken down into non-poison-

ous substances by digestive ferments, just as peptones coming from other albuminous substances.

Intermediary split products of albuminous substances, if not broken down too far, retain fully their antigenic properties and lead to the production of the same bacilli-killing and digesting specific ferments, or antibodies, as do the undisrupted molecules of the body substance of the bacilli themselves. The diphtheritic antigen contained in the toxins makes no exception from this well established rule. Its inoculation into the child leads, consequently, to a specific sensitization and to the production of specific, bactericidal ferments, or antibodies, expressed in the term "immunity."

What happens in the body of the child, happens in the body of the horse, used to produce the antidiphtheritic serum. The horse, when inoculated with the specific diphtheritic antigen in the form of toxins, produces the same bactericidal antibodies as does the child. Consequently, these specific, bactericidal antibodies must be in the serum.

The tangle, in which the antitoxin theory has enmeshed us, grows, indeed, hopeless if we ask ourselves how, after the supposed neutralization of liberated toxins, the body can all at once "readily rid itself" of the massive cultures in the throats of suffering children, though it could not rid itself of the few bacilli at the time of the infection, when no toxins as yet existed and the system was at its best, with a full and untrimmed resisting power.

The chief reason why this erroneous antitoxin theory arose and endured so long seems to be the curious fact that diphtheria bacilli grow luxuriantly on antidiphtheritic serum. But does this fact militate against the assumption that the antidiphtheritic serum contains the specific, germicidal antibodies?

In answer to this question I wish to refer to an illuminating experiment made by Fodor.[3] Under aseptic precautions he took blood from the heart of animals and added anthrax bacilli. Plates made from time to time showed a rapid diminution in the number of bacteria until, after a time, the blood lost entirely its germicidal power and became an excellent culture medium, in which the bacilli rapidly increased in number.

In order to show why in Fodor's experiment the blood gradually lost its bactericidal power and finally turned into an excellent culture medium, upon which the bacilli grew luxuriantly, as they do on antidiphtheritic serum, in spite of the fact that the germicidal antibodies are present, I wish to cite some well-known phenomena in parenteral digestion.

Ferments, or antibodies, cannot act without the presence of another substance, called "complement." This fact is fully established and undisputed. It is also fully established that the ferment is not destroyed during its action, but can disintegrate one molecule of antigen after the other. Thus a few ferments can disrupt a large amount of protein. With the complement, however, conditions are entirely different. It is consumed in direct proportion to the work accomplished. In other words, to break down a given quantity of protein, say one gram, requires a definite quantity of complement. If the complement is consumed or otherwise destroyed, the ferment becomes totally inactive. It can no longer kill and disintegrate germs or disturb their growth and multiplication. That the ferment, nevertheless, remains fully alive and retains all its inherent powers to kill and digest is proven by the fact that it resumes its activity immediately as soon as new complement is added.

Thus, the fact that germs may grow luxuriantly on a given blood or serum, for instance on the antidiphtheritic serum, is no proof that this blood or serum does not contain the potentially active, germicidal ferments, or antibodies. Lack of complement explains this fully.

There is ample direct proof at hand that complement is actually absent in all therapeutic serums. This proof will be given in a separate paper, as its details are of too great clinical importance to limit them to the space that could, at best, be allotted to them at this occasion.

An indirect proof is furnished by Besredka's so-called "toxin-antitoxin." In the light of what has been said before, this combination can no longer be considered as a union of toxin with its antitoxin, as the name would indicate, but must be regarded as a union of antigen with its specific antibody. Such combinations are well known and have been studied exhaustively in the past. They are stable only in the absence of complement. With complement present, the specific antibody would break down the diphtheritic antigen, contained in the toxin, into non-specific, non-immunizing fragments outside the body. The immunity resulting from the inoculation of a properly prepared combination proves that this is not the case. However, the specific antigen contained in the toxin is broken down by the specific antibodies contained in the antidiphtheritic serum, if sufficient serum, together with the toxin, is injected into the human body, where the complement is available. Clinically, this has been proven by the unique experience of Dr. Mulsow, of Chicago.[4] Thirty-one young adults received toxin-antitoxin inoculations. "Of these thirty-one young persons, seven have continued to have positive Schick reactions for three months or more following the injections of toxin-antitoxin. In these seven persons, immunizing doses of antitoxin had been injected shortly before, or soon after, the administration of toxin-antitoxin."

Twenty-four persons were immunized, as demonstrated by the negative Schick reaction, because the specific antibodies contained in the toxin-antitoxin combination were not sufficient in numbers to break down the inoculated specific antigen fast enough, so that the body cells took it up and became sensitized, with the resulting immunity. Seven failed to be immunized, as shown by the continued positive Schick reaction, because, with sufficient complement now available, the extra doses of antidiphtheritic serum furnished sufficient additional specific antibodies to break down the specific diphtheritic antigen of the toxin-antitoxin combination into non-specific, non-immunizing fragments before the body cells had time to take it up and become sensitized. This failure to become immunized, then, proves with the preciseness of a biologic experiment that the specific, bactericidal antibodies are in the antidiphtheritic serum, as only these specific, bactericidal antibodies can break down specific antigen.

Therapeutic Deductions.—For more than ten

years past the results obtained in the treatment of diphtheria have not been improved, the antidiphtheritic serum notwithstanding. The cause of this ostensible failure has so far remained obscure. However, the above given elaboration offers more than a mere suggestion where the fault might lie. It strongly points to the possibility, or even the probability, that many, if not most, of the children who die today from diphtheria, die for lack of complement—and that their lives may be saved, if the necessary complement is furnished. These needless deaths of children are, I believe, on par with the destruction of those horses that die during immunization, as mentioned above, and the death of animals if more than ten lethal, though fully neutralized, doses of toxin are injected. A lack of complement offers the only plausible explanation. That great quantities of complement are required in serious cases will be better appreciated if we consider that not only the ferments need complement to kill and dissolve the germs, but that also the soluble digestive split products, produced during this dissolution of the germs, have a great affinity for complement and absorb, or "fix," it eagerly. I have shown this to be a fact in a former communication.[5] Whenever these split products begin to glut the blood stream during the course of infectious diseases, an event signalized by the increase of acidosis during the height of the specific symptoms, the danger to life grows as the depletion of complement continues and death must ensue when all complement has vanished, no matter how much antiserum is injected. Practical experience supports this statement. The highly gratifying results obtained frequently under such circumstances with sufficiently large doses of sodium bicarbonate are not without significance and suggest that this drug may, perhaps, serve as a complement or protect the natural complement from destruction.

To save these children and to stay the needless deaths, we must supply complement. It should not be difficult to ascertain its exact chemical composition for those who are so fortunate as to have a good equipment and plenty of trained assistance at their disposal.

CANCER IS A BLOOD DISEASE AND SHOULD BE TREATED AS SUCH.

By ROBERT BELL, M.D., F.R.F.P.S., Etc.

LONDON.

SUPERINTENDENT OF CANCER RESEARCH, BATTERSEA GENERAL HOSPITAL.

The letter of Dr. Seelye W. Little in the 22d of October issue of the Medical Record, the article on the 29th of the same month by Dr. C. Everett Field, and that bearing the date of November 5 by Dr. George Stuart Willis, have brought to the surface of my mind a number of convictions I have long held, and which I should like to transmit across the Atlantic for the consideration of the many friends I feel proud to possess in the United States.

It is twenty-seven years ago since I commenced in earnest to devote myself to the solution of the cancer enigma, and it has been my good fortune to have it in my power to avail myself of ample opportunities of studying the disease in its various aspects. I trust, therefore, the following remarks may be looked upon in a sympathetic and friendly manner, equal to that in which they are offered, either for acceptance or refusal as the case may be.

During this period it has been my endeavor to take advantage of every new so-called remedy for this, hitherto intractible disease, with the result that from my standpoint the great majority of those so-called "cures" are founded, if they have any tangible foundation at all, upon a basis too flimsy to support the recondite and vital question which is at stake.

I am sorry I have not had the opportunity of reading the criticized article, as a whole, which Dr. Seelye Little recommends one to do. Yet taking Dr. Little's letter and Dr. Everett Field's article together, I think I can understand to a certain extent the varying conclusions he has arrived at with reference to the effects of radium and *x*-rays in the treatment of cancer. But with reference to the treatment of cancer by local measures, it beats me to comprehend, for a moment, how one can expect a cure of a blood disease, which cancer undoubtedly is, by attacking its local manifestation, and leaving the source of the disease to take care of itself, without any effort being made to improve the quality of the blood stream. For, depend upon it, every cell of the body is affected, and has been affected for a long period prior to the appearance of the local outcrop, or how does one account for the cachexia, malnutrition, and I may add rheumatism,* which manifest themselves before the neoplasm of cancer asserts its presence? This latter, as a rule, takes its seat in an organ whose periodic activity is, for the time being, in abeyance; and this is supplemented by a deprived condition of every cell of the body for these are, *pari passu*, deprived of the disease-resisting power which the normal cell possesses, as in the mamma for example; or, in the event of an injury or prolonged irritation, when the cellular tissue in these penalized localities becomes so demoralized that it ceases to recognize physiological control, and establishes a colony of rebel cells within a degraded environment, which to some limited extent remains loyal to physiological law. Yet the tissues continue in a precarious position, and so are liable to become a prey to a rapacious neighbor.

From my standpoint cancer is the outcome, in every instance, of prolonged chronic autotoxemia, and a vitiated blood supply not only acts deleteri-

*The blood picture of rheumatism bears a close resemblance to that of cancer, and, so far as my extensive experience teaches me, a rheumatic diathesis is in existence in those who become the victims of cancer. So impressed have I become by this coincidence that, when there is present a doubt as to the diagnosis, I am inclined to hold that if rheumatism is absent in the subject under examination, the case is not malignant; and vice versa.

ously upon the nervous apparatus, but coincidently with this, gives rise to inefficiency of the secretion of every endocrinic gland in the body, the natural consequence being an absence of healthy cell metabolism: and the dire disturbances which inevitably follow.

But to return to the important contents of Dr. Little's letter, I do not for a moment agree with Dr. Wood's assertion that the "increase in the number of deaths from cancer" is even "partly due to improvements in methods of diagnosis." Moreover I deprecate most emphatically Dr. Wood's proposal to cut into a tumor, for the purpose of diagnosis, as no implicit reliance can be placed upon such expedients. Besides it is a mistake to incise a malignant or even a benign tumor.

If one's tactus eruditus and consideration of the concomitant symptoms are found to be unreliable, then any remaining doubt may be dissipated by taking a microphotograph of the blood.

Referring to Dr. Little's remarks, *re* the "false hope" paragraph in the criticized paper, I venture to ask why there should exist a *false* hope; why not an *unqualified* hope if sole reliance is not placed upon treatment of the local outcrop of the disease, which only occurs in a locality in which the cellular tissue has been yet further devitalized by a depletion of normal vital resistance to disease, either by a reduction due to a physiological cause, or an injury or prolonged irritation, such as, for example, a broken down tooth, supplemented in many instances by excessive smokings; or prolonged irritation of the stomach due to chronic acid dyspepsia; or again, to the chronic retention of hardened feces in the rectum.

Would it not help matters materially if we would also adopt measures, such as a reformed diet, and the closest attention to the sanitary condition of the colon, with a view to removing the toxic condition of the blood, which, I am convinced, is the potent factor in the pathogenesis of cancer? I would also direct attention to the fact—and I use this word advisedly—that adenomata of the mamma, and also chronic mastitis, in by far the largest majority of instances are due to the repeated monthly reflexes upon this gland, for which diseased ovaries—even though of a comparatively trivial nature—are responsible. For we know that, though these adenomata are benign in the early stages of their existence, when they are readily curable, yet later on they are liable to become malignant when autotoxemia is coexistent. Moreover they are not infrequently wrongly diagnosed as malignant, and remorselessly operated upon. I can recall numberless instances when I have had the great satisfaction of rescuing the innocent mamma from the cruel knife. Hence I am inclined to conclude that the highly favorable "Statistics of Operations for Mammary Cancer" published in the Nov. 5 issue of the MEDICAL RECORD by Professor Forgue of Montpellier are to a great extent due to mistaken diagnosis, which, of course, is quite excusable. And I trust Professor Forgue will not deem it unkind of me to express this candid opinion which represents one of the fruits gathered from fifteen years' experience as an operating surgeon; while my subsequent experience during the past twenty-seven years is what I have endeavored to express in the foregoing paragraphs.

I trust I may, in conclusion, be permitted to append some evidence of the benefit derived by treating victims of this inveterate scourge upon rational lines as opposed to those operative measures which hitherto have proved a colossal failure.

CASE I.—In December, 1907, I was asked by a banker if I would agree to take under my professional care the wife of one of the bank's officials, who had been dismissed from one of the largest London hospitals as incurable. Before agreeing to this proposal I wrote to the registrar of the hospital, so that I might become acquainted with the history of the case, and in reply obtained the following information:

"December 7, 1907.—A laparotomy was performed and the following diagnosis given: Operation. Large malignant mass occupying posterior wall of cardiac end of stomach. The mesentery contained calcified (old tuberculous?) glands. The patient recovered well from the operation and when discharged was able to take some food by the mouth. She had, however, lost 2½ lbs. in weight. Weight on discharge, 75½ lbs."

The actual loss of weight, however, was 32 lbs. I may add that on her discharge I learned she was given two months to live. With such a history it was with considerable hesitation that I undertook the case.

As there were present pronounced symptoms of hypothyroidism, I gave 5 grs. thyroid extract three times a day, a diet composed of the juices of uncooked vegetables, fruit, and milk switched up with white of egg. Careful attention was also given to the daily *complete* action of the colon.

Under this regimen the patient gradually lost the severe pain she had been enduring for weeks past. The diet agreed with, and nourished, her to the extent that she gradually put on weight, the growth simultaneously slowly disappearing, and within eight months she had regained the 32 lbs. she had lost during her illness, when there remained no evidence of even a trace of the disease in existence. The last news I had of her was that she was pregnant and that she was in excellent health.

CASE II.—The following case came to me from another of our great hospitals. It was that of one of the nurses who had been operated upon for the removal of a scirrhus of the right mamma, which semed to do well for eighteen months, when a hard mass appeared under the clavicle of that side. She thereupon returned to the hospital and saw the surgeon who had operated, when she was told that the new growth was carcinoma, and that nothing more could be done for her, and that she should go home and await the end. This was six years ago, and she is now perfectly well, having recovered her health by means of a reformed diet, careful attention to the daily complete evacuation of the colon, supplemented by one thyrogangloid palatinoid three times a day. (Each of these contains extract of thyroid, gr. ii, and extract of the solar plexus, gr. iii.)

CASE III.—The next case was that of a member of the London Fire Brigade, who had been in a most unsatisfactory state of health during the previous four years, when he had upon two different occasions been laid up with an attack of jaundice, and had off and on suffered from attacks of intense pain. He was admitted to another of our well known hospitals. A laparotomy was done, when it was ascertained he was suffering from cancer of the pancreas. He was discharged from the hospital when the wound had healed, and was given two months to live; at least I was told this was the prognosis. He was brought to me at the Battersea General Hospital on the following day, when he weighed 112 lbs., his normal weight having been 154 lbs. (both naked). Moreover, he was in great pain. He was put upon an uncooked fruit, vegetable, and milk diet; while his colon was thoroughly emptied every day by means of an enema of water at bloodheat. At the expiry of the two months he had been given to live he was free from pain and had begun to put on flesh. He came under my care early in April, 1918, and on the following 1st of October he had regained all but 5 lbs. of his normal weight, and was enabled to resume his duties in the fire brigade. Since that date I have

seen him more than once, and know that he had regained his normal weight and is in daily work at his brigade.

CASE IV.—One more example from another of our well known hospitals, this being that of a workman in Woolwich Arsenal who had been admitted after a long period of ill health said to be due to dyspepsia; so much so that for a number of years he was hardly able to do two consecutive days of work. He had lost 28 lbs. in weight and was quite worn out by his suffering. He was, therefore, admitted into the above hospital and subjected to a laparotomy, when it was discovered that the disease was cancer of the stomach. After this the wound was closed, the case being considered hopeless, and he was discharged from the hospital as incurable. He then came under my care and was treated on lines similar to those above mentioned as to diet and regimen with the addition of bise dia 5i and elixir of takadiastase 5i during meals three times a day. Within a year he was quite recovered and able to resume his work at the arsenal, where he is still employed.

I have selected the above cases purposesly, as there can be no possible doubt regarding the diagnosis, and I may add there is no doubt as to the results obtained.

15 HALF MOON STREET.

CORYZA IN INFANCY AND CHILDHOOD.

BY JOSEPH H. MARCUS, M.D.,

ATLANTIC CITY, N. J.

PEDIATRIST TO THE BAMBERGER HOME; PEDIATRIST TO THE JEWISH SEASIDE HOME; AND TO THE ATLANTIC CITY HOSPITAL.

THE infant is born with healthy mucous membranes, and the foreign, noxious principles entering the body by means of the inspired air require a certain length of time in order to render the tissues susceptible to disease. Naturally the periphery of the mucous membrane, the nose, is the first tissue to become involved, since it is primarily exposed, and so making the occurrence of coryza particularly common in infancy and childhood. The bronchi and lungs remain uninvolved, and are capable of resistance for a longer period, because they are more distantly situated. Acute coryza, acute rhinitis, or "cold in the head" is a catarrhal inflammation of the mucous membrane of the nose, which may extend to the tonsils, pharynx, larynx, trachea, and bronchi, and also may involve the accessory sinuses and the middle ear.

Etiology.—Although popularly supposed to be the result of exposure to cold or wet, the prevalent view is that the vast majority of common colds are caused by infection with microorganisms, and that it is, indeed, an infectious fever. There are many factors that act as predisposing causes towards the occurrence of an attack of coryza such as an hereditary predisposition, seen in children who are particularly subject to repeated colds, and in whom the tendency to take cold cannot be explained on any other basis. In this class there are no faulty hygienic surroundings, undue exposure to cold, contagion, or irritants of any type. An acquired predisposition to a cold is very often met with in children who are subjected to certain errors in hygienic management. Children of this type do not get enough fresh air, and are kept indoors much of the time. They live in overheated rooms and sleep in rooms with closed windows. Many fear "draughts" and cannot tolerate open windows, but are content to live in a stuffy and polluted atmosphere. An abundant supply of fresh air (and sunlight when procurable) is a very valuable disinfectant. As St. Clair Thomson has remarked, the removal of this "air sewage," which gives a close, stuffy odor to a room, by means of efficient ventilation, is well-nigh as important as the removal of other sewage by good sanitary arrangements. These faults in hygiene cause the nasal mucous membrane to become more susceptible to the infectious organisms. The healthy nasal mucous membrane rapidly destroys or renders inert the majority of the invading germs, and harbors only a small portion of them in the anterior portion. Children suffering from chronic rhinitis, adenoid growths, or subacute or chronic tonsillitis are particularly liable to colds. Mechanical, chemical, or thermal irritations often furnish the cause. As examples may be mentioned trauma, the breathing of formaldehyde gas or iodine fumes, and dry and overheated air. Frequent changes of temperature, exposure to cold winds, sitting in a draught, exposure to dampness, falling in water, or otherwise becoming chilled, insufficient bedclothing at night, all act injuriously.

Accumulating evidence has firmly established the contagiousness of most colds, and the clinical course pursued by typical common colds is of such a character that there can be little doubt that they represent bacterial infection. We have further evidence from the fact that the coryza is a prominent symptom of several specific infections, such as influenza and measles. The normal mucous membrane is resistant to actual infection, and some condition that tends to lower the resistance is required for infection to occur. A great variety of organisms have been demonstrated in the nasal mucous membrane among which one can number the staphylococcus, streptococcus, *Micrococcus catarrhalis*, influenza bacillus, all of which have been found in the nasal secretions of the ordinary cold.

Symptoms and Course.—Redness and swelling of the nasal mucous membrane with a sense of fullness, and dryness in the nostrils accompanied by a difficulty in breathing, are the usual primary symptoms of the simple catarrhal rhinitis. In the course of a few hours there is a copious discharge, which at first is thin and watery, but later becomes mucopurulent, and in the severe cases seen in infants there may be a profuse purulent discharge. There is usually a slight rise in temperature; in infants the temperature may be high, while in older children there may be little or no febrile disturbance. Although the general symptoms are often slight, there is ordinarily a very evident sense of discomfort, with loss of appetite and general malaise, of a mild nature. In some cases the infants or young children are restless and irritable, do not take the usual periods of rest and sleep, failure of appetite is present, as well as a slight, annoying cough. In the more severe types there may be involvement of the lacrymal ducts, with slight or marked redness of the conjunctiva, lacrymation, and photophobia. In very young infants, coryza may become exceedingly menacing, with the temperature reaching a height of 104° to 105° F., accompanied by marked disturbances in nutrition. In consequence of the very narrow nasal passages, the nasal breathing may be greatly interfered with, and a complete stop-

page in the newborn may lead to a dangerous asphyxia. The nasal obstruction in nursing infants produces embarrassment in the act of feeding, which process is interrupted frequently. This difficult nasal breathing constitutes such an impediment to nursing that every few minutes the tortured infant releases the nipple in order to again laboriously draw some air into its lungs by way of the mouth. The sleep of the infant is also disturbed by laborious breathing which causes great fatigue, and often suffocative attacks. In severe cases there may be loss of taste and smell.

In late infancy, as well as those of older years, coryza is attended with manifold dangers. The pharynx and the tonsils quite regularly participate in the inflammation, which may cause pain on swallowing, and from here the process is apt to extend to the Eustachian tube and the tympanum, causing deafness or earache. Extension through the lacrymal ducts may give rise to a conjunctivitis. Otitis media is an exceedingly frequent complication, and should be constantly watched for, by repeated examinations with the otoscope. The anatomical structure of the Eustachian tube at this period of life makes the occurrence of otitis media more liable. The catarrhal inflammation is apt to extend, and often leads to croup, bronchitis, and bronchopneumonia. Other complications are cervical adenitis and retropharyngeal or peritonsillar abscess.

Diagnosis.—The diagnosis is usually readily made. It is sometimes difficult at first to decide whether the appearance of a rhinitis is primary or whether it is the prodromal symptom of measles or influenza. In measles and influenza the constitutional symptoms are more severe in proportion to the nasal manifestations than they are in the common cold. In cases where the discharge is unilateral, purulent, and bloody, a foreign body is usually present. A very purulent discharge in the newborn may be of a gonorrheal nature. Of great importance is the differentiation of a simple rhinitis from nasal diphtheria, on the timely recognition of which the life of the patient may depend. In nasal diphtheria there is often a profuse discharge which is frequently blood-tinged; it usually begins as a violent coryza, and even after careful examination with a speculum often no formation of membrane can be distinguished, which is usually present in the posterior part of the nares. One must bear in mind that primary nasal diphtheria is comparatively frequent in young children, and whenever a blood-tinged discharge is present, or whenever the nasal discharge is of more than a week's duration, the possibility of diphtheria should be suspected. Every case of rhinitis accompanied by an increase in temperature, excessive purulent discharge, and markedly disturbed general health is suggestive of diphtheria and requires a bacterial examination. Lues is also suggested by the persistence of the nasal discharge, and its presence can be confirmed by other manifestations of syphilis.

Prognosis.—In healthy children the prognosis of these infectious colds is usually good, as regards a rapid termination in an uncomplicated recovery. Older infants may perish from an otitis media and bronchitis, especially those suffering from malnutrition and disturbed digestion. Dunn has mentioned the death of puny, ill-nourished infants, as a result of a simple, acute rhinitis with occlusion of the nares. Any coryza in an infant should not be regarded lightly if the symptoms persist after the fourth or fifth day, and other organs such as the ears or bronchi become involved.

Treatment.—In the treatment of acute coryza a valuable procedure is a day in bed at the very outset. The rest thus secured combined with such household remedies as hot gruels, mild purge, and mustard foot-baths will often check the progress of the disease. Young children with acute rhinitis should be kept indoors, in a well-ventilated room, at an even temperature of approximately 68° F. The mild forms of nasal catarrh in infancy and childhood are self-limited as to the duration, and simple cleanliness with nursing will in most cases answer in the treatment of the disease. It is well to reduce the quantity of food, especially in infants. There are times, however, when feeble infants will not take enough milk, owing to the nasal obstruction. In such cases, milk should be given with a spoon. When there is so much nasal interference that respiration or sucking is interfered with, a few drops of adrenalin solution, 1 to 1000, diluted with saline solution, should be instilled into the nostrils with a medicine dropper. An ointment of lanolin is the best protection against excoriation of the nasal orifices and upper lip from the discharge. Frequently the dried crusts or the discharge may be removed by means of a pledget of absorbent cotton, while the sneezing that may be thus produced often promotes the discharge of the secretion. The instillation of a few drops of lukewarm olive oil containing one-half to one per cent. of menthol is of benefit; this is best given with a pipette, and with the infant or child lying on its back, with the head extended. Sprays and douches are not applicable to infants and young children, on account of the resistance made by these patients, and the danger of carrying the infection into the Eustachian tube. Where it is possible in older children, a mild antiseptic solution, such as Dobell's solution, is all that is called for. A useful remedy is the inhalation of mentholized steam. A few crystals of menthol are dropped into a jugful of hot water, and the patient then breathes in the medicated steam through the nose. In infants a solution of resorcin in olive oil (5 grains to the ounce) may be dropped into the nostrils, after removing the discharge and cleansing the nasal passages by carefully mopping with cotton or gauze. Quinine is useful in infectious colds, from one-half to two grains being given three times a day, the dose being regulated according to the age of the child. A useful drug in lessening the nasal secretion is the tincture of belladonna, which is somewhat more advantageously administered when combined with camphor and sugar of milk in the form of tabellæ. If the throat is drawn into the picture, a small dose of the tincture of iron chloride, two or three minims, combined with glycerin may be given every three hours. If the ear drum shows a redness with bulging, we may temporize, and if there is reason to believe that pain is present, a drop or two of warm oil of hyoscyamus instilled into the ear twice a day will often give relief; or we may use as ear drops carbolic acid 10 grains, in two drams of glycerin. If an increase in temperature

is not present, the open air is not contraindicated. During the acute stage, precaution must be exercised regarding the bath, and in cases where the nursing is unreliable the bath had better be omitted. Recent observers have reported good results from the use of hexamethylenamine in common colds.

Prophylaxis.—The most important measure in prophylaxis against acute rhinitis is the prevention of contagion, and those preventive measures are of even greater importance in children than in adults. Children are more susceptible to colds than their elders, and are apt to suffer severely; while a simple cold, of little moment in adult life, is often quite a serious illness in an infant. Because of this fact, no one who is suffering from a "cold in the head" should be allowed anywhere near a nursery. Prevention of colds is better and easier than cure. Fresh air is of prime importance, but other rules of daily hygiene, such as baths, exercise, and suitable clothing, should certainly receive due attention. The faulty hygienic surroundings spoken of under the heading of Etiology, should be corrected. Children should be encouraged to go outdoors daily, unless the weather is especially bad; they should live in rooms with an approximate temperature of 68° F., and should sleep in well-ventilated rooms. The coddling and pampering of delicate children is somewhat difficult to overcome. These children should be sponged with cold water, especially about the chest, back, and neck, immediately upon rising. Chest protectors should be used, and the underclothing should be woolen both in winter and summer; the very lightest weight should be used in the summer and medium weight in the winter. A child who suffers from adenoids is peculiarly liable to catch cold, and the improvement in this respect which follows the removal of the adenoids is often remarkable.

2801 Pacific Avenue.

SOME SURGICAL EXPERIENCES BEFORE THE DEVELOPMENT OF THE HOSPITAL.

By T. M. McINTOSH, M.D.,

THOMASVILLE, GA.

In May, 1874, after my first course of lectures, I made my first surgical operation, this being a cataract operation on "Aunt Mariah," a former slave and family servant. For practice I had operated on killed dogs and cats. Dr. B. W. Daniel, my preceptor, an accomplished and educated physician, whose plantation adjoined my father's, gave interested and approving assistance. We rode horseback eight miles into Jefferson County, Florida, where "Aunt Mariah" lived. My father, with parental fondness, accompanied us. The operation was done on the piazza of the log cabin, with all the details of careful cleanliness then in use. The knife was a Beer's triangular. The eye ball, after placing the lidholder, was steadied by pressure of my forefinger on the nasal side. (This suggestions I had read as being less painful than the fixation forceps.) The incision was in the corneoscleral junction and, when complete, the pressure of the steadying finger on the eyeball brought out the lens in the capsule. There was no iridectomy. Daily visits were made for a week. The result was perfect.

This was the first cataract operation by extraction performed in this section, as those with cataract went to Atlanta, Savannah, or Baltimore to be operated upon. Dr. Brandon, of Thomasville, had done two operations, and Dr. Palmer, of Monticello, Fla., had performed one by dislocating the lens with a needle—"Couching." In all these there was loss of light perception from inflammation. Since that time I have done one hundred and fifty cataract operations. Fourteen cases were reported in the *Atlanta Medical and Surgical Journal*, 1880; one hundred and three in the *Atlanta Journal Record of Medicine;* the others have not been reported.

In November, 1881, Mr. W. of Baker County, with granular lids, which produced "pannus" and blindness in one eye, did not improve under the usual treatment. With a sharp curette the granulations were thoroughly scraped. The "pannus" rapidly disappeared and vision returned. Up to that time trachoma granulations had not been removed surgically as far as I know, though some years later they were treated by crushing with a special forceps.

In 1883, I trephined the mastoid for abscess of the middle ear, Mr. J. H., Metcalfe, Ga., being the patient. This, as far as I know, was the first operation of its kind in this section. Neither Dr. Brandon nor Dr. Bruce, of Thomasville, had attempted it. Dr. Bruce, however, had made many trephinings for skull fractures.

In December, 1883, the entire right superior maxilla with part of the anterior part of the left, was removed from Alice M., aged eleven, for fibrocystic tumor. During the operation the right carotid was compressed by the fingers of an assistant. The case was reported in *Atlanta Medical and Surgical Journal* and was illustrated with photographs taken before and after operation.

In 1909, Mr. N. S., Florida, brought his three months old child with complete cleft palate; the cleft being one fourth of an inch wide its entire length. With a long and strong bone forceps, both superior maxillæ were broken, and the cleft borders brought into contact throughout their entire length. The hare lip was operated upon at the same time. The result was satisfactory both as to lip closure and palate closure. Of hereditary interest, is the fact that when the father of the child was a small boy I operated upon him for hare lip.

My first herniotomy, for strangulation, was performed in 1878. Dr. E. R. Young of Metcalfe gave the anesthetic. A negro woman held the torch (not lamp) in the hut; it was night. Pans and towels I carried with me; water was boiled in kettles. The constriction was cut, and the bowels replaced. The sac was left *in situ.* Through and through interrupted sutures of silk closed the wound. A twisted piece of gauze was inserted the length of the incision under the skin closure to get healing by granulation from below. This was the procedure employed at that time, supposedly to give a firm scar to prevent hernial recurrence. In this case recovery was smooth. There was no recurrence and patient lived many years.

In early part of November, 1882, I saw Dr. S. who had had abdominal pain, swelling, and fever, for four weeks before I saw him. Fluctuation was evident in the lower abdomen, which I thought was

due to the presence of pus, and suggested opening the abdomen. There was objection on the part of attending physicians, they believing the fluctuation was due to ascitic fluid—a compromise was aspiration. A large amount of pus was withdrawn, which was followed by subsidence of the fever for a few days. Fever recurring soon, the abdomen was opened by incision; quantities of pus came away; after a few days a fecal fistula developed. The patient lived until December 14, finally dying from exhaustion. "The propriety of surgical intervention in acute suppurative appendicitis was first established by Willard Parker, of New York, in 1867." (American Text Book of Surgery, published in 1895.) Reginald H. Fitz (*American Journal of the Medical Sciences*, October, 1886) published an article entitled "Perforative Inflammation of the Vermiform Appendix with Special Reference to Early Diagnosis and Treatment." Therefore, it was but natural that my suggestion, in 1883, to open the abdomen for abscess was not at once accepted.

Mrs. J. W. B. of Mitchell Co., Ga., was delivered of her first child December, 1892. In April 1893, she came with complete inversion of the uterus. Failing to reduce by pressure upward through the vagina, the abdomen was opened, the intestine packed off, and, with combined pressure from below and dilatation and traction from above, replacement was accomplished. The operation was reported in the MEDICAL RECORD, New York, August, 1893. Reuben Peterson, Detroit (Reprint from *American Gynecology*, June, 1903, "The Conservative Operative Treatment of Chronic Inversion of the Uterus"), says: "Of fifteen cases treated by abdominal route, eight were successful; namely, those of Consertino (two), Courtney, D'Antona, Everki, Houlton, McIntosh, Thomas."

In 1884, Lucian H. of Decatur County came after a year of suffering with frequent urination and severe vesical tenesmus. He never had had any venereal disease. The small meatus urinarius was slit wide enough to admit a No. 30 French sound into the bladder. Irrigations and diuretics were of no value. The suffering was severe. Marion Sims had made a vesicovaginal fistula in the female for obstinate cystitis, the drainage giving rest to the bladder. Therefore, I drained the (male) bladder by perineal section and drainage by rubber catheter. The finger exploring the bladder gave no idea as to the cause of the cystitis. The bladder was drained for some weeks with marked relief. After the incision closed, there was much improvement, but not complete cure. At the present time, with electrical illumination of interior of bladder and other methods of diagnosis and treatment, the method of handling this case might have been somewhat different.

The writer has performed eighteen operations for stone in the bladder in patients whose ages ranged from 3 to 72 years, all lateral lithotomy, except one in a man aged 65, where it was necessary to make a superpubic opening, because the stone was imbedded behind an enlarged prostate and could not be dislodged by the finger in the bladder through the perineal incision, which was made first. This patient died on the third day after operation from urinary suppression, having had nephritis at time of operation. Another patient, aged 72, developed lobar pneumonia one week after operation, having apparently recovered from operation, and lived four days after the pneumonia developed. One patient was operated on twice, when 12 and again when 14 years old.

Dr. Brandon of Thomasville had operated by the lateral method five times for stone in bladder, twice on one patient, an elderly man. In 1879 I assisted Dr. A. P. Taylor of Thomasville in a Battey's operation, which I think was the first successful ovariotomy in this county. I began my work in Thomasville in January, 1878. Drs. Brandon Bruce, J. R. Reid, and T. S. Hopkins were the elderly and leading men. Dr. Taylor, some years my senior, was then successfully established. In this section were Jelks of Quitman, Burton and Lang of Valdosta, Bruce and Butts of Bainbridge, Hillsman, Alfriend, and Strother of Albany, Palmer of Monticello, Fla., Betton of Tallahassee, Fla., and Le Hentz of Quincy, Fla.

In 1899, the surgical practice from surrounding territory warranted my building a private hospital. Its capacity was fifteen patients. Up to the completion of this hospital, all my operations were done at the residences of the patients, widely scattered, of course, or in boarding houses in Thomasville. A year or two before, the ladies of Thomasville had established a few rooms as a "Charity Hospital." This "Charity Hospital" at the present time is the "City Hospital"; and through large private donations and endowments, and county and municipal monthly appropriations, it has become a splendid institution, with a plant and equipment costing $150,000 or more. The writer's hospital was the first privately and individually owned and operated institution in this section, or in South George or Florida. Within a few years, however, private and public hospitals have been established by individuals and groups of physicians in towns in all parts of South Georgia and Florida; and in them is done much excellent surgical work.

Looking back over my work done in homes and boarding houses, I think the results were as good as since the establishment of hospitals, but since the hospitals are here, we wonder how we did without them.

In these notes, largely relative to personal work, mention is made of cases that were of special interest to me, and in which procedures a little out of established rule were adopted, but from them you may get some idea of the "Development of Surgery in South Georgia."

PURPURA, WITH REPORT OF A CASE.*

By J. HERBERT DAREY, M.A., M.D.,
SIOUX CITY, IOWA.

UNDER the general term idiopathic purpura are grouped three main classes of cases which are in reality not sharply defined from one another. These cases occur particularly in children and young adults, and nearly always show essentially normal numbers of blood platelets. Idiopathic simple purpura is purpura which may be accompanied by other skin lesions, but without other significant symptoms. Arthritic purpura is simply purpura

*Read before the Sioux Valley Medical Association at Sioux Falls, S. D., July 20-21, 1921.

with arthritic manifestations; other skin lesions are often present. The third class comprises those cases particularly described by Osler in which purpura and the other various cutaneous lesions of the erythema group occur, combined with visceral disturbances and often arthritis. When purpura is combined with colic, it is usually spoken of as Henoch's purpura. These three forms of purpura are closely related, and may possibly be various forms of one disease. It is not known exactly how the purpuric lesions and the associated skin lesions are produced in idiopathic purpura. It seems probable, however, that some change occurs in the small bloodvessels, increasing their permeability to the constituents of the blood. This change in the bloodvessels may occur in many parts of the body, but each lesion is to be considered as a focal one. It has been suggested, and seems rather logical, that an anaphylactic reaction is responsible for the symptoms of idiopathic purpura. Johannessen believes that idiopathic purpura is always associated with some infection, and that the symptoms are of an anaphylactoid nature. Positive evidence, however, is lacking. It is probable that the cause of idiopathic purpura is not the same in all cases. For example, an infectious process sometimes appears to be present, even though no organism can be found. In some cases absence of fever seems to be a striking feature, and in these cases it would seem to be necessary to account for the anaphylactoid symptoms in some other way, as by profound alteration of the protein metabolism. In one case Esdall found a markedly increased excretion of nitrogen, particularly at the time of a visceral crisis. The blood platelets are much more numerous than in purpura hemorrhagica. Usually the platelets are normal in number, and they are often increased when anemia ensues. The other morphological elements of the blood show no great deviation from the normal. The red cells in simpler cases are unaffected. Occasionally they may be reduced, and give a picture of a simple chronic or post-hemorrhagic anemia. The white cells in the milder cases are not increased; in cases of arthritic purpura they are sometimes slightly increased and rarely reach 15,000. In the severer cases, with abdominal symptoms, the count is usually between 9000 and 14,000; but cases with higher counts even 35,000 are not so rare. The increase of the white count is due particularly to an increase of the polyneuclear neutrophiles. The blood in cases of idiophathic purpura sometimes has a slightly prolonged coagulation time. Delayed coagulation, however, is not the rule.

The skin lesions in idiopathic purpura do not necessarily differ from those in purpura hemorrhagica, or in simple symptomatic purpura. Petechiæ are rather less common than in purpura hemorrhagica. Purpura of mucous membranes of the mouth is common in purpura hemorrhagica, and may indeed be the only hemorrhagic lesion present; purpura of the mucous membranes seldom occurs in idiopathic purpura, and then only when purpura is present elsewhere. A further difference in the skin lesions of the two conditions is that in the idiophatic form the purpuric lesions are not infrequently elevated, due to an associated urticaria or edema. This very rarely occurs with purpura hemorrhagica. Urticaria is seen particularly in the severer and more chronic forms of idiopathic purpura. Urticaria and purpura may occur, as Pratt has noted in four forms: (1) Simple slight elevations of purpuric spots (2) hemorrhage into definite urticarial wheals (3) a simultaneous outbreak of urticaria and purpura (4) purpuric attacks occurring before or after the appearance of urticaria. The edema which occurs in these cases is of the angioneurotic type. It is usually transitory, and often localized in the hands and face. Erythema of various types is also associated with idiopathic purpura. It is rare in purpura hemorrhagica.

Idiopathic simple purpura is the mildest form of the disease. It is to be diagnosed only when other diseases and toxic conditions are ruled out, and when the blood shows some of the abnormalities associated with pathologic hemorrhage. Hemorrhage into the skin is the only evidence of the condition. The purpura usually manifests itself quite suddenly, and in most cases is limited to the lower extremities, though it may occur on the forearms as well. Lesions may occur on other parts of the body. One group of lesions is commonly followed by another. The condition usually lasts about six weeks, though it may be of a shorter duration. Much more rarely it persists for a year or more. Chronic cases occur, which have recurring crops of purpura. In the mild form of idiopathic purpura, there is rarely any symptomatic disturbance though mild malaise and slight fever occasionally occur.

Arthritic purpura (purpura rheumatica) is characterized by multiple arthritis with purpuric eruptions, which are commonly associated with urticaria, erythema, and edema. Pratt and Lavergne have summarized our knowledge of this condition. This disease usually lasts about as long as simple idiopathic purpura. Fever is common at the outset. It is seldom as high as 102° or 103° F. Sore throat is also frequent with the onset of the disease. The joint symptoms are more prominent than the purpuric lesions, and it is on their account that the patient usually seeks relief. The joint symptoms consist of pain, swelling and tenderness. Several joints are usually affected, especially the knees and ankles. There is often also a general soreness in the muscles, and even a definite polyneuritis has been described. The joint symptoms usually occur before the purpura, but may develop after it appears. Arthritic purpura resembles ordinary rheumatic fever, plus the purpura. In arthritic purpura, however, the joint symptoms are usually mild, the fever slight, and endocarditis, so common in rheumatism, rarely occurs. The purpuric eruption recurs several times, typically associated with urticaria and erythema. The purpura usually appears first on the legs, as in simple purpura. Osler has emphasized the fact that cases with the erythema group of skin lesions may have visceral manifestations, particularly abdominal and renal, apparently dependent upon changes analogous to those seen in the skin. The visceral manifestations may not occur, however, in close relationship to the skin lesions. In fact they may be observed years before any skin lesion becomes apparent. Henoch in 1868 first called attention to the fact there were

cases with severe abdominal pain associated with purpura. This form is known as Henoch's purpura. In Pratt's series of Henoch's purpura, urticaria occurred in 30 per cent., erythema in 15 per cent., and edema in about 35 per cent. of the cases. The severe abdominal symptoms usually last only a few days. The illness, as a whole, usually lasts about a month. The onset resembles that of arthritic purpura, but abdominal symptoms soon appear, and dominate the picture. The abdominal symptoms, due to varying degrees of dilatation, exudation, and diapedesis into portions of the gastro-intestinal wall, consist of severe pain, of a colicky nature, which persists for several days. The pain is often general, but frequently localized about the appendix or umbilicus. The intestines become locally distended, so that a condition similar to appendicitis is produced. The walls of the intestines become edematous, or markedly infiltrated with serous, or sero-hemorrhagic fluid, being often of the size and consistency of a rubber garden hose. Such a process produces tenderness, spasm, and colic. It may produce obstruction, or intussusception. Spontaneous recovery, however, is the rule. Constipation may occur, though diarrhea preceded by constipation is more common. Blood in the stools occurs in about 50 per cent of the cases. Nausea and vomiting are common. Manifestations of idiopathic purpura, or of the erythema group often occur long before the abdominal pains. They may occur also months or years afterward. There may also be other visceral disturbances, as those of the kidney. Signs of acute nephritis are often present. A mild hematuria may persist for some time after the skin lesions have disappeared. Osler and Christian have pointed out the seriousness of the kidney lesions, though the latter remarks that these are seldom followed by chronic nephritis, and hence cannot be counted as true lesions of the kidney. Uremic symptoms may develop. Cases of idiopathic purpura may become exceedingly chronic.

Before the diagnosis of idiopathic simple purpura is made, idiopathic or symptomatic purpura hemorrhagica must be excluded. Serum disease which may closely resemble arthritic purpura, is easily diagnosed by the history of previous serum administration. Cases of idiopathic purpura and allied exudative erythema presenting abdominal crises are to be distinguished from various acute surgical conditions of the abdomen. When purpura, urticaria or edema are present, there is no difficulty in the diagnosis; it is only when these are absent that there may be some trouble in making a differential diagnosis. In children with colic and fever, purpura should always be thought of, and the skin carefully inspected for traces of purpura. Fever, leucocytosis, local tenderness and spasm may make the case closely resemble appendicitis, intussusception, etc.

The prognosis for life in idiopathic purpura is invariably good. In cases with visceral crises the prognosis is not so good. Death in 5 per cent may occur from kidney disturbance, and more rarely from abdominal or brain lesions.

There is no particular treatment for idiopathic purpura. The treatment should be entirely symptomatic. Rest in bed is desirable for all but the mildest cases.

The case I have to report is that of G. T., aged 16, female, a high school student.

On September 23, 1920, I was called to see the patient, whom I found covered with purpuric blotches on body, arms, and legs. Fingers were swollen and stiff. The ring finger of right hand was so swollen that a ring dented the flesh, and could not be removed. There was edema over the insteps of both feet. Soles of the feet and toes were swollen. Pains in the muscles and tonsils. Patient comes from healthy parents; gives a history of ordinary children's diseases, scarlet fever, and light attacks of rheumatism. The purpuric blotches would appear suddenly, last a few days, and disappear. They appeared in successive crops.

October 10, 1920.—Patient no better; very bad last night. Mucosa of mouth and gums swollen. Urine examined; acid, sp. gr. 1016. No albumin or sugar; a few hyaline tube casts.

October 11.—Blood examined. Decrease of red cells; increase of white cells. Referred to Dr. B. Meade Bolton, pathologist of the Samaritan Hospital, for blood count. He reported: Hemoglobin, 60 per cent.; red cells, 3,576,000; white cells, 10,000; small lymphocytes, 12 per cent.; large lymphocytes, 3 per cent.; large mononuclears, 17 per cent.; transitional, 1 per cent.; polynuclear neutrophiles, 66 per cent.; eosinophiles, 1 per cent.

November 19.—Dr. Bolton made another blood count, reporting as follows: Hemoglobin, 70 per cent.; red cells, 4,272,000; white cells, 6,600; small lymphocytes, 18 per cent.; large lymphocytes, 6 per cent.; polynuclear neutrophiles, 67 per cent.; eosinophiles, 1 per cent. Patient is greatly improved; practically well; going to school right along. I put the patient on a rheumatic mixture to relieve the pains in muscles and joints. Also liquor arsenicalis ♏v, increasing to ♏x t.i.d. On October 12 I put her on extract of red bone marrow three times a day, to increase the number of red cells. It acted very efficiently, as Dr. Bolton's second report shows. I also prescribed aromatic sulphuric acid, ♏x t.i.d., to diminish the minute capillary hemorrhages that produce the blotches, and extract of hydrastis canadensis, ♏x t.i.d., to correct the lowered tone of the mucous membranes. The patient made a complete recovery.

1249 Morningside Avenue.

AN ATYPICAL EXANTHEM.

By DAVID GREENBERG, M.D.,

NEW YORK.

ADJUNCT ATTENDING PHYSICIAN AND ASSISTANT IN PATHOLOGY, LEBANON HOSPITAL.

In the early part of 1920 there have come under my observation several cases of fever in children associated with a maculopapular rash which could not clinically be classified as belonging to any of the well-known acute exanthemeta. It is my object to describe these cases so that others who may have had similar cases may be stimulated to record their experiences, in order that it may be determined whether we are dealing with an atypical form of one of the known acute exanthemata or perhaps with something new.

Case I.—D. G., female, age fourteen months, with a negative family and previous history, became sick May 2, 1920, with fever and restlessness. She vomited once during the first day of illness, but did not vomit again. The bowels were regular, of normal color and consistency, except once after a dose of castor oil. The physical examination was entirely negative but for a slight congestion of throat and soft palate. The temperature at the onset was 102.5°, and fluctuated between 102.5° and 101° for the ensuing three days. On the morning of the fourth day the temperature was 100° and did not rise that day. About this time there was noticed a faint macular rash over the abdomen and buttocks. These macules were about 0.5 cm. to 1

cm. in diameter, discrete, and became slightly papular and more numerous during the following two days, appearing on the thighs, chest, shoulders and a few on the neck. The rash began to disappear on the third day, so that within four days after its first appearance it had almost entirely disappeared. The maculopapular rash was pinkish to red in color and the lesions fairly regular in size and shape, being more or less round or oval. The size of the individual lesion did not vary much except that it became reddish instead of pinkish, and slightly papular instead of macular, as at the onset. The mucous membranes were negative except for slight throat congestion on the first two days. There was no desquamation, no itching, no gland enlargement.

The other two cases occurred in children somewhat older, one in a child, R. S., twenty-six months of age, also with an acute onset and fever for three days followed by a rash lasting about three days. There were no distinctive physical signs anywhere, nor were there any disturbing symptoms or prostration. The third case, B. W., age two years, behaved in a similar manner. There was no noticeable prostration with these attacks and no complications. The urine was negative in the three cases and the blood was normal in two cases and not examined in one.

The ordinary acute exanthemata were considered but could not be diagnosed, at least clinically. Measles was eliminated because of the temperature curve in relation to the appearance of the rash, the absence of catarrhal symptoms and bronchitis and the absence of Koplik spots and desquamation. Scarlet fever was considered, but the late appearance of the rash, together with the fact that there was no throat involvement, no desquamation, no albuminuria, no noteworthy adenitis, speaks against this disease. Against German measles there is the marked febrile reaction for three days prior to the appearance of rash, the character of the rash and the absence of glandular enlargement. The possibility of a drug or food rash was considered also, but no drugs were given, at least in the first two cases. The absence of gastrointestinal symptoms, the uniformity of the rash and its appearance after subsidence of fever speaks against a food rash.

Two more cases, one in a female child, age nineteen months, and one in a male child, age twenty-three months, were seen in the early summer of 1921. No drugs were given in either of these cases and the blood was normal in both of them.

Since the preparation of this case report three articles appeared in the recent literature which describe a very similar if not identical symptom complex. Westcott describes a larger series of cases and calls them "Pseudo Rubella." (Thos. Westcott, "Pseudo Rubella," *American Journal Medical Sciences*, Vol. 162, No. 3, p. 367, September, 1921.) Levy (Levy, David J., "An Eruptive Fever of Unusual Characteristics in Infancy and Early Childhood," *Journal American Medical Association*, Vol. 77, No. 23, p. 1785, Dec. 3, 1921), in his report comprising about thirty cases, is inclined to consider it as atypical rubella rather than a new exanthem. Veeder and Hempelman (Veeder, B. S., and Hempelman, T. C., "A Febrile Exanthem Occurring in Childhood," *Journal American Medical Association*, Vol. 77, No. 23, p. 1787, Dec. 3, 1921) are inclined to consider this symptom complex as a definite entity. They include among their case reports a boy age ten, and they quote Zahorsky (Zahorsky, John, "Roseola Infantum," *Journal American Medical Association*, Vol. 61, p. 1446, Oct. 18,1913), who describes a very similar picture in 1910 and again in 1913 under the name of "Roseola Infantum."

It is evidently too early and the reports are too meager to enable one to decide whether or not these cases belong to a separate disease or are some atypical form of the well-known exanthemata. My own observations date back to the early part of 1920 and the limited number of cases observed made me hesitate to report them. However, with a view of at least contributing to the knowledge as to the prevalence of the disease in a geographical sense—none of these cases having been previously reported from New York—I am prompted to withhold publication no longer.

1220 Grand Concourse.

Medicolegal Notes.

Erroneous Instruction as to Physician's Duty to State Condition of Patient.—In an action by a physician for services rendered a decedent where the defense was negligence, the trial court refused to give an instruction requested by the plaintiff administrators that "it is the duty of a physician to disclose to the relatives of a patient who employ him to treat the case, when called upon by such relatives to state to them the true condition of the patient, to give them full, accurate and complete information as to the condition of the patient. If he should fail in this duty, and should inform such relatives that the patient was not in a dangerous or serious condition, when in fact and in truth such patient was in a dangerous and serious condition, the physician would be guilty of such carelessness and negligence as to preclude him from receiving any pay for his services in case of the death of the patient." The Oregon Supreme Court holds the instruction was properly refused, since it would have required the jury to return a verdict for the administrators if they found merely that the doctor believed the patient was dangerously sick, and, so believing, told the relatives he was not dangerously sick, even though they might also have found that the doctor exercised the very highest degree of care and skill in his treatment.—Kelty v. Fisher (Or.) 199 Pac. 188.

Right of Trial Court to Order Second Physical Examination of Plaintiff in Personal Injury Case.—The Indiana courts hold that a motion to require a plaintiff in a personal injury case to submit to a physical examination is addressed to the sound discretion of the trial court, and that the exercise of such discretion is reviewable on appeal, and correctable in case of abuse. They also hold that courts have authority to order more than one examination of such a plaintiff. The purpose of such an examination is to enable the courts to obtain, as nearly as possible, the exact and full truth concerning the matters in controversy, in order that they may bestow upon litigants equal and exact justice. A physical examination serves to promote this purpose by placing the parties on a more equal footing before the court or jury trying the cause as to the nature and extent of the injuries alleged to have been received. As stated in South Bend v. Turner (1900), 156 Ind., 418, "If a defendant must make his defense against the expert opinions of the plaintiff's chosen surgeons, without an opportunity of testing the verity of the basis for such opinions, he may be placed at disastrous disadvantage such as the law cannot and does not sanction." Affirming these principles in a recent personal injury case, the Indiana Supreme Court adds: "It is apparent that under certain circumstances a single physical examination may not fully accomplish, and possibly could not fully accomplish, the purpose stated above. Where such circumstances exist, the reasons which lead courts to assume authority to order physical examinations in the first instance afford ample justification for a further exercise of authority in that regard."—City of Valparaiso v. Kinney (Ind.), 131 N. E., 237.

MEDICAL RECORD.

New York, March 18, 1922.

D'HERELLE'S PHENOMENON.

ONE of the most revolutionary discoveries of recent years in the domain of bacteriology is that of the so-called bacteriophages. Its significance, however, is much impaired through the fact that it is a more or less isolated form of behavior seen thus far only in a very restricted field. The first report on the subject goes back to 1917, when d'Herelle, of the Pasteur Institute, Paris, made a preliminary statement before the French Academy of Sciences. In June, 1921, nearly five years later, the discoverer summed up his experience with the phenomenon in question. His initial find was then stated as follows: the stools of an individual convalescing from dysentery were emulsified with bouillon and filtered through a Chamberland filter. A cloudy broth culture of Shiga's dysentery bacilli was added to this filtrate—10 drops of the latter—and kept in the incubator at 37° C. for 10 hours when the mixture was found quite clear with all of the bacilli dissolved. A drop of the clear culture was then introduced into a fresh culture of the bacilli and caused the solution of the latter as well. It was learned that this process could be kept up indefinitely. No progressive attenuation came about and after ten passages total lysis required but 3 or 4 hours. That which had happened was the destruction of the germs by a so-called bacteriophagic principle, unlike anything thus far known.

The work cut out by this discovery comprised variation of quantities used, tests with other bacteria, tests of other discharges from the bowels, modifications possible by physiochemical agencies. An attempt to bring the status of the experimentation up to date is found in an article in *Le Bulletin Médical* for January 14, 1922, xxxvi, 3, by Francon and Marquezy. This article is of considerable length and covers the accumulation of data with the interpretation and finally the practical application. Four theses are discussed as follows: the phenomenon is produced by the activities of a filtrable ultramicrobe; the latter belongs to the myxomycetes; the lysis is the result of a diastatic enzyme, and this lysis is autolytic and transmissible. These theses do not cooperate to build up a theory, but have been separately advanced and are in part antagonistic. D'Herelle styles the lytic organism *bacteriophagum intestinale* and to this organism he attributes many properties. It cannot be classed with any known microphyte or protozoon and d'Herelle makes no attempt to classify it. Salimbeni goes further and affirms the bacteriophage to belong to the myxomycetes and probably to the so-called thallophytes, the spores of which can traverse the porcelain filter. This organism secretes a diastase. Kabeshima goes still further and makes the entire phenomenon the work of an isolated diastatic enzyme not generated by microorganisms at all. This diastase acts as a catalyst. D'Herelle says of this view that the diastatic hypothesis may be correct but adds that the enzyme inheres in the lytic secretion of the bacteriophage. Finally the distinguished Bordet, who with Cinca has investigated the phenomenon, merely sums up the latter in the statement that the Shiga bacillus has a notable tendency to autolysis, so that the phenomenon, if the writer may be pardoned the simile, is not one of assault and murder, but of suicide. Naturally there is something in the environment which brings about the autolytic tendency. The entire process means at base a defence reaction, through which by steps as yet unknown the organism antagonizes the Shiga bacillus. This tendency to autolysis is handed down to the remote progeny of the Shiga organism like an old fashioned family curse. For a defense reaction there must be a definite mechanism and it is assumed that the body secretes some kind of militant product, but this is not necessarily a powerful lysin of diastatic nature nor a catalyst. Bordet merely assumes that the substance is furnished by the leucocytes, those natural defenders of the body against pathogenic bacteria.

It was stated not long ago that the phenomenon was peculiar to the Shiga bacillus, but it now appears that it has also been observed in typhoid and paratyphoid fevers, colipyelitis, and even in bubonic plague in man, besides promising well throughout animal pathology. Thus far the phenomenon is limited to diseases in which the intestine is primarily or secondarily involved in the morbid process, the stools being the natural vehicle of the bacteriophages. It is impossible in this place to discuss the probable influence of this discovery on such vast questions as diagnosis, bacteriotherapy, vaccinotherapy, and especially immunization to disease. The admixture of bacteriophages would soon vitiate germ cultures, and this may possibly explain extensive failure of results in certain strains of bacteria used for diagnostic reactions, immunization, and treatment.

THE HISTOLOGY AND EVOLUTION OF DEEP-SEATED ANGIOMATA OF THE NECK.

THE histological picture of deep-seated angiomata of the neck consists of alveolæ lined with pavement endothelium, but in the large lacunæ the endothelial cells may be wanting in spots or are completely absent. The blood filling these cavities contains fewer leucocytes than normally, a peculiarity encountered in angiomata in general.

The trabeculæ are composed of connective tissue mixed with some elastic fibers. The fixed cells are thin or flattened. Unstriated muscle fibers may be found around these cavities and would seem to indicate a venous origin of the process. When a capsule exists, it is formed by connective tissue, but this tissue varies in thickness and make-up according to the age of the process. In the younger strata numerous nucleated cells are seen, at times small and round, at others fusiform. In the older strata the cells are fewer and the intermediary substance is denser with more or less numerous elastic elements. Since the capsule does not exist in the younger angiomata and appears only at a rather advanced stage of the process, it is evidently a mere secondary production. But it must not be supposed that it forms an invariable limit, because in those regions where the capsule is young numerous capillary masses are found whose walls are made up of the stroma of the capsule lined with endothelium, while some of these vessels are undergoing ectasis. It is probable that these areas are the site of active vascular neoformation by which the neoplasm continues to grow. The angiomata therefore are never limited in the strict sense of the word for the reason that the capsule, far from arresting its extension, on the contrary serves it as a matrix for further development in certain areas. However, when it exists and its structure is more or less embryonal, it always forms a less vascular zone at the periphery of the angioma which, from the viewpoint of operation, offers the inappreciable advantage of serving as a plane of cleavage, allowing an easy removal of the growth without going through the vascular sponge forming the tumor itself.

The general tendency of all these tumors is to grow indefinitely. The interstitial lesions become accentuated, the cavities increase in size by several becoming united into one, while ectasis extends to the adjoining vascular networks. In certain spots the vascular neoformation continues its work, the capillaries dilate and become mingled, and thus new cavities are formed. Occasionally, following inflammation or trophic or accidental ulcerations, the resulting cicatrices bring about sclerosis—partial or total—of the tumor. The vessels retract, become occluded in spots, and the angioma atrophies. The same result follows partial angiectomy.

These angiomata may be the seat of various forms of inflammation or of external or internal hemorrhage, but of all the complications the most important are those arising from the vascular system. In the midst of the neoplasm or in its immediate neighborhood, the small vessels may offer lesions similar to those of the capillaries, and the process may even extend to the large arteries and veins. In the case of the arteries a cirsoid aneurysm may result which then completely overshadows the angioma by its importance. In the veins the same phenomena occur, but their extension and lesser gravity cause them to be lost sight of. These venous varices may exist alone without arterial varices. We know of no case of carcinomatous or sarcomatous transformation of these angiomata.

Recurrence of these neoplasms is infrequent, even after partial excision. The explanation of this fact is not easy. When the rapidly progressive extension of some diffuse angiomata is considered, and on the other hand the pronounced embryonal state of the neocapillaries, their number, and also the structure of the connective tissue invaded by such a prodigious number of young cells, thus simulating a sarcoma, it may very well be asked why these embryonal tissues which have escaped removal do not continue to grow on their own account. The evolution of these growths is a phenomenon of which we have no satisfactory explanation. It would seem that the vascular neoformation requires for its reproduction the continued irritation produced around it by the angioma, and when the central mass of the growth has been removed —the cause of all these disorders—the process itself becomes extinguished.

EPIDEMIC ENCEPHALITIS IN THE BOVIDES.

Readers of the Medical Record may recall an editorial on the possibility of the origin of epidemic encephalitis in mankind from an animal source. Numerous data were given to sustain this opinion and it was pointed out that this malady and rabies were members of the same group. In each, for example, the contagious principle could escape through the saliva. At a recent session of the Academy of Medicine, Paris (*Le Bulletin Médical*, February 8-11, 1922, xxxvi, 7), Donatien and Bosselut described a new affection in cattle, first seen in the fall of 1921, in which twenty animals of an Algerian herd were attacked, with nine fatalities. This malady was evidently contagious and the clinical picture at first strongly suggested rabies. The animals were rabid as to demeanor and were salivated and no sensible lesions were in evidence. But rabies was excluded by the absence of certain paralyses and glycosuria, together, of course, with negative history of contagion by biting, etc. However to decide the question finally the bulb and spleen of the victims were triturated and inoculated into various calves, sheep, rabbits, and guinea pigs. The virus was exhibited by subcutaneous, intramuscular, intraperitoneal, and intraocular routes. Of animals tested only the sheep proved immune. In the others the incubation period varied with the route from twelve to twenty days, with a minimum in one case of four days in which the virus was inoculated directly beneath the dura. In this case the virus had also received special treatment with glycerin.

Once initiated, the picture of the malady was evolved in twelve hours or less. The animals became somnolent with spells of excitation and exhibited sialorrhea and pronounced hypothermia, the temperature going to 33° C., and before death even to 30° C. In some cases there were evidences of myelitis. Death evidently occurred in coma. The

autopsy showed marked congestion of the nervous centers. In the corpora quadrigemina, cerebral peduncles, protuberance, bulb, and anterior cornua of the cord there was an accumulation of leucocytes about the blood vessels.

In the rabbit especially the rapid evolution alone excluded rabies, the latter requiring more than twenty-four hours. It is evident that we have here a new neurotropic virus which stands in relationship with epidemic encephalitis in man and also possibly with poliomyelitis. In the earlier opinion quoted previously in the MEDICAL RECORD, the author of the original article went so far as to hazard the opinion that epidemic encephalitis might represent an attenuated or modified form of canine rabies.

ACUTE YELLOW ATROPHY OF THE LIVER.

THE relationship of this peculiar affection to gravidity, syphilis, and other general states on the one hand, and to acute phosphorus poisoning on the other, aids in making its origin problematical. Meier has recently studied the group type to which acute atrophy belongs, although without any reference to the toxemia of pregnancy. He regards it as a matter of atrophies rather than atrophy; that is of different affections having a common termination. Thus ordinary catarrhal jaundice may end in atrophy of the liver and such cases have of late years been so common as to warrant the belief that they furnish the type. Close comparison with phosphorus poisoning shows a common mechanism, despite many superficial differences; phosphorus in other words can cause lesions which end in acute yellow atrophy. The latter affection does not differ save in degree from the central lobular necrosis seen in dogs with Eck's fistula. Despite the length and thoroughness of this study which is published in the *Zeitschrift für klinische Medizin* for December 31, 1921, xcii, 4-6, there is only the slightest allusion to the pathology of the liver of pregnancy. We find no more than the statement of the frequency of acute yellow atrophy in the gravid—from one-third to one-half the cases occurring in women are of that association. It is commonly taught that in puerperal and gestational eclampsia there is always central lobular necrosis of the liver, although the lesions may at time escape observation. It thus becomes possible to connect eclampsia with acute yellow atrophy and incidentally to recognize the common nature of all hepatic necroses, which may be present in many different degrees which give rise to very different clinical pictures. In addition to phosphorus, chloroform, alcohol, poisonous mushrooms, ptomaines so-called, and an entire series of bacterial toxins are able to attack the parenchyma of the liver, one office of which is said to be the protection of the individual against the entrance of toxic matter into the systemic circulation.

BISMUTH STOMATITIS.

CERTAIN resemblances between the heavy metals lead us to expect similarities of pathological activity, which could originate through the elimination of the soluble salts by the saliva, urine, etc. The action of mercury in this respect is well known, while lead also manifests itself by alterations in the mouth and kidneys. Bismuth has been known to us in the past almost solely through the topical action of insoluble salts and only recently have its compounds been given by injection in syphilis. It is true that in animal experiment as far back as 1889 stomatitis was induced in the dog by exhibiting soluble salts of bismuth. In speaking of soluble salts it must be remembered that the substances actually injected for syphilis have been regarded as technically insoluble—chiefly the tartrobismuthate of sodium and potassium, but the sudden supervention of stomatitis which has often been encountered, as well as the therapeutic efficacy, presupposes the formation of a soluble fraction. Milian and Perin have recently called attention to the appearance of a characteristic metallic line at the gingival border as the first buccal symptom of bismuthism; in a higher degree one sees gingivitis and ulceration of different degrees in different areas of the buccal mucosa. A third manifestation is the appearance of areas of slaty pigmentation on the internal aspects of the cheeks. The authors brought the subject up at a recent meeting of the French Dermatological Society (*Le Bulletin Médical*, January 25-28, 1922, xxxvi, 5) and the discussion which followed showed that in 30 per cent. or more of cases thus far treated with bismuth injections stomatitis had developed, even in subjects with mouths in perfect condition. By spacing the injections the incidence is reduced. Salivation is apparently present, but is much less marked than in hydrargyrism. The ulcers may appear very suddenly immediately after the second injection. Two of the members had also noted albuminuria following bismuth injections. The actually soluble bismuth salts have been found much too toxic for use in therapeutics.

News of the Week.

Deaths From Lethargic Encephalitis.—The Department of Commerce, through the Bureau of the Census, has recently issued a statement showing the number of deaths in 1920 from lethargic encephalitis. In 1920 in the death registration area of the United States lethargic encephalitis was given as a cause of death on 1,505 death certificates, as against 589 in 1919, giving mortality rates, respectively, of 1.7 and 0.7 per 100,000 population. Deaths from this cause were reported for every State in the registration area except Delaware; the largest number in any one State was 364 reported for New York State and giving a rate of 3.5 per 100,000 population. Cities are credited with 1,129 of the 1,505 deaths and rural sections with 376, with rates, respectively, of 2.6 and 0.8 per 100,000. The white population with 1,453 deaths from lethargic encephalitis has a rate of 1.8 per 100,000 population, while the colored population with only 52 deaths has a rate of 0.7. Males and females contribute about equally to the total deaths from this cause, with 781 males and 724 females. More of these deaths appear for persons aged 20 to 29 than for any other age group, though nearly as many are found for the age groups 30 to 39 and 40 to 49, and no age group escapes entirely.

Leprosy in New York.—On the first of January, 1922, there were 35 reported cases of leprosy in the Greater City—an increase of 7 during 1921. Of these cases, 12 were in municipal hospitals, the others being at home pursuing their regular vocations, as the policy of the Department of Health is to regard as non-contagious all cases presenting no open sores or mucous discharges. All cases are under the periodic examination of a special medical inspector of the Department and are being treated with chaulmoogra oil.

Prophylactic Value of Pneumonia Vaccines.—On the basis of the data submitted by a number of experts at a special conference, the Public Health Committee of the New York Academy of Medicine has formulated the following statement: "The experiments of prophylactic inoculation against pneumonia carried out during the period of the war and subsequently have thus far not yielded sufficiently convincing proof of its efficacy to warrant universal application. The experiments have, however, established that: (1) The vaccines have some value against three of the fixed bacteriological types of lobar pneumonia; (2) the duration of immunity secured is not very long—probably not over 5 to 6 months; (3) the vaccinations do no harm and there have been no fatal or serious results from them; (4) the inoculation, in order to be complete, has to be given in three doses. In some cases a rather unpleasant reaction develops and about 5 per cent. of the cases feel ill for a day or two. Experiments are being made with some success, with indications of still greater success in the future, rendering the vaccines less constitutionally disturbing without being less efficacious; (5) there is a definite indication for the use of vaccines against pneumonia in persons particularly exposed or coming in continuous contact with pneumonia; (6) every effort should be continued to prevent the spread of respiratory diseases through expectoration, coughing, and sneezing. Unfortunately at the present time the regulations are difficult to enforce and are not generally observed. Under the circumstances and until such time as the rules against spitting and unprotected coughing and sneezing are universally followed, the most promising means of preventing acute respiratory diseases lies in the prophylactic vaccine inoculations; (7) inasmuch as the prevention of pneumonia by inoculation is still in an experimental stage and inasmuch as there are many preparations put on the market which are of doubtful value, the promiscuous use of vaccines should not be encouraged.

Conference on Public Health.—Under the auspices of the United States Public Health Service a conference was held in Washington on March 14 and 15, which was attended by deans of schools of public health and medical schools, presidents of universities with which these schools are connected, a selected number of professors of public health subjects and men actively engaged in public health work, on "The Future of Public Health in the United States and the Education of Sanitarians." After considering the present status of the public health movement and present facilities for the education of health officers and other sanitarians, the conference considered various newer aspects of public health and their importance in the training of sanitarians; the various kinds of sanitarians which will be needed for the future; the recruiting and training of more and better sanitarians; and the various problems connected with the training of sanitarians for the future, and the further education of those who are now employed in public health work.

The Toll of Famine and Pestilence in Russia.—Dr. Semashko, the Soviet Health Commissioner, has issued a statement placing the number of deaths in the famine districts of Russia at 200,000. Dr. Semashko estimates that some 25,000,000 people are affected by the famine, and expresses great fear that cholera and other diseases will appear with the spring. He emphasizes the lack of personnel in the medical corps because of the mortality from typhus, and also the need of serums and quinines. Russia is able to supply only about 25 per cent. of her needs in this direction. It is estimated that $5,000,000 worth of medicine would save the situation.

Would Have Doctors Pay More Attention to Infectious Jaundice.—The New York State Health Department calls attention to the fact that notwithstanding the fact that reports of epidemic jaundice have been received from almost every part of the State, that the disease is epidemic in adjoining states, and that Health Commissioner Copeland has issued a statement asking the physicians of New York City to cooperate with his department in ascertaining more fully the facts with reference to this disease, the disease has attracted little attention. The reason for this is because, so far as the State Health Department has been able to find out, there have been no deaths from the disease. Dr. Hermann M. Biggs, State Health Commissioner, points out, however, that we never know when and where these maladies may suddenly revert to original and severe types. Health authorities do know that infectious jaundice in Japan is a serious matter, from 30 to 50 per cent. of the cases terminating fatally. Recently cabled reports from Warsaw told of an epidemic, fatal and widespread, that was ravaging the Russian border of Poland, where large numbers of Russian refugees were pouring into the country. This disease was called a sort of combination of influenza and jaundice, but from the description of the ailment it would seem to be the same epidemic jaundice that manifests itself so severely in Japan.

Suicide in the United States.—According to the annual report of the Save-a-Life League recently issued, more than 20,000 persons in this country committed suicide during 1921. Suicides were 23 per cent. more numerous last year than in 1920. There were 840 suicides in New York City during 1921, an increase of 103 over 1920. According to the report, 1,200 men and women, before killing themselves, murdered more than 2,000 others. Loss of employment, commercial failure, and reactions from the war are given as causes, but many were due to amazingly trivial causes. Among the 1921 suicides were 10 editors, 10 well-known writers, 40 college students, 51 school teachers, 21 clergymen, 57 judges and lawyers, 7

mayors, 93 bankers, and 88 presidents of large business concerns.

In Jail for Barring Children's Vaccination.—Three residents of Camden, N. J., have been committed to the county jail charged with having refused to have their children vaccinated on order of the Berlin, N. J., Board of Education. They also refused to pay the fines of $100 and costs.

Increased Requirements for Medical School.—The Board of Trustees of the University of Pennsylvania have adopted a resolution that, beginning with the scholastic year of 1923, all applicants for admission to the medical school will be required to have a collegiate degree or to have completed three years of collegiate training, with the provision that the bachelor's degree will be given in the first year of the medical course.

Medical College Must Close if State Refuses Funds.—E. L. Bemis, representing the Medical College of Virginia, appeared before the Senate Finance Committee of that State and showed that unless the committee could see their way clear to add $30,000 a year to the support of the Medical College of Virginia and to the three hospitals with which it is affiliated, the doors of the college would not be opened next fall. There has been an annual deficit of $35,000 to $45,000 in the teaching department and of $36,000 in the conduct of the three hospitals.

Clinic Week at University of Alabama.—The post-graduate school of the medical department of Alabama University, Birmingham, gave a clinical week beginning on February 22. All the hospitals in the city contributed to making the course interesting and instructive.

German Students Undernourished.—The German Physicians' Association, comprising 40,000 members, has issued a resolution of thanks to the Quakers of the United States for feeding German children. The resolution urges "our American friends not to grow weary," and states that many children and students still receive insufficient nourishment. According to these resolutions, German societies are now making efforts to relieve the condition of university students, many of whom, it is asserted, have not tasted meat for weeks. They go without breakfast and eat thin soups for lunch and dinner. These university students present a pitiable appearance. Their clothes are patched and they have holes in their shoes. They are pale and look undernourished.

Oppose Chiropractor Bill.—A hearing on the chiropractor bill, now before the New York State Legislature, was held on March 7, at which the bill was opposed by Dr. Augustus S. Downing of the State Education Department, Dr. S. Dana Hubbard of the New York City Department of Health, Dr. C. E. Lateman, representing Dr. Hermann N. Biggs, State Health Commissioner; Dr. James F. Rooney of Albany, Dr. James N. Vander Veer, representing the State Medical Society. Representatives of the State Osteopathic Society also opposed the bill.

More Rigorous Legislation Asked to Regulate Pharmacists and Druggists.—Legislation to end the activities of unprincipled pharmacists and druggists, operating without licenses, was urged by more than a score of members of the pharmaceutical profession at a hearing before the Senate Public Health Committee on a measure which would prevent the owning and operating of drug stores except by licensed druggists. It was brought out that nearly 500 drug stores in the State were opened last year by unlicensed proprietors.

X-Ray Laboratories Regulated.—At a meeting of the Board of Health of the New York Department of Health, held Jan. 26, 1922, resolutions were adopted providing that no person shall maintain, operate or conduct an *x*-ray laboratory or advertise or hold out to the public that an *x*-ray laboratory is maintained, operated, or conducted, wherein radiographs are taken, diagnoses made or human beings examined or treated by *x*-rays, without a permit therefor issued by the Board of Health, or otherwise than in accordance with the terms of said permit and with the regulations of the said board; that every *x*-ray laboratory shall at all times be in charge and under the direction of a duly licensed physician or other person whose knowledge, experience and qualifications to operate and use an *x*-ray machine are satisfactory to the Health Department; that every *x*-ray laboratory shall be so constructed as to confine within the operating room the rays emanating from the machine and it shall be equipped with suitable and necessary appliances and devices at all times when the *x*-ray machine is in operation for the proper protection of patients, operators, and all other persons or property adjacent, contiguous to, or coming in contact with the electrical or other current or force or spark generated or incident to the operation and use of the *x*-ray machine. Permits may be revoked in the discretion of the Board of Health, and no permit shall be transferable as to the person or place.

Uniform Birth Registration Laws Advocated for City and State.—The Section on Pediatrics of the New York Academy of Medicine, at its stated meeting, held March 9, put itself on record as favoring the present 10-day period allowed for the reporting of births and recommended that the State law be made to correspond to the city law in this respect.

Clinic Visits Sick in Rural Districts.—As the farmers as a rule cannot come to the city to the clinic, the North Dakota Tuberculosis Association now brings the clinic to the districts far removed from the cities. Traveling in a business car, the clinic can now reach every district, no matter how far distant. In addition to diagnosing tuberculosis and relieving the sick, the traveling clinic does a great deal in teaching families how to live under difficult sanitary conditions.

National Board of Medical Examiners Meets.—Members of the National Board of Medical Examiners met in the Congress Hotel in Chicago on March 6 to discuss plans for medical examinations to be held in June. According to Managing Director Everett S. Elwood, twenty-one States have accepted the certificate of the National Board, while ten others have signified their willingness to accept it when the various state laws can be amended.

United Hospital Fund of New York Opens Hos-

pital Information Bureau.—Following the survey of hospital work in New York City made by the Public Health Committee of the New York Academy of Medicine and the disclosed need of a central agency of information about hospitals, the United Hospital Fund organized such a bureau with offices at the New York Academy of Medicine, 15 West Forty-third Street. The aims of this bureau are to keep in touch with hospital work and progress in New York City; to furnish information to all interested with regard to administration, record-keeping and other facts concerning hospital work, organization and facilities; to study and make known the hospital needs of the city; to prepare exhibits; to maintain a library of hospital reports and statistics, also of record forms and blanks used in the several departments of the hospitals; to publish annually, or more often, information concerning hospitals; to promote uniformity in hospital reporting; and, whenever called upon by the hospitals, to assist in such administrative and efficiency studies as would be of value to the hospitals, municipal and private. The committee in charge of the bureau are as follows: Mr. Francis Smyth, Chairman, Trustee of the United Hospital Fund; Dr. W. Gilman Thompson, Dr. S. S. Goldwater, Mr. Julius A. Stursberg, and Mr. Henry C. Wright. Dr. E. H. Lewinski-Corwin, Executive Secretary of the Public Health Committee of the New York Academy of Medicine, has been aappointed Director of the Bureau.

Hospital Notes.—The Harlem Eye and Ear Hospital, New York, was formally opened by appropriate ceremonies on the evening of March 14.

Plans have been filed for an eight and nine-story hospital building to be erected on the premises of Roosevelt Hospital, New York. The estimated cost of the new structure is about $500,000.

The Hospital for Deformities and Joint Diseases has purchased another parcel of property adjoining its present hospital building. This acquisition will also form a part of the site of the new hospital building to be started in the near future.

Colonel Charles E. Forbes, Director of the United States Veterans' Bureau, has ordered the immediate abandonment of the Fox Hills Hospital, Staten Island, N. Y., owing to the fact that the building is a firetrap and conditions "deplorable." The 850 patients will be distributed to other institutions in and about New York.

With informal exercises ground was recently broken for an eight-story addition to the Church Home and Infirmary, Baltimore, Md.

The new McClellan Hospital, at Xenia, Ohio, was recently opened for the reception of patients.

The Negroes of St. Louis, Kansas City, and Chicago are making arrangements for the erection of a sanitarium and hospital at Carrollton, Mo.

The Baer Memorial Hospital at Fort Smith, Ark., county tuberculosis hospital, will be ready for occupancy on May 1.

The West Mountain Sanitarium, Scranton, Pa., has been taken over by the county commissioners and henceforth will be operated as a county tuberculosis hospital.

The Lying-In Hospital, New York City, celebrated the 123rd anniversary of its incorporation on March 1. It is the oldest maternity hospital in New York City and has a record of having brought 130,000 babies into the world, 79,696 in the out-patient department and 50,957 in the hospital itself.

Contracts have been let for the erection of a new hospital at Cuching, Ariz., at an estimated cost of $50,000.

A new dispensary was opened on March 1 in connection with the Fairview Park Hospital, Cleveland, Ohio.

The new private pavilion, children's building and auditorium of Mount Sinai Hospital, New York, will be opened for the public at dedication ceremonies on April 9.

The Good Samaritan Hospital, Los Angeles, Cal., has purchased several residences on Orange Street, thus increasing the property so as to include the entire block bounded by Orange, Witmer, Lucas, and Shatto streets.

Dr. A. G. Fowler has been appointed physician and surgeon to the Atlanta Federal Penitentiary by the Department of Justice in Washington.

Dr. Roy A. Morter of Kalamazoo, Mich., has been elected president of the Exchange Club of that city.

Dr. Carl Schleich, originator of the Schleich method of local anesthesia, died recently in Berlin.

Harvey Society Lecture.—Dr. W. J. V. Osterhout, Professor of Botany, Harvard University, will deliver the eighth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, March 25, 1922. His subject will be "The Mechanism of Injury, Recovery, and Death."

The Western Electro-Therapeutic Association will hold its fourth annual meeting in Kansas City April 21-22, 1922, under the presidency of Dr. Curran Pope of Louisville, Ky. Dr. Grover's School of Electro-Therapy will hold its sessions on April 17-19, preceding this meeting. Dr. Charles Wood Fassett of Kansas City is secretary of the association.

The Medical Society of the Missouri Valley will hold its annual meeting in St. Joseph, under the presidency of Dr. Paul E. Gardner, on September 21 and 22, 1922. Further information with reference to this meeting may be obtained by addressing the secretary, Dr. Charles Wood Fassett, 115 East Thirty-first Street, Kansas City, Mo.

Surgeons of Five States Meet in Birmingham.—The first group meeting of the Alabama, Georgia, Louisiana, Florida, and Mississippi sections of the American College of Surgeons met in Birmingham, Ala., February 24 and 25, 1922. This is the second meeting of this branch of the American College of Surgeons in the South. The first meeting was held last year in Atlanta.

Obituary Notes.—Dr. JOSEPH WATSON MARTINDALE died of pneumonia at Camden, N. J., on Feb. 22, at the age of fifty-seven years. He was graduated from Jefferson Medical College in 1894. He was a member of the Camden County Medical Society, the New Jersey State Medical Society, the Philadelphia Medical Club and a Fellow of the American Medical Association. He was at one time secretary and historian of the Camden County Medical Society.

Dr. JAMES A. OWEN of Newcomb, N. Y., former coroner of Essex County, died of pneumonia in the Ticonderoga Hospital on February 17, at the age of fifty-six years.

Dr. JAMES EDWARD BURT of New York, a graduate of the New York Homeopathic Medical College and Flower Hospital in 1899, died at his home on March 4.

Dr. WILLIAM LAWRENCE MAULDIN of Greenville, S. C., a graduate of the University of Maryland School of Medicine, died on March 3, at the age of forty-four years.

Dr. M. FORD MORRIS of Atlanta, Ga., died of heart trouble on February 18, at the age of twenty-seven years. He was graduated from the Atlanta Medical College in 1916.

Dr. THOMAS CANNING CHURCH of Valley Falls, N. Y., a graduate of the University of Michigan Medical School in 1878, died on February 16, at the age of fifty-six years.

Dr. ALEXANDER W. FAIRBANKS of Chazy, N. Y., a graduate of Albany Medical College in 1874, died on February 19, at the age of seventy years. He was a Fellow of the American Medical Association and at one time a member of the State Legislature.

Dr. MARIT F. NELMS, a graduate of the Atlanta College of Physicians and Surgeons in 1900, died at his home in Commerce, Ga., on February 16, at the age of fifty-one years.

Dr. WILLIAM N. WILLIAMSON of Indianapolis, Ind., a graduate of the Indiana Medical College in 1880, died on February 21 at the age of sixty-seven years.

Dr. CHARLES W. KARSNER died at Philadelphia on March 1, at the age of eighty-two years. He was graduated from Hahnemann Hospital and Medical College, Philadelphia, in 1875 and from Jefferson Medical College in 1878. He was from 1884 to 1892 a member of the City Council and for a time a member of the Philadelphia Board of Health. He served in the United States Army during the Civil War.

Dr. F. M. AGNEW, a practitioner of medicine for sixty-two years, died at his home in Carbondale, Ill., on March 15, at the age of eighty-one years.

Dr. THOMAS R. THORNTON, formerly of Lees Summit, Mo., died in Kansas City on Feb. 26, aged seventy-eight years. He was graduated from Washington University Medical School, St. Louis, in 1878.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Feb. 22, 1922.

A Form of Influenza Resembling Scarlet Fever.—The question of the similarity in certain characteristics of influenza to scarlet fever was discussed at a recent meeting of the Manchester Medical Society when Dr. St. Clair McClure, assistant to the Manchester Medical Officer of Health, said that the diagnosis of scarlet fever was becoming increasingly difficult. He pointed out that there were many cases in which the difference between mild scarlet fever and mild influenza was not clear. At the same meeting the wisdom of sending these mild cases to the fever hospital was questioned. Dr. R. W. Marsden spoke of the necessity of good evidence that the patient was suffering from scarlet fever before ordering to hospital, and he emphasized the necessity of nursing and isolating at home all cases which could be so dealt with. Dr. McClure agreed that if isolation accommodation was practicable in the home and the parents could be depended upon, it was preferable to keep the patients at home. But the figures of Manchester showed that there was a definite advantage to individual households in the removal of cases to hospital. The greater the promptitude in removing the patient the less would infection spread among family contacts. This was shown by an investigation carried out over a series of years.

The Attempt to Scale Mount Everest.—Mr. A. F. R. Wollaston, surgeon to the Mount Everest Expedition of 1921, lectured the other day in London to the Royal Geographical Society. In giving a description of the general health of the party the lecturer said that before they left England they were warned that after a few weeks in these high latitudes they would find themselves growing irritable. On the contrary, however, the temper of the party, even during a fortnight's delay, from September 6 to 19 at the height of 17,000 feet, had been excellent. Mr. Wollaston denied the stories of the "wild snow men" which had recently been revived by the discovery on the part of the expedition of strange footprints on the mountain slope at the height of 21,000 feet. It was not necessary to inform a scientific society, that Himalayan bears did not make excursions to 10,000 feet above the last fruit-bearing tree, and there were no such creatures as wild snow men. There could be no doubt that what they saw were the tracks of a wolf, loping along at a very good pace. He had met the story of "snow men" at two places as far apart as Dutch New Guinea and the middle of Africa and did not believe it.

Crime a Pathological Condition.—At a meeting of the Royal Society for the Assistance of Discharged Prisoners on February 20, Major-General Sir F. H. Sykes said that the question was often heard, Is crime a disease? At last they knew that in many cases it was due to disease. The burly ruffian was no longer, if ever he was, typical of the criminal. It was not brute strength, but disease, drunkenness, starvation, heredity, in fact all these things leading to spiritual weak-

ness, which bred the criminal of to-day. Nor should prevention be the final aim of punishment. It was not through fear of punishment that a man should desist from crime, but through the strengthening and evolution of character which made wrongdoing revolting to him. The real solution, therefore, lay in cure, and it was to this end that men were beginning to work. Sir Frederick said that he was speaking more especially on behalf of those soldiers, sailors, and airmen who in many cases had served their country with honor, but had subsequently suffered from moral relapse and had been committed to prison. These men offered only fresh proof that crime was in no small part a mental disease. They had suffered much, they had passed through mental strain, they were physically weakened and no longer possessed the strength of will to fight against the terrible conditions which the aftermath of war had imposed upon the poorer classes. The majority were young men convicted of first offenses. Was it to be believed that these men, many of whom had fought with distinction for their country, were irredeemably lost? The answer must be in the negative. The best cure for crime, in both its mental and economic aspects, was hard work, and the first object of this society was to obtain for these men suitable employment and to remove them as far as possible from contaminating surrounds. To effect this one of the methods which most appealed to him was sending youths and young men to sea, where they had hard work to do in a healthy atmosphere. There is no doubt that a criminal is not normal and when his propensities render him a menace to society, for the protection of the community at large he must be isolated. Many criminals may be treated successfully so as to become useful citizens, and it has long been a question in this country whether harsh punishment, such as imprisonment for protracted periods, does not do more harm than good. It is argued, and with a good deal of reason, that such punishment does not act as a deterrent but rather the reverse. It tends more to aggravate the criminal instincts than to prevent them. The stigma of imprisonment never leaves a person. As said before many criminals can be successfully treated, and the methods in vogue in America generally, that is, wherever possible of not attaching the brand of crime to offenders against the law, but of attempting to cure them of their mental disease, is beginning to find favor in this country. The horrors of the war by acting on the nervous system of those unstable from heredity or other causes and the difficulty found by many of the poor of gaining an honest livelihood have greatly augmented the number of criminals in Great Britain and it seems as far as may be, that the majority of these should be regarded as sufferers from mental disease and given every chance to recover their social status. Undoubtedly hard work and change of scene are excellent remedies, as it is futile and dangerous to coddle individuals thus afflicted. Although improvements have been introduced already into the British system of punishing the breaker of the law, it still errs on the side of harshness, and the whole penal system requires investigation and revision where necessary. Perhaps some useful hints in this direction might be gathered in America despite the fact that it is generally believed here that the other extreme is sometimes reached in your country. That is to say, that sometimes the tendency is to treat criminals with undue leniency. The freedom of criminals of a certain type must be rigidly restricted for the sake of the public, even though they may be suffering from mental disease. It must be borne in mind that there are many physical diseases which are not amenable, or only slightly so, to treatment and, of course, the same is true of mental diseases. As in the case of physical disease, so it is in mental disease, they must be accurately diagnosed ere any treatment is possible. The incurable ones, so far as criminal mental disease is concerned, should be treated kindly, but at the same time must not be allowed to be a danger to society.

Preliminary Report of the British X-ray and Radium Protection Committee.—This report is the first of its kind issued from the above committee. The standpoint taken is that the dangers at the present time of work with *x*-rays and radium are known and can be adequately guarded against by thorough and systematic precautions. The following recommendations are made: (1) To provide adequate space and ventilation in radiological departments; (2) To give appreciable off-duty and holiday periods to compensate for the hours necessarily spent in dark rooms; (3) To insist on a strict adherence on the part of the personnel to the precautions recommended for their safety. In working with radium the dangers of manipulating large quantities of the emanation are considered as well as those due to the penetrating gamma-rays. The blood changes which have been observed in people who have suffered from overexposure to radiation induce the committee to recommend that systematic blood counts of the personnel be made with a view to recognizing any such changes as soon as possible.

Tuberculous Milk for London.—During the three months ended September 30, 1921, under the London County Council Act, 1907, 624 samples of milk from 23 English counties were taken at London railway stations, with the result that 19, or 3.04 per cent., proved tuberculous; 456 cows at 18 farms situated outside the county of London were examined by the L. C. C. veterinary inspector. As the result 11 cows were found on inspection to be affected with generalized tuberculosis. In addition, the inspector revisited 61 farms and inspected 2,152 cows. The animals except 18 of them, were found to be in a satisfactory condition.

Prostatitis in Cystostomized Prostatics.—Alapy has noted that in the inoperable prostatic patient who is subjected to cystostomy the enlarged prostate is very apt to inflame with resulting adhesion of the gland to its capsule. This accident forms at times an indication for prostatectomy and the author has performed the latter in fourteen out of seventeen cystostomized subjects who developed prostatitis.—*Wiener klinische Wochenschrift.*

1 Address before the Worcester Surgical Society. E. H. Trowbridge.
2. Experiences with Tumors of the Spinal Cord. W. J. Mixter.
3. End Results of the Surgical Treatment of 48 Cases of Tuberculous Cervical Adenitis. Frank H. Lahey and Howard M. Clute.

2. Experiences with Tumors of the Spinal Cord.—W. J. Mixter analyzes a group of 54 cases giving the symptom complex of spinal cord tumor, in which some 21 different pathological processes were encountered. In this group of 54 cases laminectomy was performed on 45 patients, with 9 being deemed inoperable. The mortality was 4.1 per cent. Mixter's rule at present is to operate on any case presenting signs of a definite cord lesion, even if degenerative processes are strongly suspected. He finds Dr. J. B. Ayres' method of combined puncture of the cisterna magna and lumbar space a very valuable means of differentiating between the degenerative lesions and those in which surgery may be successful. Its use should be restricted to those very thoroughly versed in the procedure. The writer has operated on some 18 cases following double puncture and has always found tumor, if indicated by puncture. There is little new to offer as regards the technique of laminectomy. Wide exposure is essential; short incision and unilateral laminectomy are both to be condemned. A point upon which emphasis is laid is that after dissection has been completed on one side the spinous processes can be undercut close to the laminæ, with heavy forceps, and turned aside with the muscles of the other side. It is necessary to undercut one spinous process above and one below the laminæ whose removal is contemplated. This is done, however, without additional dissection. The interspinous ligament is preserved with the spinous processes, thus considerable dissection is avoided and a structure of great strength is retained, while the exposure obtained is just as satisfactory as if the spinous processes are completely removed. The differential diagnosis of cord lesions depends on careful, painstaking neurological examination, good *x*-rays and the examination of the spinal fluid. Cord tumors have been treated for chronic appendicitis, gall-bladder disease, and various orthopedic and genitourinary troubles, as well as diagnoses of degenerative troubles before coming to operation. Chronic cord compression is more common and more amenable to treatment than some of us have believed. A number of supposedly incurable paralytics will be found to reveal the opportunity for well-nigh marvelous surgical results, and the risk of operation is hardly greater than in many of the more serious abdominal lesions.

3. End Results of the Surgical Treatment of 48 Cases of Tuberculous Cervical Adenitis.—Frank H. Lehey and Howard M. Clute state that in 46 of these 48 cases the results were classed as excellent; yet in 26.08 per cent. of the series, they found evidence of paralysis of the trapezius muscle from interruption of the conductivity of the spinal accessory nerve or the third and fourth cervical nerves. Surgeons must admit that "bloc dissections" result in spinal accessory or third and fourth cervical nerve paralysis, with consequent functional disability, too often to permit its being resurrected from the oblivion into which it has, for the most part, sunk in the treatment of tuberculous cervical adenitis. Surgery, in the writers' opinion, should not be resorted to in tuberculous adenitis until *x*-ray therapy has been tried for a considerable length of time—from six months to a year—providing the disease is not spreading and involving the adjacent glands. Surgical removal of the glands should be undertaken when in spite of *x*-ray and hygiene, either the neighboring glands are becoming involved, or, after a fair trial of radiation, shrinkage is not apparent. Where one or two large glands must be removed, *x*-ray failing, it is unnecessary to remove the small, soft, non-caseous glands which surround them; these may be treated by radiation. Whenever an extensive neck dissection for a not necessarily fatal condition is undertaken, one should have definitely in mind the possibility of spinal accessory paralysis, and that that paralysis is a serious one, limiting arm abduction to less than a right angle with the body.

2. Metabolism During Starvation and Undernutrition.—Francis G. Benedict, as the result of observations on men during short and long periods of starvation, concludes that the withdrawal of food for periods of four to seven days with a large number of individuals and for a period of at least thirty-one days with one individual was brought about without distress, notwithstanding that the human being is most sensitive to his food supply and personal comfort. There was complete absence of so-called hunger pain. The withdrawal of food for periods of seven to thirty-one days did not result in any sense in permanent injury. This Benedict points out is a most fundamental and revolutionary conception. An experiment was carried out on twelve students of the International Y. M. C. A. College in Springfield, during which these men were kept for four months on an energy content a little more than one-half their caloric requirements prior to the test. Practically every morning the members of this squad had their basal metabolism taken. The outstanding effects dealing with the basal metabolism was a gradual reduction in weight to a point 12 per cent. below the initial weight during a period from three to ten weeks, with low calories and a moderate amount of protein in the food intake. One squad of twelve men subsisted for three weeks on 1400 net calories without special disturbance. After the loss in weight of 12 per cent. had been reached, the net calories required to maintain this weight averaged about 1950, or but a little more than half the original amount required. At the end of the reduction in weight, the actual heat output during the hours of sleep, as computed by indirect calorimetry, was approximately one-fourth less than normal. There was no seasonal variation in the metabolism. The analyses of food, feces and urine were sufficiently complete to permit a nitrogen balance to be made, and it was found that throughout the period of loss in weight and for some time subsequent thereto, there was a marked loss of nitrogen to the body. There was an intimate relationship between the surplus nitrogen and the metabolic level. Removing what may be designated surplus nitrogen, distinctly lowers the stimulus to cellular activity. The pulse rate and blood pressure, both systolic and diastolic, was distinctly lowered. The skin temperature in some subjects was lower than normal. The rectal temperature was practically normal. The psychological changes in these men were not such as to interfere materially with the discharge of duties common to student life. Endurance tests showed that these men in the diet squad were not appreciably inferior to that of the average men of the student body. With the resumption of normal diet the body weight recoveries were perfectly marvelous and the tendency was to take on much more than the amount lost during the fast. The conclusions seem warranted that prolonged curtailment of diet is not necessarily disastrous to adults. No argument, however, is needed to point out that marked undernutrition is distinctly disadvantageous to children and youths.

9. Blood in the Digestive Tract.—L. Winfield Kohn calls attention to the definite significance of blood anywhere in the intestinal tract. It is his opinion that no one single test has greater importance in the study

of diseases of the alimentary tract than that of the blood test, visible or occult, but many important factors must be borne in mind lest the importance of the test dwindles into obscurity. Practice with the smaller tubes will reduce the probability of trauma to a minimum. Bleeding from the respiratory tract, teeth, gums, etc., or from hemorrhoids, rectal growths, or anal fissures, may as a rule be accounted for, and such bleeding should be ruled out. Those conditions which do not give evidence of blood in either gastric contents, duodenal contents, or stool, are generally functional in origin or nature, though the absence of blood in the stool alone does not exclude the possibility of small hemorrhage above as in the stomach and duodenum. Very small amounts of blood may accumulate in the fasting stomach as a result of a breech in the gastric lining, yet will not accumulate in the short hour following the administration of a test breakfast, hence no positive blood reaction will be obtained in the test breakfast contents. When bleeding can be assigned to certain portions of the tract, the fact of the existence of organic disease is established, and such a breech in continuity may indicate ulcer, erosions, papillomatous growths, chronic inflammation, passive congestion, or malignancy in the mucosa, corresponding either to the area of the stomach or bowel from which it has been obtained, or to a point in adjacent organs connected with the bowel tract, such as the liver, pancreas, gall ducts, or gallbladder. To learn that bleeding exists is a most worthy accomplishment; to ascertain the direct cause requires study from every angle and through every possible means at our command.

11. Race Immunization.—Casper L. Redfield points out the impossibility of vaccinating each person against all different germs of a pathological character, and that we must therefore look for some means of building up resistance to disease in general. The power which fights disease of any kind is common mechanical energy. The quantity of energy in any organs may be increased by properly exercising them. The supply of one organ may be drawn upon to help out another organ which is subject to an unusual load. Such transference of energy from one organ to another may also involve a transformation as when mental energy is drawn upon to help out a tired arm muscle. As bacterial attacks are local, this power of transforming energy and transferring it from unaffected places to points of attack is important in both prophylaxis and therapeutics. Redfield pictures an individual immunized to a number of pathological organisms and taking a mild course of physical training to keep up his general physical powers, also occasionally inoculated with mixed vaccines, and propounds the question as to whether it would be necessary to repeat this operation generation after generation. He thinks not, inasmuch as it has been demonstrated that powers developed by exercising them are inherited. Consequently, if parents are made immune before their children are conceived they will inherit a high degree of resistance to the diseases involved. He points out that we have a direct case of the inheritance of resistance developed by vaccination against smallpox in the decreased incidence and lessened virulence of this disease even among the unvaccinated descendants of vaccinated progenitors. Data are presented showing that earlier children suffer much more from tuberculosis than do later children. This means that the greater the extent to which the parents have exercised their powers of fighting tuberculosis before their children are conceived, the greater is the resistance of the children to that disease. Syphilis is another lingering disease against which a person develops resistance by fighting it. It is well known that the earlier children of syphilitic parents suffer more from this disease than do later ones. Clearly children inherit the resistance which parents develop by fighting disease.

1. The Growing Menace of Benzene (Benzol) Poisoning in American Industry.—Alice Hamilton calls the attention of the medical profession to this increasing menace in American industry. Since the beginning of the war, benzene, which is a much more powerful solvent than petroleum benzin and naphtha for fats, gums, and resins, and which is below the latter in price, is being increasingly used in the industries. It is exceedingly difficult adequately to protect men engaged in work in and about an apparatus that has been used for the manufacture or storage of benzene; even a Draeger helmet may not be enough. In acute benzene poisoning the blood in the heart and vessels is fluid, in the veins of the abdomen, engorged. There are hemorrhages into the gastric mucosa, bloody foam in the air passages, no benzene odor and no benzene demonstrable chemically. Sury Bienz records finding conspicuous bright red spots over the body, bloody fluid and dark petechial hemorrhages into the gastrointestinal mucosa and pleuræ, general venous congestion, and bloody mucus in the air-passages. There is also profound blood destruction. Lehmann found that loss of consciousness might occur when there were from two to three parts of benzene to 100,000 parts of air. An instance is recorded by T. M. Legge of a man dying of typical benzene poisoning when there was 1 part of benzene to 10,000 parts of air. The practical difficulties in the way of overcoming the danger of this solvent in industry seem to be insurmountable. To the physician it can seem only a disastrous innovation in industry.

3. The Therapeutic Index of Silver Arsphenamine: Comparison with that of Arsphenamine and Neo-Arsphenamine.—Abraham Strauss, D. M. Sidlick, M. L. Mallas, and B. L. Crawford have treated three groups of 25 patients each with silver arsphenamine, arsphenamine, and neo-arsphenamine, respectively. The dosage employed throughout the treatment was silver arsphenamine, 0.2 gm.; arsphenamine, 0.4 gm., and neo-arsphenamine, 0.6 gm. The determination of the comparative values of the three drugs was based on the Wassermann reaction. The seropositive findings in Group I were changed to negative in only one instance. In Group II the positive Wassermann reaction became negative in 13 cases. In Group III the Wassermann reaction was changed from positive to negative in nine cases. From these serological comparisons it is concluded that the spirocheticidal activity of silver arsphenamine is far inferior to arsphenamine and neo-arsphenamine in the treatment of syphilis.

4. The Antiscorbutic Value of Dehydrated Fruits.—Philip F. Eckman records the results of feeding experiments in guinea pigs to determine to what extent, if at all, antiscorbutic vitamines are contained in dehydrated fruits. The fruits used were peaches, apricots, apples, pears, prunes, cherries, and loganberries. It appears from these experiments that the only one of these dried fruits containing sufficient antiscorbutic vitamine to maintain the life of a guinea pig when fed in not too excessive quantities is peaches. Of this fruit it appears that 4 gm. a day, although insufficient to prevent scurvy, delay it for three or four months. Although further trial did not bear it out, earlier experiments indicated some value in apricots and apples. Pears, prunes, loganberries, and cherries seemed to have even less value.

7. The Collection and Preservation of Human Milk.—Paul W. Emerson presents this preliminary report, describing the work of the Boston Floating Hospital in co-operation with the Lying-In Hospitals and obstetricians in collecting human milk daily in the mothers' homes. He also tells of their experimental work with methods of preserving human milk. He was led to try, after reading Finkelstein's experiment, a method of

preserving the fat alone, and homogenizing it with cow's skim milk. By preparing a 12 per cent. fat from human milk, combining this with cow's skim milk, and adding lactose, a milk was obtained with the formula: Fat, 3 per cent.; sugar, 7 per cent.; protein, 1 per cent. This human milk fat can be preserved at least a month. When combined with cows' skim milk and fed to a baby for a short period of time, one may expect a gain in weight equivalent to that obtained with whole breast milk. Such milk might be used to advantage with babies who have an intolerance for cows' milk fat, but the milk prepared in this way is expensive and difficult to prepare. Drying human milk, the writer feels, is more feasible and much less expensive.

9. **The Etiology of Orthostatic Albuminuria.**—Willy Rieser and Sidney L. Rieser have made observations from which they conclude that orthostatic albuminuria is due to renal stasis caused by a compression of the left renal vein, in arterial pincers composed of the aorta and the mesenteric artery. These arterial pincers become operative when the aorta is projected forward by a lordosis or when the mesenteric artery is pulled to tautness by the visceroptotic tug from the mesocolon. The writers hope to be able to show whether the abdominal visceroptosis alone can produce it, or whether both are productive factors in the productive mechanism. The magnitude of the pulse pressure holds no relation to the albuminuria, nor has it any influence on the elimination of water, urea, or chlorides. It is hoped that further investigation will throw light on what influence the circulatory disturbance of the left suprarenal gland may have on the general vasomotor instability in this condition.

3. **Ingleby Lectures on Endocrine Functions of the Female Reproductive Organs.**—Swale Vincent enumerates some general considerations indicating that the ovaries are not the only organs which determine the secondary sexual characteristics. Thus it is urged that the quality of "femininity" is dependent upon the manifold activities of all the internal secretions, including those coming from the adrenal bodies, the thyroid, the pituitary, as well as those derived from the ovary, corpus luteum and placenta. The adrenal cortex appears to have certain important functions in connection with the development and growth of the sex organs. Tumors of the adrenal cortex are frequently associated with sex abnormalities. When cortical tumors occur in the female there is a development of male secondary characters and hypoplasia of the internal genital organs. The adrenal cortex is enlarged during breeding and pregnancy. As for the thyroid, this is relatively larger in women than in men, and this is especially noticeable during puberty, pregnancy and menstruation. Sexual intercourse increases the size and activity of the gland. It is stated that the ovaries exert an inhibitory action on the thyroid; in fact, the latter becomes hyperactive after castration; and there is an increase of the colloid substance. This is the cause, it is said, of the large number of cases of exophthalmic goiters after the menopause. The pineal gland is causes a rapid development of the genital gland. The pituitary has an influence on many of the metabolic functions necessary for the establishment of puberty. Removal of the thymus, performed before puberty, causes a rapid development of the genital gland. The whole subject is complicated by the influence of the various internal secreting organs upon each other. The psychological characteristics of women are, of course, partly accidental and dependent on social conditions, but of those which are more fundamental, some depend on the influence of the ovary, and others on general metabolic processes, which are largely conditioned by the general reactions of the internally secreting glands.

4. **The Treatment of Gastric Ulcer.**—Berkeley Moynihan adds certain figures to his statistics on gastric ulcer presented before the British Medical Association in July, 1920. The number of gastrectomies for gastric ulcer which he has performed since 1909 is 118. There have been two deaths, a mortality of less than 2 per cent. There is only one unsatisfactory case in the series; in none have there been the development of carcinoma or a return of the ulcer. In the same period he has operated upon 651 cases of duodenal ulcer with three deaths. He finds gastrectomy the most satisfactory operation. All other methods fail in one or more particulars. Gastrectomy has a small mortality, the quality of the recovery is excellent, and the results are as near perfection as they can be. The operation of gastrectomy has been much simplified. When the stomach is freed from the duodenum and along the two curvatures the question to decide is as to the method of attachment of the jejunum to the part of the stomach which remains. At the present time Moynihan joins the cut end of the stomach to the jejunum drawn straight across the colon near the splenic flexure from left to right. The proximal part of the jejunum meets the greater curvature of the stomach, and no jejunal loop is left. This reduces the operation to its simplest terms, and to the easiest and speediest performance.

5. **Complete Heart-Block with Post-Mortem Examination.**—Henry Waldo and C. E. K. Herapath report this case occurring in a bachelor 62 years of age, who contracted a primary sore 25 or 30 years ago. He suffered from attacks resembling petit mal. His systolic blood pressure was 110 mm. Hg. The diagnosis was heart block with destruction, probably complete, of the auriculo-ventricular bundle. He died in an unconscious attack. Post-mortem complete destruction of the bundle of His was found; the junctional tissues had been picked out for attack and the damage was almost confined to this area, the whole bundle being destroyed, even to the upper part of the two main branches. The heart had evidently been contracting for some years, with no connecting link between the auricles and ventricles; in other words, the stimulus for the ventricular contractions had been rising from some part of the bundle, and the rhythm was what is termed the idioventricular rhythm. Cessation of ventricular action occurred because the fibrosis finally cut the ventricles off from this last stimulus-producing area, and no further stimulus for contraction could reach the ventricular muscle.

1. **The Choroid Plexus and Psammomas.**—John Bland Sutton shows that the structure of psammomas supports the idea that they arise from choroid plexuses and arachnoid tufts. The tissue is arranged in whorls, and in the center of each there is a blood vessel. The idea of a cluster of villi surrounded by fibrous tissue, and the whole encapsulated by a laminated capsule, is irresistible. When the mass of choroid plexus or arachnoid tuft, is completely invested, and the growth arrested, the sequestered epithelium becomes impregnated with cholerterin sand. Hence the picturesque names—psammoma, cholesteatoma, and pearl tumor. A psammoma infiltrated with cholerterin is a dead tumor, but it rarely dies before it has wrecked the life of the man or woman by damaging brain or spinal cord. The clinical symptoms produced by these extraordinary tumors sometimes permit of exact localization; often

they are complicated tangles difficult to unravel. The villi of the arachnoid erode bone, as the Pacchionian foramina prove; chorionic villi, normal and abnormal, can penetrate the walls of the uterus, and ovarian papillomas in a favorable environment erode bone. These facts furnish sufficient evidence to justify the removal of psammomas from the miscellaneous group at present labelled endotheliomas.

3. **Gastric Syphilis.**—David J. Galloway asserts that gastric syphilis, while by no means common, is by no means the excessive rarity it is commonly assumed to be. The reason for this opinion may be owing to the fact that the writer's experience is almost wholly with Asiatics. Of four cases which he reports only one occurred in a European. Clinically these cases were very presentable pictures of three distinct gastric conditions—malignant tumor, gastric ulcer, and a subacute gastritis. From the histories all of them were the result of acquired disease. The only symptom that might give a pointer as to the nature of the lesion is the character of the pain. While there do occur cases of malignant disease of the stomach which throughout their course are "silent," they are the exception. Pain in gastric syphilis is never at any time pronounced, but is always there, dull and constant, sometimes better, sometimes worse, especially at night, and limited to a zone extending right around the body a little below the level of the diaphragm. There is, of course, always the possibility of such cases merging into malignancy. A second group of cases, mimetic of gastric ulcer, are not as a rule difficult of diagnosis. Though vomiting is a symptom, excessive vomiting is unusual, and unless of spinal origin not easily explained. The symptoms common to all were thickening, almost amounting to tumor formation, in the epigastrium, tenderness on palpation, vomiting and presence of blood in the vomited matter. In ulcerated gumma of the stomach there is a constant substratum of pain, not much aggravated by eating, but greatly so by the effort of vomiting, radiating laterally, and forming a girdle of pain which, as usual, is worse at night. Hemorrhage in gastric ulcer is usually copious, coffee-ground or bright red color. In gummatous ulcer the blood comes up only with food, is in small clots, and bright red only at the end of a severe effort at vomiting. In that class of cases resembling subacute gastric catarrh, some assistance may be had from test meals, as all the cases in which it was given had a pronounced hyperchlorhydria. The signs of gastric syphilis are enlargement of the liver (and occasionally also of the spleen), with smooth outline, present in three-fourths of all cases; secondly, rapid development of cachexia, and thirdly, stigmata of syphilis. The real test is the empiric, the therapeutic, and that may be applied from both its negative and positive aspects.

5. **A Case of Primary Carcinoma of the Lung.**—G. S. Haynes and J. F. Gaskell report this unusual case in which the chief points of interest are: The age of the patient, 27 years; the duration of the symptoms, five months; the similarity to tuberculosis of the lungs—wasting, fever, cough, hemoptysis, pleural effusion, and pneumothorax; the temporary improvement under open air treatment due to the elimination of secondary infection; the total absence of pain; the involvement of one lung only, and the rapid enlargement of the mediastical and cervical glands. The right lung was extensively involved while the left lung was unaffected, but yet the left cervical glands were considerably more affected than the right, the path of spread being probably among the course of the thoracic duct.

8. A Note on the Treatment of Vomiting in Malaria. F. Lomax Wood.

1. **Epilepsy and Some Kindred Attacks.**—Robert Armstrong-Jones says that in the treatment of epilepsy it is essential to separate cases of organic brain disease from those due to such causes as intestinal troubles, worms, dentition, lead-poisoning, uremia, and the diathetic diseases. In the treatment of idiopathic epilepsy it is most important that the epileptic be kept in good general health. The best remedies for controlling the fits and the three bromides in 5-grain doses, together with 1 grain of the soluble luminal sodium twice a day, on alternate days, and then stop three days, late in the afternoon and early in the evening, so as to secure the maximum effect toward bedtime. The biborate of sodium with bromides may be substituted if there is a tendency to drowsiness. Hydro-bromic acid has in drachm doses three times a day been most beneficial in cases with noises in the ears, and for these tablets of oxy-quinotheinmeine have been effective. Monobromide of camphor in 5-grain doses has helped to control the number of fits, oxide of zinc in 3-grain doses, and in children tincture of belladonna in 10-minim doses three times a day. Nitrate of potassium, 5-10 grains has been useful when there has been an increase of blood pressure. The reputed value of some physical remedies, such as deep inspiration before the aura, is confirmed and may ward off an attack, while compression of the carotids, and even ligature fo the vertebrals, have their advocates, but the value of some remedies may be due to suggestion. It is helpful in treatment to record the number of fits daily and nightly, and the hour at which they occur, keeping a chart of the sleep, the organic functions, and the body weight in order to compare these under the influence of different remedies. This chart—which can be kept by the relatives—provides a useful history of the progress of the case and keeps up an interest in the cure.

8. **A Note on the Treatment of Vomiting in Malaria.**—F. Lomax Wood has found that 7 to 8 minims of adrenalin hydrochloride in 1½ ounces of water controls attacks of vomiting in malaria. He first gave the adrenalin solution for the control of hematemesis and found that it rapidly brought about a cessation of vomiting. The adrenalin solution has relieved the vomiting in all patients suffering from malaria to whom it has been given.

Hypertrophy of the Hypophysis in Pregnancy.—Jung refers to the original discovery of this coincidence by Erdheim and Stumme, with the occasional supervention of acromegalic alterations in the women. There is abundant evidence of an antagonism between gonads and hypophysis. In gestation underfunction of the ovaries is associated with overfunction of the hypophysis. The increased size of the latter appears in radiograms through the expansion of the sella. Despite this enlargement it seldom leads to clinical manifestations of a severe character. In but two recorded cases did the hypertrophy cause symptoms of acromegaly or tumor in the sella. Petty symptoms pointing to the hypophysis are not so rare. The aim of the author is to add to the two severe recorded cases another personal to him, which is strikingly like one of its predecessors. The woman was forty-five years old, seven months pregnant, with history of nine normal pregnancies in which naturally there were no visual disturbances. Ever since the last conception she has complained of progressive impairment of vision. On admission with this history an enlargement of the hypophysis was suspected and the *x*-ray showed the correctness of the assumption. The condition was so urgent from the standpoint of the prevention of blindness that abdominal hysterotomy was at once performed with tubal sterilization. At the end of three days the patient could distinguish objects and individuals. Aside from the evidences of compression of the chiasm there were no other symptoms, hyperpituitarism being absent throughout in all of its manifestations. At the present time there is some improvement in visual acuity, but the fundal finds point to considerable permanent damage of both optic nerves. There is complete bitemporal hemianopsia with contraction of the visual fields to the fixation point.

Book Reviews.

THERAPEUTIC IMMUNIZATION IN ASYLUM AND GENERAL PRACTICE. By W. FORD ROBERTSON, M.D., Pathologist to the Scottish Asylums. Price, $4.00. New York: William Wood and Company, 1921.

THERAPEUTIC Immunization implies the immunological attack on diseases wrought through the activity of the specific stimulation of the defensive mechanism of the body against actual bacterial invasion with the object of destroying or expelling the offending organism, thereby restoring health to the patient.

Practically, the book deals especially with the administration of vaccines, or better, bacterins. Dr. Robertson discusses the value of autogenous and stock vaccines and summarizes the topic of "detoxicated" vaccines, mentioned especially by Dr. David Thomson. The inference is drawn that detoxicated vaccines may be objected to on the ground that their exact dosage is not easily regulated and that the chemistry involved in their preparation permits the inference that the detoxicated vaccine no longer stands in physical relation with the organism causing the disease.

The bacteriological methods incident to the practice of therapeutic immunization are discussed in a series of chapters characterized by intense practicability in that the technque is brought within reach of average clinical training. It is important to observe the author's criticism on the standardization of vaccines in which he points out the error incident to standards of turbidity and actual counts. The method proposed is accredited to J. J. Ritchie and depends upon the weight in milligrams of bacterial protein present in each cubic centimeter of vaccine. It is recommended that they be prepared of such strength that one-tenth of a cubic centimeter contains the initial dose of the vaccine in question.

The remaining half of the book is devoted to a brilliant résumé of the indications and methods for the treatment of bacterial infections by therapeutic immunization, the author dividing the subject into diseases grouped as originating from types of organisms: (1) Staphlyococci; (2) Streptococci; (3) Coli-typhoid Bacilli; (4) *Bacillus proteus;* (5) Gramnegative diplococci; (6) The Bacillus of diphtheria; (7) Diphtheroid bacilli; (8) Influenza bacillus; (9) Tubercle bacillus; (10) *Diplococcus crassus;* (11) *Bacillus septus;* (12) *Micrococcus tetragenus;* (13) *Bacillus pyocyaneus;* (14) Strepothrices; (15) *Bacillus lepræ;* (16) *Bacillus mallei.*

In conclusion, the author summarizes the cause of failure of therapeutic immunization, mentioning "the unsuitability of the case, a defective bacteriological analysis, faulty vaccines, wrong dosage, relapses from natural causes, the acquirement of new or reinfection, the infection of closed cavities, toxin saturation, and persistent hypersensitiveness." Of these, the one that leads most to unsuccessful therapeutic immunization is the defective bacteriological analysis.

There are many good reasons for welcoming so authoritative a treatise on a subject in which our knowledge is fragmentary and scattered. Dr. Robertson advances principles, the following of which will eliminate the improper and random use of vaccines and will make for the standardization of an excellent therapeutic method applied according to scientific indications and in anticipation of defintely premeditated results.

DIE IMPOTENZ DES MANNES (Die psychischen Störungen der männlichen Sexualfunktion) Störungen des Trieb- und Affeklebens. IV. Von Dr. WILHELM STEKEL, Nervenartz in Wien. Price, 75 marks. Berlin and Vienna: Urban & Schwarzenberg, 1920.

THIS fourth volume of Stekel's work on "Disturbances of the genesic function and their effects" is a pretentious book of nearly five hundred pages. It is divided into twenty-one chapters, which deal with impotence from every viewpoint, but particularly through the vision of the psychoanalyst. He gives adequate consideration to the social relation of men and women, the physiology of coition, unconscious love and hate, onanism, and occupation as influencing impotency. One chapter is give to special conditions affecting male potency. He furthermore discusses the relation of the impotent man to general social and economic institutions and conditions, such as religion, war, and criminality. The section on Pollutions was written by Dr. Tannenbaum of New York. The work abounds in case reports and literary references illustrating specific mental states. It is replete with aphorisms such as "Inventions are the spiritual translation of most sexual problems into the language of technique;" "Man's erectile ability begins with birth and ends with his death;" and "Man is only as old as he feels. Impotent becomes the man who gives up his potency." The last is small consolation to the sexual cripple suffering from sequelæ of venereal infection. The reader is impressed with the author's sincerity, mental honesty, his desire to teach, and the generous credit given to his cotemporaries.

THE CARE OF EYE CASES—A Manual for the Nurse Practitioner and Student. By ROBERT HENRY ELLIOT, M.D., B.S. (Lond.),, Sc.D. (Edin.), F.R.C.S. (Eng). Lieutenant-Colonel I. M. S. (retired); Late Superintendent of the Government Ophthalmic Hospital, Madras, and Professor of Ophthalmology, Medical College, Madras, Honorary Fellow and Gold Medallist of the American Academy of Ophthalmology and Oto-Laryngology, Lecturer in Ophthalmology, London School of Tropical Medicine, Ophthalmic Surgeon to the Seaman's Hospital Society, to the Hospital for Tropical Diseases, Endsleigh Gardens, London, and to the Prince of Wales' Hospital, Tottenham With 135 Illustrations. Price, $4.50. New York: Oxford University Press, American Branch, 1921.

THE first part of this little book contains a great deal of interesting and instructive material not only for the nurse but even for the practicing eye man, as it treats of subjects that are accepted as matters of fact and therefore passed over in most of the text-books. While the average training nurse in a general hospital may be taught the care of general surgical, gynecological, and other cases. she comes but rarely in touch with eye cases, and therefore requires special training to become competent in handling them. Besides, the eye cases require greater care and gentleness than possibly any other postoperative cases, as negligence may be fraught with irreparable loss of vision. It is preeminently here where careful attention to details and a clear conception of the aim of the operation count for much. The eminence of the author and his enormous practical experience lend great weight and authority to all he has to say. The second part of the work is devoted to a very cursory review of various eye diseases. It is rather doubtful whether such a superficial and fleeting summary or digest of important pathological eye conditions will serve the purpose of enriching the mind of the nurse with any knowledge on eye conditions. There is surely a limit to conciseness beyond which it becomes absolutely useless, and we hope that in future editions the author will devote more space to the diseases of the eye the elementary knowledge of which is of such great importance to the eye nurse.

HEART DISEASE AND PREGNANCY. By Sir JAMES MACKENZIE, M.D., F.R.C.P., LL.D., Edinburgh and Aberdeen, F.R.S., F.R.C.P.I.; Hon. Consulting Physician to His Majesty the King in Scotland; Director of the Institute for Clinical Research, St. Andrews; Consulting Physician to the Victoria Hospital, Bombay, and the London Hospital. Price, $3.50. New York: The Oxford University Press, American Branch, 1921.

THIS is a book of which apparently there is a real need. The author said that his attention was called to the subject when listening to a paper on "Pregnancy Complicated by Heart Disease," in which the reader gave evidence of knowing nothing of the advances made in cardiology during recent years. Sir James was thus led to examine a number of the latest treatises on Obstetrics and found that the same ignorance was displayed by them all. The result of this quest was a determination to supply the missing information which is done in the present book in the author's usual lucid style. Every obstetrician should, for the sake of the suffering woman women who look to him for help, make himself thoroughly familiar with the modern teaching in cadiology so far as it affects his special practice, and this he can do by a study of this excellent little book.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 19, 1922.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Digitalis—Its Absorption in Man.—Dr. CARY EGGLESTON and Dr. JOHN H. WYCKOFF presented this communication from the department of Pharmacology, Cornell Medical College, and the Second (Cornell) Division, the Third (New York University) Division of Bellevue Hospital. They stated that as was well known different samples of digitalis differed widely in their effectiveness when administered to man, and likewise when administered to animals. The literature in regard to the absorption of the various digitalis preparations was scant in amount. Dr. Hatcher and one of the authors for some years had been investigating the action of the various digitalis preparations. They had worked out a method by which the dosage of various digitalis preparations could be standardized. This they had called the "cat unit" by which was meant that amount of the drug which was just sufficient to kill one kilogram of cat when slowly and continuously injected into the vein of of the animal. This was expressed in milligrams of the drug. They had also demonstrated in their former articles that in order to induce effects rapidly by oral administration digitalis must be administered in larger doses than formerly were considered desirable or necessary. They had further shown that 0.066 of a cat unit or 0.023 mg. per pound of body weight was the average therapeutic dose of digitoxin, and also that there was great variability in the degree of absorption of various preparations. Wedd had shown that infusions of digitalis leaves contained a chloroform soluble and a chloroform insoluble part and that the chloroform soluble portion was absorbed at least as rapidly as the best tinctures. Hatcher had shown that there was a part of the digitalis body which was rapidly absorbed and rapidly eliminated and produced a fleeting effect. The present paper had to do with the comparative action of various pharmaceutical preparations of digitalis and that of numerous preparations and combinations of preparations purified by a special method which was described in detail. The action of these purified preparations and of the ordinary pharmaceutical preparations was observed in a series of some seventy patients suffering from auricular fibrillation, sinus arrhythmia, partial heart block and extrasystole. The observations made in 52 of these cases were tabulated, including data in regard to the dosage in cat units, the time at which the first effects of the various preparations became evident, what these effects were, the time at which they reached their maximum intensity, etc. The doses administered varied from 0.04 to 0.073 of a cat unit per pound of body weight, the average dose being 0.054 of a cat unit per pound. Among the more general observations brought out by this investigation were the following: The present observations confirmed former work as to the value of the comparatively large doses of digitalis advocated by the writers. The effects of the drug were manifested in a short time after its administration, from six to eighteen hours, instead of at the end of two or three days, as formerly believed. The effect of digitalis was as a rule manifested before nausea or vomiting appeared and the appearance of these symptoms was a warning to desist from the further administration of the drug at least temporarily. With the purified preparations the size of the dose and the variation from the average dose was not quite as marked as with the ordinary official preparations. In a former study the variation was 50 per cent. above and below the average; in the present study with the purified preparations the variation above and below the average dose necessary to produce similar effects was 30 per cent. In a general way, it might be stated that on the whole the average high grade, pharmaceutical preparations of digitalis on the market were fairly trustworthy agents. One must ascertain the proper dosage for each individual patient. There were still two undetermined factors involved in the estimation of digitalis dosage. One of these factors was the variation in the strength of different digitalis preparations and the other was the difference in the response of the individual heart to the drug.

Dr. ALFRED E. COHN said they had all no doubt been struck by two points in the paper, which two points presented new and important additions to the knowledge of the use of this drug. The first one was that the action of digitalis could be obtained in a few hours after its administration—in some instances even as soon as 1½ hours. It was the general impression held several years ago that it required two or three days before one could count on getting the effect of digitalis. This was a very important advance from the clinical standpoint. The second point was that it was possible to obtain a satisfactory effect from digitalis before nausea and vomiting was brought on. He recalled that a few years ago an eminent professor had made the statement that one could not be certain of an effect from digitalis until the patient was seen to be nauseated or to vomit. When one recalled how serious or at least disagreeable these untoward symptoms were it was easy to see how great the advances were which had been made. Dr. Cohn said he had really nothing to add to what Dr. Eggleston had said nor had he anything new to add to the state of knowledge of electrocardiography about which he was asked to speak. He had, however, brought a few slides which might be of interest as they demonstrated the relation of changes in the T-wave in the electrocardiogram to the administration of digitalis. He showed records of one case in which 1.5 gms. of digitalis had been administered. The inversion of the T-wave which was fully developed on December 7th, continued for 19 days. Then the T-wave reverted to its initial form. While Dr. Eggleston had shown how rapidly digitalis was absorbed, he had not said much in regard to the length of time during which its effect was manifested. Cases like that, the curves of which were projected on the screen, showed the prolonged influence of the drug. More recently they had been interested in quinidine. Electrocardiograms from a patient so treated showed changes similar to those due to digitalis. Digitalis, therefore, did not exert a specific effect so far as the electrocardiogram was concerned. An inspection of the slides showing the inversion of the T-wave showed that the process really began in the R-T interval before the beginning of the T-wave; the changes in the heart that produced this change had not yet been satisfactorily explained. Neither was the mechanism by which the change was brought about understood. However, Dr. Cohn recalled observations which had been made with the galvanometer and which he described by means of a diagram, which seemed to show that the inversion of the T-wave was dependent upon prolonged activity in the lower portion of the ventricular muscle. He showed tables, demonstrated at the Academy by Dr. Levy in 1920, in which some of the phenomena described by Dr. Eggleston were illustrated. One of these showed that when the heart's mechanism was normal the onset of the inversion occurred 24 to 48 hours (average 36 hours) after the administration of digitalis and lasted 6 to 15 days (average 10 days). Thirty-six hours was rather a long period before the onset of inversion of the T-wave. In 27 cases of auricular fibrillation examined by the electrocardiograph with reference to this point it was found that onset of the change occurred in 7 to 48 hours, the average time being 24 hours. An effect on rate was seen as early as from 1 to 11 hours (average 3 hrs. 15 mins.) after the administration of 0.7 to 2 grams of the drug given in two doses with an interval of one hour. The duration of the inversion of the T-wave was on an average 12 days, the shortest duration being 3 days and the longest 31 days. It was rather an extraordinary thing that digitalis should preserve its action as long as one month after a dose administered on a single day, and the point he particularly wanted to bring out was that the duration of the inversion of the T-wave in the electrocardiogram might be employed to give one a conception of the rate at which digitalis was eliminated. To have this method was important in the absence of a chemical or other means of making such an estimation.

Dr. ROBERT A. HATCHER said the composition of digitalis was known to be extremely variable and anything like a discussion of the composition of the various

preparations was out of place at this time. He might say, however, that all the therapeutic effects which followed the oral administration of digitalis were probably due to digitoxin or digitoxin-like substances. There was no way of estimating the amount of digitoxin in any preparation. There were preparations of digitalis on the market for which it was claimed that the amount of digitoxin had been estimated. But this was not correct for when the manufacturer referred to digitoxin he meant impure substances. There was present in digitalis a principle which was eliminated in a few hours, the nature of which was unknown and had never been described. The only advantage in this purified digitalis was that it was possible to estimate the proportion of the preparation which was active, that was the proportion of digitoxin and digitoxin-like substances. They had tried to do that with the tincture but they had not been able to determine the amounts present in the tincture. As to the nausea and vomiting, the evidence seemed to indicate that the amount of digitalis required to produce nausea and vomiting was proportional to the amount of digitoxin-like substances present in the preparation and not proportional to the total activity of the tincture. They had not been able to prepare the digitoxin-like substance in any uniform way. Work was under way which afforded hope that a process would be devised by which any chemist or pharmacist could make the preparation.

Dr. B. S. Oppenheimer said there was a large gap between the preceding speakers who were authorities on digitalis and pharmacologists and himself who had had experience with digitalis only as a hospital doctor. He believed that this gap between the pharmacologists and the practitioner should be bridged over so that the two might get together as was done in the particular instance which he wished to cite. (In this connection it might be of interest to mention that in 1910 Professor Cushny, an authority on digitalis, used to make rounds with Sir James Mackenzie once a week.) In 1919, it was noticed in several wards of Mt. Sinai Hospital that the standardized digitalis in the usual dosage seemed inactive in cases of auricular fibrillation, and the matter was referred to him for investigation. Three cases of auricular fibrillation which should have shown digitalis effects were selected: (1) Male, aged 64, auricular fibrillation and pulse deficit. He received 540 m. of the tincture of digitalis and 21 ounces of the infusion in 23 days (equivalent to a total of 134 c.c.). After 23 days he showed no slowing and the pulse deficit persisted. (2) A male, aged 24, mitral stenosis and insufficiency, auricular fibrillation, pulse deficit. He received 3090 m. of tincture in 38 days with no effect. (3) Male, aged 23, mitral stenosis and insufficiency, auricular fibrillation, constant pulse deficit, and rapid rate in spite of 3735 m. of tincture of digitalis (equivalent to a total of 233 c.c.), in 43 days. Ordinarily therapeutic or even toxic effects would have followed such doses. The three patients received at least five times the maximum average dose in the ordinary tincture the speaker had been using. It was true the dose had been distributed over fairly long periods. A sample of this digitalis was turned over to Professor Hatcher and Dr. Eggleston. They reported that the specimen was of average activity when tested by the biologic method, but that it was very low in the chloroform-soluble fraction, that was, in the fraction that was readily absorbed and slowly excreted. About the same time two other samples of inactive digitalis came from Cleveland and one from New Jersey, and it was found that all three came from the same reliable drug house. On further investigation it was found that during the war period, this digitalis came from an unusual source, and the matter was promptly corrected. They learned then for the first time that not only should digitalis be assayed for its activity, but that absorbability was a factor that must be considered. Professor Hatcher subsequently gave them a supply of the purified tincture, which Dr. Eggleston and Dr. Wyckoff had been using clinically, and with it they had satisfactory results.

Dr. T. Stuart Hart said he thought all would agree that digitalis was a real drug. Some years ago they had reached the conclusion that in order to get results with this important therapeutic agent it must be administered in quantities to get the physiological effects. Then the question arose as to how they were to specify in minims or ounces or grams the amount of drug they were to administer. When they found out how most patients with auricular fibrillation responded to the administration of digitalis by a slowing of the rate and a diminution in the deficit it seemed an easy matter to standardize the dosage. But then their troubles commenced. They found that with different preparations different quantities were necessary in order to produce full therapeutic effects. At this point the pharmacological assays, chemical and biological, came to their aid, and frogs and cats were pressed into service. These tests demonstrated that certain digitalis leaves contained much more of the active glucosides than others, so they then selected good leaves properly preserved. Further, certain preparations kept better than others and they began to use only freshly prepared stock and to devise better ways of preservation. Even then they did not get uniform results from the standard dose. Dr. Cohn gave them a new method of testing the earliest evidences of digitalization and this was one more step forward in determining dosage accurately. Then the determination of the rate of elimination was studied and Dr. Pardee and others showed them that the time element was a very important one, that elimination occurred at a rate which they could definitely estimate; it made a great deal of difference whether one administered a given amount of digitalis in a period of two days or spread the same amount over a week. The degree of saturation became an important consideration. To eliminate the time element Dr. Eggleston introduced his so-called massive doses and this simplified the study of dosage. With all this added knowledge their results were still very uneven and from time to time they all had experience such as Dr. Oppenheimer had just described. Dr. Hatcher, who had been a leader in all these studies, discovered that certain fractions obtained by extraction of the leaf were more readily absorbed than others and that certain leaves contained more of these absorbable fractions than others. The work of Dr. Eggleston and Dr. Wyckoff presented in the paper of the evening had taken this problem of absorption from the laboratory of animal experimentation to the bedside. In a well-equipped hospital under effective supervision and control they had made these observations which appeared to him to effectively prove a vast difference in the rate of absorption of these fractions of digitalis leaf. He thought they should be congratulated on an excellent piece of work and on the fact that they had brought results obtained in the clinic and which therefore were of immediate practical value. Every one of the steps he had recounted had brought them nearer to an understanding of an approximation of an average standard dosage of digitalis. He felt, however, that even with our present knowledge we could not state the exact dose which the individual which we cared for in the home should receive to be effectively digitalized. There one could not have the elaborate instruments to watch every change in the heart activity, nor could one have as a rule the close personal supervision which a well organized hospital afforded. As the readers of the paper had pointed out there were still some unsolved variables such as the different rates of absorption in different individuals and possible also a difference in the reaction of individual hearts to the drug. The figures presented showed a considerable variation in the time of the initial reaction and the time and effective amounts when cases were compared which were treated with the same purified tincture. These differences, Dr. Hart said, were too great to be disregarded and he, therefore, believed it was safer, in general (unless the need was very urgent) to administer the drug gradually, watching the effects. The use of this new "purified tincture" apparently showed a great improvement over old tinctures in the variation of dosage to which different patients reacted. With the old tinctures the variation in dosage to which different patients reacted was 50 per cent. above and below average. With the purified tinctures this difference had been reduced to 30 per cent. above and below average. In an urgent case he felt one could safely give the large doses outlined in the paper. In reference to the symptoms by which the effect of full digitalization should be measured in the home, the elec-

trocardiogram need not be discussed; this was of great value when available but of course was usually impossible. In auricular fibrillation digitalis should be pushed until the rate was in the neighborhood of 70 and the pulse deficit had disappeared. In cases with a regular heart one might use the polygraph to detect changes in the conduction period or with eye, ear and finger one could watch for changes in the rhythm indicating a partial block or a coupled rhythm, etc. To give digitalis intelligently one must be able to distinguish between sinus arrhythmia, auricular fibrillation, extrasystoles, partial heart block, etc. Nausea and vomiting were important symptoms in patients with serious heart disease and cardiac insufficiency, were frequently due to chronic passive congestion of the viscera and usually what these patients needed was digitalis. If one was giving only small doses, for example 0.01 cat unit per pound of body weight, that was about 5 minims three times a day for a patient weighing 150 pounds, and nausea developed one should not attribute this to digitalis, it was much more likely due to the need of more digitalis. Dr. Hart said that, in his opinion, while each one of these lines of investigation had added very greatly to our knowledge of this valuable drug, and while the massive dosage was of very great value in experimental work with patients under the best control, he believed that in general practice the more gradual approach to digitalization was to be preferred. The size of the dose must be adapted to the individual patient. One should get the very best preparation of digitalis he could secure, made from potent leaves, in a form that would not deteriorate, and the kind that was best absorbed, study and use this preparation until he knew all about it and what he might expect from it, but above all else he should study the reactions of the individual patient.

Dr. ROBERT H. HALSEY said that the question of the control of tachycardia by digitalis was important to understand. It was not necessary to spend time to prove the possibility for it was well known that some tachycardias could be controlled. Tachycardias could be controlled by the various methods of dosage which had been outlined by previous speakers and were familiar enough to those present not to require more time in discussion. What he desired to emphasize was the effect that digitalis exerted upon the rhythm and rate of the heart. This he could best accomplish by showing on the screen a few lantern slides of illustrating electrocardiograms. The electrocardiograms of three cases of auricular fibrillation and impure auricular flutter, with grossly irregular and regular ventricular rates from 140-160 per minute, showed that the rate could be slowed very promptly by digitalis. In a case of paroxysmal ventricular tachycardia with complete block the ventricle beating at 165 per minute and the auricle at 75, digitalis had repeatedly brought about a return of the normal sequential rhythm. To demonstrate that complete block existed the patient was given some simple exercise and it was shown that the ventricle did not increase its rate though the auricular rate became 100 per minute. It was characteristic of paroxysmal tachycardia that rest and exertion were without effect on the rate. Dr. Eggleston and Dr. Cohn had mentioned the time it required for the digitalis effect on the heart to wear off; in this case it required 18 days for the electrocardiogram to return to normal. Large doses of digitalis could produce ventricular tachycardia with complete dissociation of auricle and ventricle as was shown by the electrocardiagrom. From the record one could not be sure whether the pace-maker was dislocated to the auriculo-ventricular node and retrograde conduction or whether there were similar rates in both auricle and ventricle. There were one or two places where there was sequential rhythm for one beat and then the return of the ventricular tachycardia. This condition had been brought about in a man who had drunk his tincture of digitalis, as he would whiskey, from the bottle. On admission to the hospital the high rate had suggested the need of the electrocardiogram for the analysis of the mechanism and when the record had been studied with the history all therapy had been discontinued and, as the subsequent records demonstrated, all grades of block occurred in what might be called retrogression until normal sequential rhythm of auricle and ventricle remained unaffected. The final records showed the complete disappearance of digitalis effect, when the T-wave had resumed in full its upward direction. Another slide illustrated the effect of Cheyne-Stokes respiration upon the ventricular rate of a heart which was being digitalized. It was shown that the hyperpnea phase of the periodic breathing slowed the ventricle very much, to 40 or 50, while during apnœa the rate became as high as 130-150. During the slow period the patient was in very great distress, sitting up and gasping for breath. During the period of rapid rate he was comfortable. To learn what effect the rate had upon the condition atropine was administered hypodermically and the rate promptly escaped from the vagus control remaining at 150-160 per minute. During the persistence of the high rate the patient was comfortable and quiet though the periodic breathing persisted. Subsequently the records showed that the patient was much more comfortable without the digitalis although the ventricular rate become considerably increased. Thus under the conditions it was better for the patient to be without digitalis though having fibrillation of the auricle. The main idea Dr. Halsey said he desired to emphasize was the importance of knowing by careful observation, the rate and rhythm of the ventricle from the beginning of digitalis therapy, in order to decide whether to increase, decrease, or discontinue the use of digitalis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF NORTH CAROLINA.

Raleigh, June 20, 1921.

(*Continued from page* 396.)

CHEMISTRY, PHYSIOLOGY, AND HYGIENE.

1. Define: Inorganic, organic, acid, base, salt, efflorescence, deliquescence, and catalytic action.

2. To what is temporary and permanent hardness of water due, and how may temporary hardness be removed? How is ethyl ether made and what are its properties?

3. What are the halogens, and what do they form when combined with other elements? What are alkaloids, and to what chemical group or groups do they belong? Name the liquid volatile ones.

4. Define enzymes, and give their general properties. What is a hormone and chalone? Are all proteins of equal value as food? Why?

5. What are the functions of the leucocytes? Are leucocytosis and leucopenia both always pathological?

6. What are vitamines, and where are they found?

7. Trace briefly the fifth cranial nerve from its deep origin to its final distribution, and give its general functions.

The following to be answered by those only who are taking final examinations.

8. Define the terms hygiene and sanitation. Name the common acute communicable diseases, and by what means each may be communicated.

9. Name the different sources of drinking water, and tell how each may be safeguarded. In estimating a city's water supply, what should be the minimum for each inhabitant per diem?

10. How may night-soil of small towns and rural communities be disposed of so as to be of little danger? What is a septic tank and what is the theory of its operation?

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. Discuss briefly the pathology and bacteriology of epidemic influenza.

2. Discuss wound healing.

3. Discuss the criteria of malignancy of tumors; (*a*) Name three malignant tumors giving sites. (*b*) Name three benign tumors giving sites.

4. Give an outline of the method of the Wassermann test for syphilis.

5. Given a laboratory culture of an organism growing on agar agar, how would you distinguish between typhoid, paratyphoid A, paratyphoid B, and *Bacillus coli?*

6. Describe the bacteriology of Vincent's Angina.

7. Discuss briefly the method of infection of: (*a*) Two diseases caused by protozoa. (*b*) Two diseases caused by filtrable virus.

8. Name diseases against which you would recommend prophylactic vaccination.

9. Name diseases against which you would recommend curative sera.

10. What is the difference between active and passive immunity?

ANSWERS.

CHEMISTRY, PHYSIOLOGY, AND HYGIENE

1. *Inorganic chemistry* is the chemistry of substances which do not contain carbon.

Organic chemistry is the chemistry of carbon and its compounds.

Acid is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for a metal or its equivalent without the formation of a base.

Base is a ternary compound capable of entering into double decomposition with an acid to form a salt and water.

Salt is a compound formed when a metal or its equivalent replaces part or all of the hydrogen of an acid.

Efflorescence is a property possessed by certain crystalline bodies, by virtue of which they lose their water of crystallization and fall to powder on exposure to the air.

Deliquescence is that property possessed by certain solids whereby they absorb moisture from the air, and eventually become liquid.

Catalytic action is that property possessed by certain bodies whereby by their mere presence certain chemical reactions are brought about or accelerated.

2. *Temporary hardness* of water is due to the presence of the bicarbonates of calcium or magnesium.

Permanent hardness is due to the presence of sulphates.

Temporary hardness may be removed by boiling the water.

Ethyl ether is made by the action of sulphuric acid upon ethyl alcohol, and the further action of ethyl alcohol on the sulphovinic acid which results from the first reaction:

$$C_2H_5OH + H_2SO_4 = H_2O + C_2H_5HSO_4$$
$$C_2H_5HSO_4 + C_2H_5OH = H_2SO_4 + (C_2H_5)_2O$$

Properties of ethyl alcohol. It is a colorless liquid, with a peculiar and tenacious odor; it is lighter than water; it is very volatile; it is very inflammable; its vapor forms an explosive mixture with air; it is a good solvent of fats, resins, alkaloids, etc.; mixes with water in all proportions; and it boils at 95° F.

3. *The halogens* are: Fluorine, chlorine, bromine, and iodine. When combined with (some) other elements they form salts; as calcium fluoride, sodium chloride, potassium bromide, potassium iodide.

Alkaloids are organic, nitrogenous substances, alkaline in reaction, and capable of combining with acids (to form salts) in the same way that ammonia does.

Alkaloids are generally regarded as secondary or tertiary amines.

The liquid, volatile alkaloids, are: Coniine, nicotine, sparteine.

4. *Enzymes* are bodies produced by living cells, and are capable of producing certain definite chemical changes in certain substances under certain well-defined conditions, and without themselves undergoing any alteration. Their chemical composition is unknown; not one of them has ever been isolated in an absolutely pure condition; it has been assumed that they are of a protein nature.

General properties of enzymes: They are generally soluble in water, or salt solutions, or in glycerin; they do not work in extreme temperatures, but require an "optimum" temperature approximating that of the body; they are precipitated by excess of alcohol; they require a suitable medium to work in; the products of their activity must be removed; they are capable of causing change in a large amount of material, while they themselves remain unaltered; and each enzyme will act on only one kind of substance.

Hormones, or "chemical messengers" are substances formed in one organ, and carried (probably by the blood stream) to another organ to induce this latter organ to perform some function.

A *Chalone* is an inhibitory hormone.

All proteins have not an equal food value; this is on account of the difference in the number and character of the different amino-acids of which the proteins are composed.

5. *Functions of the Leucocytes:*—(1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

Leucocytosis may be physiological as well as pathological.

Leucopenia is probably pathological.

6. *Vitamines* are accessory food substances which are necessary for the proper nutrition of the human body. They are known as Fat-soluble A; Water-soluble B; and anti-scorbutic vitamines.

The fat-soluble A is present in: Milk, butter, cream, cabbages, potatoes, beans, fat fish, and some meat.

The water-soluble B is present in: The husks of cereals, eggs, yeast, most vegetables, and some meat.

The anti-scorbutic vitamine, is present in: Fresh vegetables, fruit juices, raw meat juice, milk.

7. FIFTH CRANIAL NERVE. *Superficial origin.*—From the side of the pons Varolii. *Deep* (sensory root), from the medulla and upper part of cord; (motor root) from the floor of fourth ventricle and side of the aqueduct of Sylvius. *Exit:* The ophthalmic division, through the sphenoidal fissure; the superior maxillary division, through the foramen rotundum; the inferior maxillary division, through the foramen ovale. *Branches and Functions:—Ophthalmic branch* distributed to conjunctiva, skin of upper eyelid, cornea, skin of forehead, and nose, lacrymal gland. *Superior maxillary,* to skin and conjunctiva of lower eyelid, nose, cheek, upper lip, upper teeth, and palate. *Inferior maxillary,* to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, and skin of lower part of face. Also to muscles as indicated below. It supplies sensation to all the parts mentioned above; but, in addition, inferior maxillary supplies motion to the muscles of mastication, the mylohyoid, and anterior belly of the digastric.

8. *Hygiene* is the science and art of all that concerns the preservation, promotion, and improvement of health, and the prevention of disease.

Sanitation is that branch of hygiene which is concerned with the suppression or removal of the predisposing causes of disease; it is the practical side of a part of the subject of hygiene.

The common acute communicable diseases are:—Cerebrospinal meningitis (may be communicated by contact, droplet infection from sneezing or coughing, or carriers; the source of infection is in the nasopharyngeal discharges). Chickenpox (communicated by contact with patient or articles soiled by discharges from lesions). Diphtheria (conveyed by contact with discharges from case or carrier; also by fomites, and milk). German measles (communicated by direct contact with patient, or fresh oral or nasal secretions). Measles (communicated by direct contact with patient or oral or nasal secretions). Mumps (communicated by direct contact with case, or articles freshly soiled with secretions of mouth or nose). Poliomyelitis (communicated by direct contact with case or carrier, and articles soiled recently with virus in discharges from nose, throat, or bowels). Scarlet fever (communicated by direct contact with case or articles with infectious discharges from nose, throat, or ear: also by contaminated milk). Smallpox (communicated by personal contact, flies, and articles soiled with discharges). Whooping cough (communicated by direct contact with cases, or articles freshly soiled by discharges).—(From Stitt's *Practical Bacteriology, Etc.*)

9. The sources and varieties of water have been classified thus:

Wholesome.	1. Spring water...	very palatable.
	2. Deep-well water	
	3. Upland surface water	moderately palatable.
Suspicious.	4. Stored rain water	
	5. Surface water from cultivated land	palatable.
Dangerous.	6. River water, to which sewage gains access	
	7. Shallow-well water	

The first four may be used for drinking water, but will require filtration and disinfection.

The amount of water required is usually estimated at 17 gallons a day for each person.

10. *Disposal of night-soil of rural communities.* The first thing is to secure as good a privy as possible; it should be watertight, fly-proof, well ventilated and capable of being cleaned. Dry earth or sand should be thrown into the vault to absorb the liquid portion. The privy should be emptied regularly, and the contents buried in a field, not less than two feet deep, and with the use of a disinfectant such as chloride of lime.

A septic tank is a specially constructed tank for the treatment of sewage; in it the sewage as such is destroyed, and new substances are built up in its place. In *Cameron's septic tank* system "the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of anaerobic bacterial action, which is favored by the darkness, the absence of air, and the perfect stillness at which the sewage is maintained. Under these circumstances much of the solid matter is rendered soluble and dissolved."—(Notter and Firth's *Hygiene.*)

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. INFLUENZA *Bacteriology.*—"The *Bacillus influenzæ*, discovered by Pfeiffer in 1892, is a very small rod-shaped organism (0.2 μ wide, 0.5 μ long), Gram-negative, and occurring singly, or in pairs or clumps. It is non-motile, and does not bear spores. It can be cultivated on blood-agar, on which it forms very minute colonies. It is found in the respiratory secretions, and less commonly in the lung, heart, central nervous system, etc., but very rarely in the blood. Contagion is conveyed by the moist secretions of the nasal and bronchial mucosa. The incubation period is from two to six days. One attack confers no immunity."

Pathology.—"The characteristic changes are—1. Inflammatory swelling of the nose and neighboring sinuses. 2. Hyperemia of the trachea and bronchi, the surface of which is covered with tenacious mucopus. 3. In fatal cases patches of bronchopneumonia. 4. When the central nervous system is involved, hyperemia of the meninges of brain and cord."—(Wheeler and Jack's *Handbook of Medicine.*)

2. Healing is an incised wound, if aseptic, and the edges are in apposition, occurs by *first intention.* "Exudation of plasma from the neighboring blood-vessels occurs, and its fibrinogen is converted into fibrin, so gluing the edges of the wound together. Leucocytes are poured out and infiltrate the wound, absorbing any blood clot present. These are followed by fibroblasts (connective-tissue cells), which take their place. New capillaries form by budding out from adjacent ones, and vascularize the new tissue. Fibrous tissue is formed by intercellular exudation from the fibroblasts and so the fibrocicatricial union is complete, for at the same time epithelium is spreading over the narrow surface line."

Healing by granulation or second intention occurs when the edges of the wound have not been brought together. "Exudation of plasma and leucocytes occurs, followed by fibroblasts and budding from the capillaries, thus forming granulation tissue. The dead tissues or sloughs are separated, and a red area of granulation is then exposed. The deeper layer of granulation tissue is converted into fibrocicatricial tissue, which contracts, and so the wound gradually lessens in size. In the meantime epithelium spreads in, from the edge over the surface, and so the scar is completed."—(*Aids to Surgery.*)

3. "*Benign tumors* are usually very slow in growth and distinctly localized, having a definite capsule. They rarely attain excessive size, but occasionally, owing to their intrinsically benign character, may attain huge dimensions without injury to the general economy. Generally they are movable (unless bound down by surrounding inflammatory tissue or primarily attached to bone). They do not metastasize or become disseminated throughout the body, and when completely removed do not recur. They exert no influence whatever upon the general economy when favoraby situated, but may endanger life by their size and situation when they interfere with the normal functions of any of the important organs of the body. They constitute the bulk of the tumors of youth, and need be removed only because of their size and location and because of the ever present danger of transformation into their correlated forms of malignant disease. *Microscopically* they can be distinguished by their non-infiltrating character, by their distinct encapsulation, by their tendency to conform to some definite type of normal adult tissue, and the absence of an actively growing edge with an abundance of cells showing karyokinetic figures.

"*Malignant tumors* exhibit diametrically opposite characteristics. They grow rapidly and usually diffusely. They are not encapsulated and may quickly attain considerable size, although huge malignant tumors are rather exceptional, since they usually prove fatal before they attain such proportions. They are intimately connected with the surrounding tissues and quickly become bound down and immovable. They metastasize and become disseminated rapidly through the lymph or vascular system, progressing steadily toward a fatal termination by the interference with vital functions caused by metastatic growths, or by an autointoxication which undermines the general health and produces the condition commonly known as cachexia. *Microscopically* they can be distinguished by the embryonal character of the cells constituting the growth and by their atypical structure, conforming to no definite adult normal tissue. They can be seen to be rapid in their growth by the abundance of cells undergoing indirect cell division. They are not encapsulated, but tend to invade surrounding structures, blood and lymph channels, a circumstance which explains their ready metastasis."—(Rodman's *Diseases of the Breast.*)

Three malignant tumors.—(1) Carcinoma; occurring in breast, stomach, rectum, ovary, testicle. (2) Sarcoma, occurring in bone, lymphatics, breast, testicle, ovary, skin. (3) Epithelioma; occurring in nose, lip, palate, tongue, larynx, penis, stomach, gall-bladder.

Three benign tumors.—(1) Adenoma; occurring in breast, ovary, testicle, thyroid, parotid, rectum. (2) Chondroma; occurring in bones, salivary glands, testicle. (3) Glioma; occurring in brain, retina, spinal cord, optic nerve.

4. *Wassermann reaction.*—"In this test a watery extract of syphilitic fetal liver is used as the antigen to fix the syphilitic immune body present in the serum, and the hemolytic system is arranged as follows:

"The serum from the patient previously inactivated by heating (therefore only containing immune body), mixed with liver-extract and a small quantity of fresh serum (to provide the complement), is incubated at 37° C. for one hour; to it are then added sensitized red cells (that is to say, red cells mixed with their appropriate but inactivated, hemolytic serum) and the mixture is again incubated for two hours at 37° C., removed to an ice chest, and allowed to stand for twelve to eighteen hours before examination. A similar hemolytic system is put up at the same time to act as a control, in which the suspected serum is replaced by that from a normal individual. If syphilitic antibodies are present in the suspected serum, no hemolysis will take place, as the complement required by the sensitized red cells for this reaction to occur will have been already utilized and bound by the syphilitic immune body to the lipoid of the liver extract. This constitutes a positive reaction. In the absence of immune body from the suspected serum, however, complete hemolysis will take place and a negative reaction is recorded."—(Bosanquet and Eyre's *Serums, Vaccines and Toxines.*)

5.

B. COLI	PARATYPHOIDS.	B. TYPHOSUS.
Motility is not pronounced in most cultures; often only a few individuals in the field show independent movement; few flagella. Dextrose and lactose are fermented with gas production, some varieties fermenting saccharose also. Milk is curdled, usually within forty-eight hours, at 37°, with abundant acid production. Luxuriant growth on potato, usually with a brown tinge. Indol is produced by most varieties in large amount. Under most conditions not pathogenic for man or the lower animals. When injected intraperitoneally into rabbits and guinea-pigs a fatal result usually ensues, but considerable variation in virulence is shown by different strains.	Actively motile; 10 to 14 flagella. Dextrose is fermented with gas production, but no gas or acid is formed from lactose. Milk is never curdled; on prolonged cultivation under aerobic conditions the milk acquires a slight primary acidity, then becomes strongly alkaline, and finally the casein is dissolved. Indol is produced not at all or very scantily. Distinctly pathogenic for many of the lower animals and for man.	The typhoid bacillus is actively motile and possesses 10 to 14 flagella. B. dysenteriæ, otherwise closely related, is slightly motile or devoid of motility, according to some observers. Dextrose is fermented with production of acid, but gas is never produced; no acid is produced from lactose. Milk is never curdled, although a slight initial acidity develops, followed by a return to the original reaction; an alkaline reaction is produced in milk by some strains, but not to such an extent as in the preceding group. No indol is formed under ordinary conditions of cultivation. Pathogenic for man, less so for the lower animals.

—(From Jordan's *Bacteriology.*)

6. *Bacteriology of Vincent's Angina.*—"In smears from the lesions there has been demonstrated a spindle-shaped or fusiform bacillus, together with which there is usually found a spirillum not unlike the spirillum of relapsing fever. The two microorganisms are almost always found together in this form of disease and were regarded by the first observers as representing two distinct forms dwelling in symbiosis. More recently identity has been claimed for the two forms, it being believed that they represent different developmental stages of the same organism.

"The fusiform bacilli are from 3 to 10 micra in length and have a thickness at the center varying from 0.5 to 0.8 micron. From the center they taper gradually toward the ends, ending in blunt or sharp points. The length of these bacilli may vary greatly within one and the same smear preparation. They are usually straight, sometimes slightly curved. They do not stain very easily with the weaker anilin dyes, but are readily stained by Loeffler's methylene-blue, carbolfuchsin, or better, by Giemsa's stain. Stained by Gram, they are usually decolorized, though in this respect the writers have found them to vary. Stained preparations show a characteristic inequality in the intensity of the stain, the bacilli being more deeply stained near the end, and showing a banded or striped alternation of stained and unstained areas in the central body. The bacilli are not motile.

"The *spirilla* found in Vincent's angina are usually somewhat longer than the fusiform bacilli, and are made up of a variable number of undulations, shallow and irregular in their curvatures, unlike the more regularly steep waves of Spirocheta pallida. They are stained with even more difficulty than are the bacilli and usually appear less distinct in the preparations. The stain, however, is taken without irregularity, showing none of the apparent metachromatism observed in the bacilli.

"The microorganisms of Vincent's angina, when occurring in the throat, are rarely present alone, being usually accompanied by other microorganisms, such as staphylococci, streptococci, and not infrequently diphtheria bacilli."—(From Hiss and Zinsser's *Bacteriology.*)

7. TWO DISEASES CAUSED BY PROTOZOA.—(1) *Malaria,* transmitted by the bite of an infected Anopheles mosquito. (2) *Amebic dysentery,* transmitted by eating contaminated foods, drinking contaminated water, by flies, and by direct contact with infected material.

TWO DISEASES CAUSED BY FILTRABLE VIRUSES.—(1) *Acute anterior poliomyelitis,* transmitted by contact with an infected person or carrier, or by contact with articles freshly soiled by discharges from nose, throat or bowel of infected persons or carriers. (2) *Foot and mouth disease,* transmitted by direct contact with man or animals infected.

8. *Diseases against which prophylactic vaccination is recommended.*—Smallpox and typhoid fever.

9. *Diseases against which curative sera are recommended.*—Diphtheria, tetanus, cerebrospinal meningitis, lobar pneumonia, bacillary dysentery, plague.

10. *Active immunity* is due to the direct participation of the organism concerned and depends upon increased cell activitv. Such immunity is gained at the expense and often at the risk of the organism acquiring it. Immunity to smallpox may be obtained either by an attack of the disease due to natural exposure or by deliberate inoculation by vaccination with cowpox virus. This immunity depends upon a specific reaction on the part of the cells and tissues of the individual organism.

Passive immunity, on the other hand, involves no active generation of protective substances by the immunized animal. The latter is simply the recipient of substances formed in the body of another animal and transferred to the individual to be protected. When a child has been exposed to diphtheria it is the custom to inject about 1,000 units of diphtheria antitoxin into the body of the child for protective purposes. The child is then measurably assured against an attack of diphtheria, and is said to have been immunized passively, since its own tissues have in no way shared in the manufacture of the protective substance. Passive immunity may be quickly acquired, but is also much less permanent than active immunity, and tends quickly to disappear.—(Jordan's *Bacteriology.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CLINICAL ELECTROCARDIOGRAPHY. By Dr. FREDERICK A. WILLIUS. 188 pages with illustrations. Price, $5.00 net. Published by W. B. Saunders & Company, Philadelphia, Pa.

GRUNDRISS DER KLINISCHEN THERAPIE INNERER KRANKHEITEN. By Dr. GEORG KLEMPERER. 237 pages without illustrations. Price, 108 Marks. Published by Urban & Schwarzenberg.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS. By Dr. JAY FRANK SCHAMBERG. Fourth Edition, Thoroughly Revised. 626 pages with illustrations. Price, Cloth, $5.00 net. Published by W. B. Saunders & Company, Philadelphia, Pa.

PAPERS FROM THE MAYO FOUNDATION FOR MEDICAL EDUCATION AND RESEARCH, Covering Period 1915-1920. 695 pages with illustrations. Price, Cloth, 10.00 net. Published by W. B. Saunders & Company, Philadelphia, Pa.

TUBERKULOSE BIBLIOTHEK. By LYDIA RABINOWITSCH. 32 pages without illustrations. Published by Johann Ambrosius Barth, Leipzig, Germany.

MODERNE BIOLOGIE. By HANS MUCH. 66 pages. Published by Curt Kabitzsch, Leipzig, Germany.

Medical History.

NEW BOOKS AND OLD.

XXV—OSLER'S EVOLUTION OF MODERN MEDICINE.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

WITH remarkable perspicacity the authorities of Yale College chose for Silliman lecturer in 1913, Sir William Osler. After the lectures were delivered they were set in type and the correction of the galley proofs was underway when the war broke out, so that nothing more was done by the author himself. Later on the proofs were revised and corrected by Garrison, Cushing, Streeter and Leonard Mackall. Of this "Aëroplane flight over the progress of medicine through the ages," as Osler himself called it, which has recently been issued by the Yale University Press, under the able guidance of Garrison, the author of the preface says:

> This work, composed originally for a lay audience and for popular consumption, will be to the aspiring medical student and the hard working practitioner a lift into the blue, an inspiring vista or "Pisgahsight" of the evolution of medicine, a realization of what devotion, perseverance, valor and ability on the part of physicians have contributed to this progress, and of the creditable part which our profession has played in the general development of science. The editors have no hesitation in presenting these lectures to the profession and to the reading public as one of the most characteristic productions of the best-balanced, best equipped, most sagacious and most lovable of all modern physicians.

There are 107 well chosen illustrations which add much to the attractiveness of the volume which has been divided into six chapters bearing the headings: Introduction; Greek Medicine; Medieval Medicine; The Renaissance and the Rise of Anatomy and Physiology; The Rise and Development of Modern Medicine, and The Rise of Preventive Medicine.

The book is written in the delightful Oslerian manner, the style of a master of English and of his subject, free from pedantry though full of classical allusions. His phrases are often wonderful, as for example: "Civilization is but the filmy fringe on the history of man."

Some idea of the scope of the lectures may also be gleaned by noting that Osler mentions considerably over four hundred names. Quickly the reader is carried along from the beginnings of medicine, through the beliefs and practices of the Egyptians, the Assyrians and Babylonians, the Jews, the Chinese and Japanese, until the bright light of Greece breaks in upon the story. Osler was a lover of Greece and its culture and knew it intimately. With Lucretius he sings that wonderful pæan:

> "Out of the night, out of the blinding night
> Thy beacon flashes;—hail, beloved light
> Of Greece and Grecian; hail, for in the mirk
> Thou dost reveal each valley and each height.
>
> Thou art my leader, and the footprints thine,
> Wherein I plant my own. . . .
>
> * * * * * * * *
>
> The world was thine to read, and having read,
> Before thy children's eyes thou didst outspread
> The fruitful page of knowledge, all the wealth
> Of wisdom, all her plenty for their bread."

He goes on:

> "Let us come out of the murky night of the East, heavy with phantoms, into the bright daylight of the West, into the company of men whose thoughts made our thoughts, and whose ways made our ways—the men who first dared to look on nature with the clear eyes of the mind."

The value of the Greek was that he lifted the veil of nature, unlike the Egyptian who on one of the temples of Isis carved "I am whatever has been, is, or ever will be, and my veil no man has yet lifted," the man of the Aegean Sea looked nature full in the face and wrested not a few of her secrets from her. Osler gives a charming account of the Greek and his medical gods, his temples of healing, of Hippocrates and the other masters. The humanity, the directness of thought of the Greek, his common sense appealed strongly to Osler who embodied so much of their spirit.

An account of the Alexandrian School and its philosophers, and we are brought to the feet of Galen who receives full praise from the lecturer who said:

> "No other physician has ever occupied the commanding position of Clarissimus Galen. For fifteen centuries he dominated medical thought as powerfuly as did Aristotle in the schools. Not until the Renaissance did daring spirit begin to question the infallibility of this medical pope. But here we must part with the last and, in many ways, the greatest of the Greeks—a man very much of our own type, who, could he visit this country today, might teach us many lessons. He would smile in scorn at the water supply of many of our cities, thinking of the magnificent aqueducts of Rome and of many of the colonial towns—some still in use—which in lightness of structure and in durability testify to the astonishing skill of their engineers. There are country districts in which he would find imperfect drainage and could tell of the wonderful system by which Rome was kept sweet and clean. Nothing would delight him more than a visit to Panama to see what the organization of knowledge has been able to accomplish. Everywhere he could tour the country as a sanitary expert, preaching the gospel of good water supply and good drainage, two of the great elements in civilization, in which in many places we have not yet reached the Roman standard."

What a striking introduction he gives us to medieval medicine!

> "There are waste places of the earth which fill one with terror—not simply because they are waste; one has not such feelings in the desert nor in the vast solitude of the ocean. Very different is it where the desolation has overtaken a brilliant and flourishing product of man's head and hand. To know that
>
> . . . The Lion and the Lizard keep
> The Courts where Jamshyd gloried and drank deep
>
> sends a chill to the heart, and one trembles with a sense of human instability. With this feeling we enter the Middle Ages."

In a few words Osler sets before us the state of mind of the period with its Jerome and his remark: "Does your skin roughen without baths? Who is once washed in the blood of Christ needs not wash again." The lecturer goes on to say "In this unfavorable medium for growth, science was simply disregarded, not in any hostile spirit, but as unnecessary." This gives the lecturer a setting for his account of the south Italian school, Byzantine and Arabian medicine, the last of which he gives in some detail. Then follows the story of the rise of men and the Universities; Mundinus and Bologna; Arnold of Villanova and Montpellier; Peter of Albano and Padua; Albertus Magnus; Guy de Chau-

liac; Roger Bacon and others and an account of the medieval medical study and practice, as well as astrology and divination which had such a hold on the mind of man in the middle ages.

> "Wonderful tales had our fathers of old—
> Wonderful tales of the herbs and the stars—
> The Sun was Lord of the marigold,
> Basil and Rocket belonged to Mars."

The page portraits of Linacre, John Caius, Conrad Gesner and Paracelsus, tell us that we are entering the Renaissance. It takes great skill to condense the work and lives of these worthies together with Copernicus, Vesalius, Harvey and the other contemporary workers. He speaks of Boyle but neglects John Mayow—to my mind one of the greatest scientific men of his age. Quickly, but with a discerning, discriminating touch, he comments on Morgagni, Sydenham, Boerhaave, Lancisi, Baglivi, Cullen, Rush, John Brown, John Hunter, Jenner, Auenbrugger, Laennec, and brings us almost suddenly down to Pasteur, Koch and Lister. Thus we arrive at the present time and the last chapter as remarked above is entitled "The Rise of Preventive Medicine." Osler knew full well that the present endeavors of the public health workers are but feeble groping in the dark. The day will come when someone will write the history of the *development* of preventive medicine. It should be a glorious chapter when the collective mind of man has dealt successfully with the problems of eliminating the feebleminded, the physically unfit, endocrine disturbances, neoplasms and infections. The present practitioners of physic, however, need have no fear of losing their present clientèle through the dawn of this medical millennium.

The last chapter contains a quotation from Hippocrates which I cannot refrain from quoting together with the first lines of comment:

> " 'But on that account, I say, we ought not to reject the ancient Art, as if it were not, and had not been properly founded, because it did not attain accuracy in all things, but rather, since it is capable of reaching to the greatest exactitude by reasoning, to receive it and admire its discoveries, made from a state of great ignorance, and as having been well and properly made, and not from chance.' "
>
> "I have tried to tell you what the best of these men in successive ages knew, to show you their point of outlook on the things that interest us. To understand the old writers one must see as they saw, feel as they felt, believe as they believed—and this is hard, indeed impossible! We may get near them by asking the Spirit of the Age in which they lived to enter in and dwell with us, but it does not always come. Literary critidism is not literary history—we have no use here for the former, but to analyze his writings is to get as far as we can behind the doors of a man's mind, to know and appraise his knowledge, not from our standpoint, but from that of his contemporaries, his predecessors and his immediate successors. Each generation has its own problems to face, looks at truth from a special focus and does not see quite the same outlines as any other."

Osler understood the true value of medical history. He had profited himself from his intimate knowledge of the past so that he had no hesitation in recommending the study of other days to his students and contemporaries:

> "It is one of the values of lectures on the history of medicine to keep alive the good influences of great men even after their positive teaching is antiquated. Let no man be so foolish as to think that he has exhausted any subject for his generation. Virchow was not happy when he saw the young men pour into the old bottle of cellular pathology the new wine of bacteriology. Lister could never understand how *aseptic* surgery arose out of his work. Ehrlich would not recognize his epoch-making views on immunity when this generation has finished with them. I believe it was Hegel who said that progress is a series of negations—the denial today of what was accepted yesterday, the contradiction by each generation of some part at least of the philosophy of the last; but all is not lost, the germ plasm remains, a nucleus of truth to be fertilized by men often ignorant even of the body from which it has come. Knowledge evolves, but in such a way that its possessors are never in sure possession. 'It is because science is sure of nothing that it is always advancing' (Duclaux.")

One marvels as one reads these lectures. They were intended for laymen and to such they will be enlightening; to medical students they will come as a well nigh perfect introduction to the history of medicine; to the student of the past to whom the facts presented are not new the lectures will prove the most interesting, because such students are the only ones who can appreciate the wonderful judgment, the discriminating niceness with which Osler has balanced his presentation of the story of the evolution of medicine.

History of the Surgical Treatment of Pulmonary Tuberculosis.—When we consider the universality and nature of pulmonary tuberculosis, the number of classical writers on this subject must be regarded as very small. Pallasse, writing in *Le Progrès Médical*, xlix, 26, can recall only Sydenham, Baglivi, Van Swieten, Lieutaud, Morton, and Bennett, the two latter alone having produced monographs. The author naturally does not come down to the level of the XIX Century. But he suggests that while the above writers are well known today, there may be others who have been overlooked entirely. Leaving out of count a number of the older authors and writings on phthisis which contain nothing of importance, the author has sought to trace some writer of merit who has been genuinely ignored by his successors. Such a one he thinks he has found in Jeannet de Longrois who flourished late in the XVIII Century. This man is mentioned by many writers. He made but one contribution to literature, a work of 200 pages entitled "De la pulmonie," etc., which appeared in 1781. Evidently his attention was drawn to this affection because of his own state of health which threatened him with consumption. We find nothing striking until the chapter on treatment for the author adheres quite faithfully to Bennett, Morton, and others. Neither predecessors nor contemporaries had spoken of a surgical treatment. The first physician known to have recognized systematically the possibility of surgical treatment is Gilchrist in his book on the utility of sea-voyages, published in 1770. He seems to have proposed a sort of empyema operation for isolated foci of tuberculosis in the lung. The merit of Longrois in the eyes of the author seems to have been that he gave a section to the surgical treatment of this disease in which he cites cases taken from literature. He was unaware apparently of Gilchrist's suggestions along this line. Two years later he was followed by Baumès in giving a chapter on the surgical treatment. Both report cases seen originally by Baglivi and Blegny.

THE STEPFATHER.

A MEDICAL COMEDY, WITH A PSYCHOANALYTIC TREND, IN ONE ACT AND FOUR SCENES.

BY CHARLES L. DANA, M.D.,

NEW YORK.

CHARACTERS

DR. BLEUER, a neurologist.
MISS JEANETTE DAILEY, a patient.
MISS GLADYS DAILEY, her sister.
DOORMAN.
PATIENTS.
By telephone: MR. CURTIS, the stepfather; ALGERNON CURTIS, the brother.
In consultation: DR. YOUNG, a psychoanalyst.

SCENE I.

Doctor's Office.

The office contains various important looking apparatus; many books, files and journals, and instruments of precision.

The Doctor sits at a desk near the window. The desk is covered with books and notes. Miss Jeanette Dailey sits before him in the patients' chair—a pleasant faced young woman of 22. Miss Gladys, her sister, also attractive, sits in a chair to the left.

Miss Gladys.—Well, Doctor, we've come to see you.

Dr. B.—Yes, young ladies; what is the story?

Gladys.—Well, Doctor, you see my sister here has epileptic fits, and we thought that you could help her. (Miss Jeanette, the patient, smiles deprecatingly.)

Dr. B. (to Jeanette).—How long have you had them?

Miss Jeanette.—Since I was fourteen. They are pretty hard, too.

Gladys.—She had a fit last night, and she broke three teeth — nearly. (Miss Jeanette shows her teeth.)

Jeanette (with emphasis).—Yes, I've loosened nearly all of them.

Dr. B.—Your teeth look very well—I do not find them loosened. Perhaps you are too apprehensive. Do you have these spells very often?

Jeanette.—About twice a month or so; but you see I never can tell.

Dr. B.—And you are getting no better?

Jeanette.—I think not; they are just as bad. I don't dare to go out alone.

Dr. B.—And have you not had treatment all these eight years?

Jeanette.—Well, I guess not much. We had a homeopathic doctor once, but I hadn't much faith in his medicine.

Gladys (nervously)—Doctor, do you think distress of mind could make them worse?

Dr. B.—Probably. Distress of mind is distinctly unhealthy.

Gladys.—Because, you see, Mother's married again, and we don't like *him*. And he has two children.

Jeanette (sharply).—They are horrid, common things.

Gladys (with intensity of feeling).—And he is just a low down Dutchman. And Mother's mad because we won't speak to him.

Dr. B.—But this stepfather, isn't he a nice man?

Gladys.—No, indeed; he's a policeman. He lived opposite us for years and we always hated him. I am sure Mother must be crazy. She thinks he is all right.

Dr. B.—But she supports you and cares for you?

Gladys.—Oh, no; Mother doesn't care for us. She doesn't love us any more. I live with her, but when I am twenty-one, I guess I will have to leave the house.

Dr. B.—But hasn't your Mother paid any attention to this sickness of yours, and tried to get you well?

Jeanette.—Well, I should think, not much. I haven't seen any doctors specially. I think she didn't want to spend any money.

(Knock at the door.)

Dr. B.—Come in.

(Colored doorman puts in his head.)

Doorman.—Mr. Ragadski says he is very nervous; he wants to know if he must wait very much longer?

Dr. B.—Tell him to have patience and read this: I will see him soon. (Hands copy of Osler's "Aequanimitas.") And just tell him patients often do better in the waiting room than in the office. (Turning to Jeanette.) So your mother just lets things go? Didn't she send you here today?

Gladys.—Oh, no! Mother doesn't know we are here. You mustn't write her or let her know, either. She wouldn't want us to spend the money.

Dr. B.—Has she money?—not that I want it—

Gladys.—Oh, yes! I guess she's money. We do the housework and she gives us an allowance.

Jeanette.—And I do some embroidery and sell it at the Women's Exchange. I brought some down today.

Dr. B.—Yours is not a happy family?

Gladys (emphatically).—I guess not; we don't even speak at table. It is dreadful.

Dr. B.—And worse, it's unsanitary. You ought always to talk when you eat. But have you tried to be amiable and kind to these new people?

Gladys.—We tried at first. We spoke to these children when they didn't behave and told them

how they ought to act; but Mother glared at us and didn't like it. Now we won't speak to them. They are just common, low, contemptible things. You should see them eat at table!

Dr. B.—I should love to, I am sure. But haven't you any relatives?

Gladys.—Oh, yes; we have three brothers. Two of them left the house when *he* came. One of them is engaged, but we didn't go to his engagement party, and we aren't going to his wedding, either. We don't like his girl.

Dr. B.—Young ladies, your family life has complications. I think truly, Miss Jeanette is made worse by distress of mind, and I can't do her much good until there is a better feeling in the Dailey family. Aren't you told to love your neighbors?

(Both giggle.)

Jeanette.—Gladys does!

Gladys.—Now, Jeanette!

(Jeanette turns pale. Her eyes roll, then become fixed; she gasps.)

Gladys.—She's got it! (Jumps up; seizes her sister and steadies her.)

(The Doctor gets some salts and holds the bottle to Jeanette's face. Jeanette flushes and recovers herself. The Doctor makes some examinations—writes a prescription and a note and hands them to Jeanette.)

Dr. B.—Be sure and take this medicine as directed. Go to this address next Monday morning and do exactly as the doctor there directs you; answer all his questions. As your life isn't happy in waking hours, cultivate the habit of having happy dreams; be pleasant to your stepfather. Come back a week from today.

(Enter Mr. Ragadski, Mrs. Ragadski (with a shawl over her head), and Mr. Ragadski's brother-in-law.)

Mr. R.—Are you a professor for the nerves?

Dr. B.—I suppose so—some people say not. Please sit down and we will see.

SCENE II.

Same scene; a week later. Much later in the morning. Enter same young women.

Dr. B.—Good morning; be seated, please. I'm sorry you had to wait. I suppose you were a little puzzled by the things Dr. Young made you do yesterday.

Gladys.—Yes, I just thought it foolish; only we don't care as long as Jeanette gets better. He took a lot of time.

Jeanette.—And such awful questions! He isn't going to hypnotize me, is he? Doctor—where is my complex (feeling about her stomach).

Dr. B.—Oh, not there, anyway; we will talk about it later. Have you been well, Miss Jeanette?

Jeanette.—Yes, Doctor, very well. We told Mother we had been here.

Dr. B.—Did she seem pleased, or was she at all interested?

Gladys.—I guess she was interested, Doctor—she gave us back the money we paid. She says we can come again.

Dr. B.—So you have been talking to your mother?

Gladys.—Yes, Doctor, we've been talking to her some, not too much; she will pick a fight if we do. We go out every evening so as not to talk to her much.

Dr. B.—Out every evening, and in Mt. Vernon? It must have large social resources?

Gladys.—Yes, Doctor, we have to go; at first we used to stay upstairs, but Mother said we'd have to come down, or she would make us pay the gas bills.

Dr. B.—But where can you go every evening?

Gladys.—Oh, picture shows.

Jeanette.—Then Gladys has a friend, a young gentleman. She visits his family. (Giggles.)

Gladys (snappishly).—You needn't say anything about that! You've got a friend, too.

Jeanette (looking serious).—Well, but he's different. I don't visit his home yet. I told Dr. Young about that.

Dr. B.—Never mind these young men now. There seems to me a great deal of unnecessary friction among the Daileys. Perhaps you girls aren't trying to be as nice as you ought.

Gladys.—Oh, yes, we've tried—but you should see stepfather!

Dr. B.—You have one brother who lives with you?

Gladys.—Yes.

Dr. B.—And he doesn't quite sympathize with your point of view?

Gladys.—Well, not exactly; but he treats us girls real mean. He's called me terrible names, and we won't speak to him. He's going to get married, and he wants us to go to the wedding, but we won't do it.

Jeanette.—He used to be a good brother, but now he's different. He's a chauffeur.

(Telephone rings.)

Dr. B.—Yes, yes, this is Dr. B. You are in Mt. Vernon, Mr. Curtis? What! the two Dailey sisters? Yes, Jeanette is all right. Tell your wife they just had to wait. Well, stepfather seems anxious about you.

Gladys.—Well, I think he's just got to. That's all.

Dr. B.—You think your brother is not so bad, Miss Jeanette? Don't you speak to him?

Jeanette.—Well, sometimes, but Gladys won't.

(Gladys looks very firm.)

Gladys.—It never would do to give in to him.

Dr. B.—He's engaged? Is she a nice girl?

Gladys.—His girl? No, she isn't! She's all airish and nothing back of it. I mean, you know, she lives up on the Hill and is very swell, but when her father died, there wasn't any money. She works daytimes in a dentist's office, passing tools, and water—and things.

Dr. B.—And stepfather, isn't he after all an amiable man?

Gladys.—Perhaps he's amiable, but you should just see him at the table—and the kids! It's awful—you couldn't eat.

Dr. B.—Perhaps not—still, I should like to go up and lunch with you some time. I want to see the inside of this happy home.

(Shriek of protest.)

Jeanette.—Oh, no—you couldn't do it!

Dr. B.—And see mother and the kids—

Gladys.—It wouldn't be possible.

Dr. B.—Well, I'm not so sure. I want to see your stepfather also. You eat with him, do you not?

Jeanette.—Yes, now we do. We used to go into the kitchen and eat by ourselves, but Mother wouldn't let us continue.

Gladys.—She took the dishes away.

Dr. B.—Mother plainly wants you to get acquainted with stepfather. Upstairs, no gas; in the kitchen, no food; everywhere else, stepfather and the kids. But there are other homes. You have two other brothers, Jeanette; can't they take you in and care for you?

Jeanette.—Oh, yes; they would like to help, but they are just starting and they haven't any money.

Gladys.—And Joe has only got one kidney; and besides, they are both out in California.

Dr. B.—That does make it difficult just now!

Jeanette.—We had one lucky brother. He knew enough to get typhoid fever a year ago and he died of it. He was a good one.

(Jeanette weakens a little. She brings out her handkerchief. Gladys looks anxious and reaches for the salts.)

Dr. B.—Perhaps some other girl's brother who lives nearer than California might help?

(The girls look at each other consciously.)

Gladys.—No, it's no use—not now. Sometimes I dream it's different.

Jeanette.—And I, too.

Dr. B.—Did you tell about the dreams to Dr. Young?

Jeanette.—Yes, I wrote out one for him. It was funny. I was riding on a red horse into a lot of water.

(Telephone rings.)

Dr. B.—Yes, this is the doctor. You are Algernon? What, Algernon Dailey? And you will have your ear here for your sister, if Jeanette is ill? Well, she is not. She is all right. Good-bye.

Dr. B.—Well, Miss Jeanette, please straighten up and notice this placard here: "It's against the rule to have fits in my office." Take this little schedule I have written out, follow it; don't forget Dr. Young. And do you perhaps remember the Fifth Commandment? It contains a very old-fashioned suggestion—

Jeanette.—"Honor thy father and mother"—

Dr. B.—Yes.

Gladys.—But there is nothing said about honoring that policeman—

Dr. B.—Well! That's only going a (apologetically) step farther! Good day. Come in another week.

SCENE III.

Same Scene. A Week Later.

Dr. B.—Good day, again. I hope you have had no attacks.

Jeanette.—No, I am all right. Say, Doctor, I dreamed of you last night (much pleased), and I saw you up at our house talking to Mother.

Dr. B.—You dreamed then of my unfulfilled wish. Did I carry a cane or did you notice the snake in my scarfpin?

Jeanette.—I don't remember that; but Mother was real pleased and you gave the kids ten cents.

Dr. B.—I do such things in dreams. But have you broken the silence and been talking to your relatives?

Gladys.—Yes; but brother had to speak first. It was Christmas time and he did a real mean trick, anyway. He just came and laid a package of candy on the table and says: "I suppose we might as well be pleasant Christmas time."

Dr. B.—And were you both pleasant?

Gladys.—Oh, yes; we've been very sweet. Brother's a great talker, anyway.

Dr. B.—And stepfather; you spoke to him?

Gladys.—Yes, but he didn't talk very much. He's afraid.

Dr. B.—I thought policemen had to be courageous?

Gladys.—Well, we won't let him talk much, anyway. Besides, he's resigned.

Dr. B.—Are you getting ready for the wedding?

Gladys.—No, indeed; we are not going to the wedding. That's the trouble. They want us. You see, it will show Mother up if everyone sees we are not there.

Jeanette.—Mother doesn't like it because Gladys can't get married for two or three years. She don't want to support her so long—and stepfather, too.

Gladys.—I've been thinking of leaving and going back to my stenography.

Jeanette.—And I would do embroidery.

Gladys.—There's a clerk in Jones's store who would say something to Jeanette—only for the policeman. He don't like him.

Dr. B.—You are not a loving couple, and it seems due mostly to the fact that your mother has married again and married beneath her.

Gladys.—Yes; why didn't he marry that waitress? He was engaged to her and he'd have done it, only Mother hooked him. People ought to marry in their own class. Father was a nice man.

Dr. B.—An honest plumber?

Gladys.—Yes.

Dr. B.—Well, the thing has happened and the situation is not so dreadful as to cause so much distress of mind as you seem to suffer. I have a letter here from your brother. (Girls sit up.) May I read it to you?

"DEAR DOCTOR:

"Jeanette and Gladys are all right, but they have had some hard times and they get excited sometimes. They say they are not going to my wedding, and I don't think they had better. I wouldn't want anything to happen to Jeanette. Please let me know what they should do. They are pretty terrible when they get excited. Now they are excited over me. I want them to my wedding, of course; but if you say it would be bad for Jeanette, it will be all right. Please let me know about this and what you think of her? Yours truly,

"A. DAILEY."

Jeanette.—Do you mean you're going to say I can't go to the wedding?

Dr. B.—You can't go to an exciting ceremony unless I am sure you can take care of yourself. And Gladys should not go alone.

Jeanette.—But we want to go!

Dr. B.—Listen! You came to me with a story of Jeanette having "fits." I examined her and sent her to Dr. Young, who asked her strange questions, gave her tests of words, made her talk and talk and tell her whole history, and even her dreams.

Dr. Young and I have conferred about her—about both of you, in fact; because Gladys also has fits—

Gladys.—I don't! Never in my life!

Dr. B.—Has fits—of violent temper—(Gladys looks quieter), which are as serious as Jeanette's; for Jeanette has no real fits at all, only what shall I say—"Complexes"—carry that word to Mt. Vernon. You are both in love, and in love badly (girls look very conscious), but your love affairs are blocked — suppressed — buried alive, but still living—while the unconscious longings and burnings—

Gladys.—We haven't any.

Dr. B.—Wait, please — Show themselves in explosions of unreasonable and spiteful conduct toward stepfather. The mental conflict with the buried complex of your loves turns stepfather into an obsession—your single ruling idea. You make him the starting point and source of all your woes and annoyances. Resenting him, you are undutiful to your mother, unkind to the children, silly and disagreeable to your brother. You, Jeanette, frame up an imitation fit, and Gladys breaks out in genuine storms of unpleasantness, and all due not to stepfather at all; but to those young men, James and Timothy, whom you love and do not possess. Through this, two naturally sweet and affectionate girls are made the most soured and unreasonable and disagreeable females that commute above the Bronx. Now you know the reasons: Think them over. And you, Jeanette, if you understand and believe, and will cease your conflicts, your fits will be over. If you need a little more help, go to Dr. Young and let him finish my task. I have given you the cure. Take it, and good-bye.

(Patients retire. Dr. B. aside: Well, I wonder if there is anything in those hectic remarks?

SCENE IV.

Same place a month later, Doctor at telephone; doorman waiting.

Dr. B.—Hello! Is this 20 Mt. Vernon? Is this Mrs. Curtis? This is Dr. Bleuer. How are the girls—the girls, Jeanette and Gladys? I haven't heard a word from them or about them since they left here a month ago. Yes, how are they? What?

Voice.—Just the same.

CURTAIN.

HEADACHE AND CHRONIC MASTOIDITIS.*

BY WILLIAM LEDLIE CULBERT, M.D.,

NEW YORK.

AURAL headache, although occurring less often than optic or nasopharyngeal headache, is of sufficient frequency to make a general knowledge of it important, especially as certain types of aural headache are very difficult of diagnosis.

Headache consequent on involvement of the ear is of two kinds: organic and functional. A brief résumé of an article by Loughran[1] shows that organic pain in the head, when referred to the ear, is produced as the result of an "inflammatory process present in the mucous membrane or bony structures of the various divisions that go to make up the organ of hearing, or in structures that may be involved by extension from these parts. Pain in a nerve associated with an inflamed mucous membrane is produced by pressure on its terminal filaments or by external pressure against the congested mucous membrane, as in any cavity filled with fluid under tension with no means of escape. Pain from internal pressure is present in those forms of acute disease of the middle ear where the lesion is one of acute congestion without exudation of the mucous membrane within the Eustachian tube and middle ear cavity."

Functional headache may occur from toxemic absorption from any acute or chronic suppurative process in the middle ear, mastoid, or internal ear; in other words, from focal infection. The mechanism of headache resulting from such absorption phenomena is explained by Dr. Foster Kennedy by the fact that the toxins probably travel along the neurolymph channels accompanying the nerve to the cranial ganglia, particularly the fifth, which supplies the dura. Another type of functional headache is produced reflexly from irritations of the auditory canal, or the mucous membrane of the middle ear or Eustachian tube; from chronic suppurative conditions, or from sclerosis or necrosis of the bony walls of the middle ear cavity or mastoid cells. As regards bone destruction, the greater the involvement of the inner table of the skull, the greater the likelihood of headache. From necrosis in this location, the toxins would enter the lymph channels along the dura. The gravity of such conditions in relation to infection of the meninges and the production of brain abscess is most obvious. For a general review of the subject of aural headache, the paper by Loughran, here quoted, and one by Oppenheimer[2] are recommended.

The present article is concerned primarily with functional headache caused reflexly by sclerosis and necrosis of the mastoid cells, and through toxic absorption of focal infections in the mastoid. I have had a dozen or more cases with chronic mastoiditis with a practically complete absence of objective symptoms and with headache as the only or the most prominent subjective symptom. It is rather surprising, however, to find in the literature so few reports of this condition, since such cases have a certain clinical picturesqueness, as it were, first, because of the uncertainty of diagnosis and the hesitancy of the operator to open the mastoid until he has made the most careful examination in these extremely quiescent mastoid conditions; second, because of the frequent difficulty in getting the patient to consent to operation after one's own mind is made up to it; and, third, because of the relief of headache experienced after operation. As has been said, cases presenting headache with slight or no ear symptoms are difficult to diagnose as aural headache, particularly as most of the cases usually have some concurrent trouble in the nose, the sinuses, or the tonsils which must be eliminated before the mastoid can be positively accused as the final cause of the headaches. However, unlike headaches of nasal or pharyngeal origin, these headaches accompanying a latent mastoiditis, though sometimes partially relieved are never eradicated by the preliminary work on the nose and nasopharynx.

*Paper read and discussed at a meeting of the New York Hospital Graduates' Club, April 28, 1921.

The causes of functional headache in latent mastoiditis have already been stated as toxic absorption and sclerosis and necrosis of the mastoid bone. However, I cannot positively distinguish whether the different clinical types of functional headache seen in various cases were due exclusively to one or to the other of these causes; probably headache phenomena from absorption and reflexly from bone destruction and attendant suppuration would both be present in the same patient.

It is very important to emphasize that the middle ear and the mastoid may be foci of infection quite as much as the tonsils or the teeth, as this is a fact apparently unknown to the general public, often unobserved by the general practitioner, and even overlooked at times by aurists. The relation between headache and mastoiditis has never been brought to general attention. The literature of headache is endless, but the reference to the ear in that literature is utterly insignificant. The papers previously referred to by Loughran and by Oppenheimer are the only adequate ones on aural headache that I have been able to find. Hidden away in the literature of latent mastoiditis, may be cases reported with headache as a symptom, but they are not available through any index. Behan[3] in the 1920 issue of his book, "Pain," gives these words, only, to the subject of pain caused by ear trouble: "Ears cause head pain. The principal causes acting upon the ears to produce head pain are anemia and mastoid disease." Henry Head[4] in his classical monograph on "Disturbances of Sensation," states that "lesions of the membrana tympana and middle ear cause referred pain." This statement, however, refers only to conditions accompanying an *acute* purulent otitis media. Even the text-books on the diseases of the ear are also quite barren of observations of headache in chronic middle ear and mastoid disease; Dench, Phillips, and Kerrison make no mention of the symptomatology of headache in these conditions. Dan McKenzie[5] in his recent work, "Diseases of the Throat, Nose and Ear," in the section on *chronic* otitis media, states that among the danger signals of middle ear disease, "is headache in the occipital or temporal regions; or what is in reality much more frequent, in the frontal region." He says further that "quite commonly frontal headache of a low unobtrusive character attends chronic middle ear suppuration, and, as it is due to the general effects of simple septic absorption, it need not occasion alarm." Further search of the literature shows that Gill[6] and Goldsmith[7] include headache from the middle ear and the mastoid in general articles on headache from the nose, pharynx, eye, and ear; and that Patton[8] and Macpherson[9] have both reported cases of chronic mastoiditis with headache as a symptom. Beyond these few references the literature furnishes nothing, and it is small wonder if the general practitioner and men of other specialties are not inclined to believe that an apparently quiescent middle ear or mastoid can produce cases of such extreme headache as those to be reported.

Of the dozen or more cases seen, three which are especially clear examples of the clinical picture of mastoid headache have been selected to detail. The first of these also illustrates particularly the difficulty of getting other physicians to see the importance of the mastoid condition in cases of headache:

Case I.—Mrs. T., about 40 years of age, residing in a nearby Jersey town, complained in September, 1917, of extreme nauseating periodic headaches, which she described as starting at a point sometimes in the frontal, sometimes in the occipital region, and then spreading over the entire cranium. They never began at the ear. They were at times so intense that her physician was obliged to administer hypodermics of morphine. These attacks had been recurring for a number of years; formerly she had been treated by several aurists and she was still going to other different specialists for relief.

Examination: A small but strong and sturdy woman; the nose tight and undeveloped; the septum fairly straight; the turbinates enlarged, in contact with the septum, and occupying most of the lumen of the nose; the right ear normal; the left ear showed an O. M. P. C., residual; hearing impaired. She gave a history of having had occasional discharge from this left ear, but it was dry when I saw it, and had been so for the past few years. There were no further signs of mastoid involvement; no changes in the external auditory canal; no tenderness over the mastoid. She was given general nasal treatments. The following spring she returned with the same complaint of violent uncontrollable headaches. The radiographs showed granulations in the frontals and in both ethmoids; the left mastoid contained granulations or pus, with a possible slight amount of bone destruction toward the tip. At this time the left middle turbinate was removed, the infundibulum broken into, and the frontal and ethmoidal cells drained. I asked for an interval mastoid operation, which was refused. After the relief of the nasal condition, and by taking greater care of her general health, she got through the next two years a trifle more comfortably than formerly; there was some diminution in the severity and frequency of the headaches, although there were still occasional flare-ups in which she required hypodermics of morphine. During this period, as has been said, specialists in other lines were attempting in every way to solve the problem of her headaches; they were attributed to gastric disorders, anemia, etc. The blood chemistry was carefully gone into at Roosevelt Hospital and was found practically normal. One very excellent internist wanted to apply Dr. Vincent Lyons' method of gall-bladder drainage.

In March, 1921, conditions changed. The patient caught cold through getting her feet wet, and immediately had an exacerbation of the trouble in her left ear, which had been quiescent for several years. The ear now began to discharge profusely, and the two aurists whom her local physician had called in were treating it by irrigations. The discharge kept increasing in volume; the headaches at this time were so severe that the patient was delirious and had to be kept under morphine. When called in consultation I found an acute exacerbation of the old chronic mastoiditis with profuse discharge, but still no tenderness over the mastoid. Fever, nausea, and vertigo were present. Immediate opening was advised.

Dr. Law's report of the second radiograph reads: "The left mastoid shows sclerosis in the tip and posterior to the anterior wall of the sinus. The cellular structure contains granulations or pus with evidences of bone softening." Operation revealed an unusually thick cortex, very sclerotic, with necrotic bone all around the mastoid antrum and running down to the tip and above to the temporosphenoidal lobe, a large area of which was exposed.

After operation, complications arose; the patient had severe chills, the temperature went up to 105½°, and the delirium was more marked. A white cell count gave 19,000 leucocytes with 89 per cent. polynuclears. Although the blood culture was negative, the typical signs of lateral sinus involvement were present; it became necessary to obliterate the sinus and to excise the left jugular. After this second operation the irrational condition persisted for some days even after the temperature went down. I was fearful of intracranial complications, but in the absence of the Babinski and Koenig reflexes, and of word deafness, Dr. Foster Kennedy pronounced the delirium as due solely to "nerve

exhaustion and strain." The patient recovered and her headaches have ceased.

Two years had elapsed from the time that the mastoid operation was first advised to the time it was performed, and in the meantime those headaches had baffled many specialists, but it was quite impossible to persuade them that the mastoid was the exciting cause. In the absence of obvious mastoid signs, such as tenderness, or collapse of the external auditory canal, they could not believe that pain which started in the frontal or the occipital region instead of near the mastoid could be referred to apparently so slight a condition as showed in the middle ear. Yet, Dr. Loughran in his article states that a neuralgia, the result of toxic absorption due to an acute or chronic suppurative process in the middle ear or mastoid, is not necessarily confined to the nerves directly connected with the temporal bone, but may occur in any portion of the cranium, chiefly the frontal or occipital region, in the same way as with those conditions of nerve irritation produced by absorption from the gastrointestinal tract or foci of infection in any portion of the body. He also states that reflex neuralgias from chronic suppurative conditions or necrosis of the bony walls of the middle ear cavity or the mastoid cells, while usually confined to the side of the head connected with the diseased ear, are as frequently found located in the occipital or vertex region. In the case under discussion, it is plain that for a very long time a process of toxic absorption was going on from the condition of the mastoid which may very well have aggravated any toxemic process in the gastrointestinal tract, and been, in turn, influenced by it, so that a vicious circle was formed. It is true, however, that the ear was the main source of trouble, as proof is furnished by the relief of headaches with the relief of the ear condition.

Another patient with the same type of headaches as those in the case just described was seen at the Manhattan Eye, Ear and Throat Hospital, in the service of Dr. Rae. Her case is impressed upon my mind by the fact that the patient, who was too ignorant to appreciate the seriousness of the mastoid condition, insisted upon coming around to thank us for relief from the unendurable periodic headaches from which she had previously suffered.

Case II.—Two other cases out of the total number seen seem particularly illustrative of the varying clinical histories of these conditions. The first, a boy of 18, had an acute otitis media and a mastoiditis during the summer of 1917. The mastoiditis did not warrant operation and later subsided and the ear became dry. Colds and symptoms of infection of the ethmoids were greatly benefited by nasal treatments and breathing exercises. He continued in pretty good condition for almost two years as far as the ear was concerned, as there was no running or pain whatsoever. However, during this period he had attacks, how frequent cannot quite be determined, as the boy tried to make light of them, of severe hemicrania on the side of the affected ear, which he described as "neuralgia all over the side of the head." These attacks came on consequent to any disturbance of the circulation, due particularly to colds and indigestion. In June, 1919, because of infection following a severe cold, the left middle turbinate was removed and the ethmoidal cells and antrum cleaned out. He responded well to the treatment during the following summer, but in January, 1920, following another cold, he had an especially severe attack of his so-called "neuralgic headache," and complained a little of his left ear. Examination of the ear showed simply a tubo-tympanitis. The radiograph revealed sclerosis of the lower one-third of the mastoid including the tip, with some granulations or pus in the cellular area. Operation showed up a particularly large area of sclerosis with underlying necrosis. The patient is well to date, over a year since operation; the "neuralgic headaches" disappeared immediately after the removal of their cause and have not returned at all.

Case III.—The last case is perhaps the most remarkable one with headache as a symptom of chronic mastoiditis that I have encountered. A girl of 16 years seen in the spring of 1912 complained of severe frontal and occipital headaches. Examination showed that her nose was "crowded" and undeveloped, and her tonsils small but diseased. Both ears were apparently perfectly normal. Inquiry revealed that she had had discharge from the left ear for a short time in childhood, but it had long since dried up and been forgotten. Local treatment was given the nose and pharynx. I had no suspicion at this time that the ears were implicated in the headaches. Two years later, in 1914, the girl returned with the same frontal headaches. The *x*-ray plates showed cloudiness in the frontal sinuses, deflection of the nasal septum, and unusual size of both turbinate bodies. Again, two years later, in 1916, she made the same complaint of frontal headches. As the tonsils were exuding much cheesy matter they were enucleated and the adenoids removed. It was after this that she first made mention of pain in the left ear, but examination showed nothing abnormal. Several months later a submucous resection was performed and both the enlarged middle turbinates removed. A few weeks later she again complained of pain in the left ear, and her temperature rose. The pains became more severe and radiated all over the left side of her head. For the first time there was a slight drooping of the superior canal wall. The radiograph showed an old chronic involvement of the mastoid. The mastoid operation was performed March, 1917, just five years after she had first complained to me of headache. In those years she had had regular periodic acute frontal headaches and no ear symptoms whatsoever. Operation showed a very large mastoid all badly infected. Some of the dura and the emissary vein were exposed. The patient has been permanently relieved of her headaches; she is well today, four years after operation.

Summary.—Among all the cases of chronic quiescent middle ear and mastoid trouble, there is a certain proportion of cases in which the objective symptoms do not apparently account for the subjective symptom of acute periodic headache. The proportion is small; the literature furnishes no figures; it is impossible even to give exact figures for the number of cases I have seen myself, as I had observed such cases before beginning to classify them in my own mind. I can safely say, however, that I have had over a dozen definite cases in which headache was caused by latent mastoiditis, and as many more which I believe to be cases of this type, but without definite proof, as they never came to an operation or were lost sight of. This is, of course, a trifling percentage out of the total number of cases of chronic latent mastoiditis seen by any aurist.

Conversely, among all the cases of periodic headache, there is a still smaller proportion which are due to chronic conditions of the mastoid. However, these cases, although infrequent, are serious—not only because of the severity of the headache, but because of the difficulty of diagnosis, and the gravity of the latent mastoiditis of which the headache is a symptom.

The mastoid conditions underlying these headaches may be: focal infection in the mastoid cells; or, chronic suppuration, or sclerosis, or necrosis of the bony wall of the middle ear cavity and mastoid

cells. Since it is possible for a diseased condition of the mastoid to be present for a long time with no subjective symptoms whatsoever, it is impossible to say why certain patients should present acute periodic headache as a symptom, while others do not.

Given this underlying condition of the ear, the recurring headaches may be still further precipitated by any disturbance of the circulation, by congestion from gastrointestinal upsets, constipation, colds, fatigue, worry, a thousand different things, a fact which further confuses diagnosis when examination of the ear has been overlooked.

Headache is a general symptom. Cases of periodic acute headache come to all physicians, most frequently probably to the general practitioner. In making his examination, the physician takes into consideration the condition of the alimentary tract, the kidneys, the heart, the lungs. He may examine the stomach contents and the stools and find conditions that lead him to believe that improper functionating is the cause of the headaches. The blood chemistry may show want of proper elimination or implicate the kidneys. Again, if there is obvious eye strain, the physician will turn the patient over to the oculist, or if there are repeated colds and pain in the frontal regions, he may suspect the sinuses.

The point to be emphasized is that when a patient complaining of headaches is examined, a complete history is not obtained unless the ear is considered. There does not have to be any *active* process present to demand consideration; the most innocent looking ear may harbor an underlying infection. Information should be elicited from the patient as to whether he ever had an earache or had the ear opened in childhood or even in infancy. This information is often hard to get; the trouble occurred so long ago that the patient has forgotten or never knew of it and may have to call on his family for information. Frequently the physician finds out that the ear was opened at some remote period and that there has never been any further trouble.

In cases presenting headache as a symptom, ears that have once been infected, no matter how long ago, must be suspected of being a possible focus of infection or of producing reflex pain through suppuration or sclerosis, particularly in those patients who show no other focus of infection and who do not respond readily to treatment directed at other conditions. Such patients to be treated fairly must have a functional examination of the ear by a competent aurist, and equally important, an *x*-ray picture. If such examination reveals a chronic latent condition of the mastoid, proper treatment should be seriously considered while the mastoid is quiescent, without waiting until it has the chance to become acute. There is no possible way of curing headache due to infection of the mastoid except by operation for the removal of that infection. In this very limited series of cases such operation has never failed to remove the headache along with its cause.

FLUOROSCOPE IN THE DIAGNOSIS OF DISEASES OF THE HEART*.

BY LOUIS FAUGERES BISHOP, A.M., M.D., SC.D., F.A.C.P.,

NEW YORK

PRESIDENT, GOOD SAMARITAN DISPENSARY; CONSULTANT IN HEART AND CIRCULATORY DISEASES, LINCOLN HOSPITAL.

I HAVE observed that the fluoroscope is relatively more employed in Edinburgh than in New York City. An *x*-ray examination of the heart was a routine measure in 1908 in the Clinic of Dr. Groedel of Bad-Nauheim, though strangely enough little stress was laid on it. The profession was still laboring under the belief that when the exact size of the heart had been determined, the supreme question of the condition of the heart had been decided. So much was said in those days about the size of the heart and so little was known about its shape during life that those men spent most of their time making measurements rather than in observing the shape of the heart and the functional activity in its various chambers.

It was the custom at that time, if any of you remember, to speak of enlargement of the heart as a matter of importance from a point of view of treatment and to measure the benefits of treatment by supposed reduction in the size of the heart.

For these reasons the *x*-ray examination in the form of orthodiagraphy was used to make a definite outline of the heart with particular reference to measurement of its size. Curiously enough the fluoroscopic diagnosis of the activities of the different chambers of the heart and the probable auricular and valvular defects as well as the discovery of congenital lesions was passed over lightly. The idea that this method could compete with the ancient and honorable institution of auscultation and percussion never entered the mind of even so skillful a worker as Franz Groedel.

Nevertheless, unconsciously they gained a great deal of skill and I remember how often the younger Franz Groedel could independently conclude by sight what his father had determined by history, auscultation, and a general examination of the person. In fact, it is extremely easy to distinguish a mitral heart from an aortic heart and many other important points. Fluoroscopy, I venture to assert, will become a routine measure in every physician's office before very long. The fact that it was desirable to have a meeting of this kind to popularize

*Read at the meeting of the Medical Society of the Greater City of New York at the New York Academy of Medicine, January 16, 1922.

this method of examination of the heart in New York City will be looked upon as a curiosity.

For several years I have examined with the fluoroscope every patient who has come to me. I have at the same time recorded the picture with a film. The fluoroscopic examination which allows me to observe the relative activity of the various chambers of the heart and the pulsations of the large vessels, has furnished me with a real impression of the condition. The film has enabled me to recall the visual observation at a later period. I doubt very much if the photographic print, alone, would be able to give me anything like the same knowledge of the heart condition as the fluoroscope. I would rather forego the roentgenogram than the privilege of observing the heart in all of its activities.

Although a series of *x*-ray plates furnish a permanent record, many people are excluded from the benefits of an *x*-ray examination entirely on account of the labor and expense involved, thus making it a rather formidable matter. As a result, physicians are deprived of the training which comes only from repeated examinations. In my opinion there is nothing that can take the place of fluoroscopy as a short-cut in the diagnosis of cardiac disease. It must not, however, be allowed to lead into error. Like every method of examination, fluoroscopy must be combined as much as possible with every other method. There will, of course, always be instances where the accompanying history and findings are necessary to check results. I venture to say at this time, what I do not believe ten years from now any one will deny, that in the detection of minor impairments of the heart the fluoroscope is vastly superior to the stethoscope, and when it is supplemented by the electrocardiograph, at least 30 per cent. of otherwise unknown conditions are added to the factors that must be considered.

The effect on people suffering from heart disease of adding to the number of conditions that must be taken into consideration is, on the whole beneficial. Many individuals with minor impairments are perfectly conscious themselves that something is the matter with them and they will not take a negative opinion from any one. If somebody is able to recognize the impairment and explain it, the person can be relieved or he may even be able to carry his impairment in a philosophical manner, which was not possible when his trouble was a mystery.

Medical students are now receiving an intensive training in the anatomy and physiology of the heart so that facts which are at present known to only a few will be a matter of course to the next generation of physicians. In the interim, it behooves our larger institutions to adopt fluoroscopy as a routine matter because it will reveal a large per cent. of unsuspected impairments and will thus save an immense amount of labor in drawing inferences without sufficient data. It will also occasionally reveal a condition of the abdomen or chest which calls for prompt operative intervention and as a result save life.

When physicians first began to examine the chest with the *x*-ray their impression was that it would prove of great importance in the diagnosis of intrathoracic conditions. It was soon shown, however, that on account of the distortion of the shadows and so forth, nothing very precise could be made out. This led to the development of the orthodiagraphic methods and improvement in the technique of making pictures. These methods have been carried on for many years, but it is now possible for us to retrace our steps and take up the study of fluoroscopy and make a definite diagnosis. In other words, founded upon the precise findings of orthodiagraphy and radiography, we are able with sufficient experience to make a definite diagnosis by fluoroscopy.

The fluoroscope gives only a general view of the thorax. When the chest is placed behind the screen and the roentgen tube is charged one sees the shadow of the mediastinum outlined on the clearer borders of the lungs. The heart pulsations are clearly perceived and the respiratory movements are interpreted by the vertical displacement of the heart, by the raising of the ribs, by the outline of the thoracic cavity, and by the raising and lowering of the diaphragm. The anterior and posterior mediastinal spaces are shown by rotating the body of the patient from right to left and from left to right. These appear clearly because of the slight density of the tissues and it is easy to observe the outline of the denser organs as well as to discover additional shadows of pathological origin. Finally, examinations in the dorsal or lateral positions complete in a very short time a series of observations of the thoracic shadows as a whole.

The mental process of discounting a distortion of the shadows due to the nearness of the tube in fluoroscopy is much easier than one would suppose. I have records of 2,000 such examinations. In each instance I studied the heart with the fluoroscope and subsequently in a teleoroentgenogram. I believe that I have acquired the faculty of mentally discounting the larger shadows of the fluoroscope. At any rate the observation of the heart with the fluoroscope enables me to form an opinion of the condition that is usually confirmed by collateral investigations.

When I have had the opportunity to stand beside an accomplished fluoroscopist and observe hearts as they passed in rapid succession, I have found there was very little difference in opinion as to the diagnosis of the condition in the vast majority of cases and that this impression was confirmed when the details of the case were known later. I prefer seeing a heart with the fluoroscope before knowing much about the condition because even in the absence of disease, the direct observation of the heart makes me acquainted with its general personality, as it were, which forms a good basis to build my survey upon. Indeed, one of the great difficulties in the whole subject of the heart is this matter of the individuality of hearts. The student insistently demands a description of what he is pleased to call a "normal heart." There is really no such entity as a normal heart. The nearest approach can be found in a heart which is normal to the person carrying it. The heart of a laborer would be abnormal to a bookkeeper; and the heart of a tall, thin man would be a strange finding in the chest of a short, fat person.

When the heart is observed from the front, one sees the right side of the heart, that is on the left when looking into the fluoroscope, the curved mov-

ing border being the right auricle. Above this, one observes the contour of the aorta, although in many people it is concealed behind the sternum. On the left side of the heart, which is the right of the observer when looking into the fluoroscope, there are three semicircular outlines; the upper one represents the aorta, the one next below the pulmonary artery and the outline below this one, which is a large curve, is the left ventricle. One definitely considers each of these curves in practical fluoroscopy.

The heart, as seen by the fluoroscope, varies according to the position of the patient so that one must be familiar with the fluoroscopic images in various directions. As a rule, the fluoroscopic examination in the anteroposterior positions is sufficient, but the person may be rotated and various views obtained. The upright position fulfills all purposes in most instances.

The following description of the various positions of the heart is adapted from the section on clinical significance of *x*-ray examination in "The Radiogram and Orthodiagram," by Carl J. Wiggers, pp. 244-246.

Combined fluoroscopic, radiographic and orthodiagraphic examination of diseased conditions give evidence of the nature of affection through the occurrence of changes in (*a*) the character of the pulsation, (*b*) the position of the heart and (*c*) the size and form of its outline.

In fluoroscopic examinations the lower right border (right auricle) expands extensively during systole in some cases of tricuspid regurgitation. The upper left border (aorta) gives strong systolic expansions in aortic insufficiency. Whenever the pulsations of the left auricle become visible, as in mitral lesions, they are differentiated by being presystolic in time. Strong pulsations of the pulmonary artery are evident on the left side in cases of persistent ductus arteriosus, or more frequently, when a severe stasis due to mitral lesions is present. They have been observed when an aneurysm ruptures into the pulmonary artery, but this event is rare. Abnormal rhythms, as heart block and pulsus alternans, have been studied and diagnosed by fluoroscopic methods, but this procedure possesses no obvious advantages over auscultation.

A change in the position of the heart may occur (*a*) from congenital causes, as situs inversus viscerum, (*b*) from pleural and pericardial adhesions, or (*c*) from changes in the intrathoracic volume. These last are very common. Even normal variations are caused by the varying position of the diaphragm. In long-chested individuals the cardiac shadow is long and narrow, the axis being more vertical, while in short-chested individuals or in those in whom the diaphragm is pushed up by abdominal distention, it is broad and assumes a horizontal axis. Its position changes as the diaphragm ascends and descends in respiration. It should be remembered that normally the heart is subject to considerable shifting and undue weight should not be attached to slight variations in position. If for any pathological cause (*e.g.* enlargement of the liver) the right dome of the diaphragm is pushed upward, the heart shadow will be displaced to the left. Pulmonary affections such an atalectasis, tuberculosis and pneumothorax cause a traction on the heart toward the side of the lesion. On the contrary, pleural effusions, tumors, etc., push the heart toward the opposite side.

Changes in the size of the heart shadow or orthodiagram when sufficiently marked to be safely beyond the limits of normal variation, are of the greatest practical importance when obtained by guarded technique. The heart shadow probably decreases whenever the heart accelerates (*e.g* in exercise, tachycardia, after atrophine), although the results obtained concerning this point have been discordant. During asthmatic attacks the heart is also reduced in size. A condition stimulating asthma, as far as the effect upon the circulation is concerned, can be produced by the well-known experiment of Valsalva which consists in taking a deep inspiration and then, with closed glottis, making a forced expiration. This diminishes the blood content of the heart which accounts for its decreased size. In tuberculosis the shadow is decreased, and here it is often assigned, but without good reasons, to an actual hypoplasia of the heart muscle.

The heart outline increases after continued hard labor or exercise, pathologically also in nephritis and arteriosclerosis. In these cases an actual hypertrophy resulting from the greater strain to which the heart has been continually subjected is usually the cause. The increase in size (often temporary) associated with acute infections such as diphtheria, scarlet fever and polyarthritis is no doubt accounted for by a dilatation of the heart.

The details of the enlargement are of the greatest importance in heart lesions in which case it is due either to dilatation or to hypertrophy and hence accompanies only lesions of considerable duration and severity. The nature of the dilatation or hypertrophy determines the direction of the enlargement and the contour of the shadow. A left ventricular enlargement takes place to the left. Dilatation or hypertrophy of the right ventricle displaces the shadow partly to the right but also, to a marked degree, upward and to the left. In typical cases of aortic insufficiency the heart shadow is enormously increased toward the left and the contour resembles a horizontal oval or is sometimes called "shoe-shaped." The aortic shadow is increased in width and the apex is never merged with the shadow of the diaphragm. Aortic stenosis causes very similar though less pronounced changes in the radiographic outline. In mitral stenosis the heart shadow which is relatively small, resembles more nearly a vertical oval. The enlarged left auricle becomes prominent on the left margin and above it the pulmonary artery bulges, thus giving the entire left border a step-like appearance. In mitral insufficiency the enlargement tends to be uniform in all directions giving the shadow the appearance of a poorly rounded circle. The right auricular border is distinctly enlarged to the right and the pulmonary artery dilated. The left ventricular shadow is increased toward the left.

With reference to shadows of the heart in its normal state, an excellent description is to be found in Chapter II of the "Heart and the Aorta," by Vaquez and Bordet.

The one disappointing element in this subject of fluoroscopy is that the question of personal skill comes in and training of the observer is necessary. It is always the ideal of scientific work to substitute some mathematical formula or instrument of precision that will eliminate the personal equation. In cardiology nothing is more popular than the arithmetical formula, but so far it has usually failed to be useful.

Fluoroscopy, however, is capable of systematic development and of very definite interpretation. It is particularly valuable in proving and disproving a negative diagnosis. Striking instances appear in daily work where pretty good men pronounce a heart normal when the fluoroscopic examination, even to the casual observer, shows enlargement or deformity of the cardiac image.

I particularly advocate fluoroscopy as a routine procedure in the examination of large numbers of patients to determine which are deserving of detailed cardiologic study and which are not.

Syphilis and Cancer.—Some years ago Ozenne wrote a valuable monograph on the relationship of these two affections and quite recently made an official report on the same subject before the Société de Médecine de Paris. He has not changed his opinion that the syphilitic is a candidate for cancer, chiefly through leucoplakia and the occasional development of epithelioma in a gummatous lesion.—*Le Progrès Médical.*

CARCINOMA OF THE PANCREAS.*

By JOHN B. DEAVER, M.D.,

PHILADELPHIA, PA.

I do not know whether what I have to say on Cancer of the Pancreas will contribute a great deal to the deliberations of cancer week. The condition is fortunately not a frequent one. I believe statistics rank it as comprising from one-half to one per cent. of all carcinomata with which the human body is afflicted, and not many of which are curable even by radium.

The solid tumors of the pancreas are rarely benign, and the most frequent type of malignant tumor is carcinoma. Like other diseases of the pancreas, carcinoma is a disease of middle life with an apparent preference for the male sex. The tumor is usually small in size, in fact it may be overlooked until the liver or stomach has become involved, so that very often a mistaken diagnosis of cancer of the liver or stomach is made. Again, as in other diseases of the pancreas, the head is more frequently involved than the body or the tail of the organ. This fact at once accounts for the outstanding symptom of cancer of the pancreas namely, jaundice due to obstruction of the common duct, although no very typical picture of the disease can be outlined since it is subject to many variations. The jaundice associated with cancer of the head of the pancreas is painless and is marked by persistence without intermission or remission, together with the constant absence of bile and pancreatic ferments from the duodenal contents. As a rule, the jaundice begins with a light icteric hue and gradually deepens in intensity. When the tumor causes obstruction of the ducts of the pancreas itself, there results pancreatic insufficiency, signs of chronic toxemia, as evidenced by marked digestive disturbances and signs of absorption, together with rapid emaciation and exhaustion ending in death in from four to six months. The gall bladder becomes distended in about one-half the cases, particularly where there is no history of previous disease of the gall bladder. The distention results from back pressure of bile due to obstruction of the common duct. This distention does not take place when the gall bladder, owing to the pressure of the disease, has lost its elasticity. It is for this reason that obstructive jaundice assumes such importance in the diagnosis of carcinoma of the pancreas. The tumor may or may not be palpable. Owing, however, to the usual small size of these neoplasms, and the deep seated location of the pancreas they usually are not palpable. Other clinical manifestations are the clay-colored stools, disturbed pancreatic digestion, as evidenced by undigested food particles in the stools, and the reduction or absence of ferments in the stools and the duodenal contents. Study of the stools, however, has not resulted in any benefit to the writer.

Among the subjective symptoms pain is not a prominent one, although when present it occurs late in the disease and usually is deep seated and apt to be severe, marked by exacerbations and radiations to the back and the lumbar region. There is often a history of epigastric fullness after meals, nausea, loss of appetite, often with a particular aversion to fatty foods and to meats; progressive anemia and rapid emaciation.

The symptoms of the disease are subject to numerous variations, but at the same time the following outlines may be said to present a fairly satisfactory delineation of its most prominent features: Often the first signs of the disease are those of indigestion, followed by the onset of jaundice, dilatation of the gall bladder, unassociated with previous biliary colic, deep seated pain in the epigastrium or the liver, radiating to the back or to the lumbar region, anorexia, anemia, rapidly progressive emaciation.

So much for the signs and symptoms of cancer of the pancreas as they can be set forth in this kind of discussion. Cancer as we all know is neither an hereditary nor a contagious disease. But the greatest importance, as in all diseases, attaches to prevention. The key note of this entire week's deliberation is early attention to conditions that may ultimately develop into cancer. So far as cancer of the pancreas is concerned, such a precancerous state is recognized in chronic pancreatitis, in which the head of the pancreas develops a degree of hardness, which even at the operating table is scarcely distinguishable from carcinoma, and often is the forerunner of malignant disease of the pancreas.

The anatomical relations of the pancreas are such that infection of the neighboring organs is readily carried to the pancreas by way of the lymphatic system which is in free intercommunication with these viscera, such as the stomach, the gall bladder, the bile ducts and the liver. Although it seems to be an established clinical fact that previous attacks of biliary colic do not form part of the history of cancer of the pancreas, there is little doubt but that chronic pancreatitis very often accompanies disease of the bile passages and of the duodenum and the stomach. The conclusion therefore is at hand that one possible way of preventing the development of cancer of the pancreas is by preventing the development of chronic pancreatitis, and that is by early attention to disease of the viscera above referred to. That these latter conditions can be cured to a very great extent is generally conceded. But cancer of the pancreas can never be cured, the only thing that surgery offers is to relieve back pressure of the bile and the intolerable itching caused by the jaundice. The pancreas represents one of the few regions which the modern surgeon still approaches with a considerable degree of hesitation. Complete removal seems to be necessarily fatal. Resection and partial removal have been tried with a little success, but they can scarcely be considered safe operations. Surgery, as I have said, offers little, if anything in a way of a cure; palliative measures are the only ones at our disposal. Again I desire to emphasize the role played by preventive surgery. We can by early surgical attention cure certain diseases of the stomach, the duodenum, the gallbladder, and the bile ducts, and thus to some extent prevent chronic pancreatitis and possibly cancer of the pancreas.

*Read before the Philadelphia County Medical Society during the Cancer Week.

The object of these discussions is not to spread unnecessary alarm, but rather to spread a little knowledge on the subject of cancer, knowledge which in this instance is not a dangerous thing. Cancer is a baffling disease whose cause and origin are still enshrouded behind the veil of mystery, and the cure for which will not be found until the veil is lifted. All that we do know at the present time is that irritation forms the basis of cancerous disease. The conditions which I have mentioned are a source of irritation to the pancreas. So that every effort must be directed to prevent that irritation, just as in cancer in general at present all our endeavors must be aimed at prevention.

NOTES ON THE CLINICAL VALUE OF RADIUM IN THE MANAGEMENT OF UTERINE HEMORRHAGE.*

SOME END RESULTS.

By JOHN OSBORN POLAK, M.Sc., M.D., F.A.C.S.,

BROOKLYN, N. Y.

(From the Clinic of the Long Island College Hospital.)

Radium has established for itself a definite place in gynecology in the treatment of uterine hemorrhage; not only in the bleeding caused by fibroids, but in the so-called myopathic bleeding in young girls and spinsters, and the excessive menstrual flow met with in women with subinvolution and fibrosis of the uterus. It has a further place in the treatment of leucorrhea resulting from cervical inflammation, and while it cures this condition by the destruction of the glands and the substitution of scar tissue, it is less destructive to the cervical tissues than any of the several forms of excision.

Its admitted use in cancer is granted, and personally we feel that it is only a matter of time when it will replace operation, for all cancer is cured by the individual producing an immunity against the disease. This immunity, operation breaks down, and hence cancer grows and metastasis takes place unless the removal has been complete. Gaylord has shown that it is possible for mice and rats to produce immunity against implanted growths and live for months and even years with a localized swelling which has no tendency to spread until the resistance is lowered by blood loss or anesthesia—then the cancer promptly grows.

When one thinks of the long, radical operation, with its extensive tissue exposure and trauma, and the prolonged anesthesia necessary to perform this operation, one can readily see how the patient's immunity is necessarily reduced. This explains the prompt recurrence following many of our incomplete efforts at removal and is to me the most striking illustration of why radium, which has a special selective action for certain tumor cells, effects a cure, or at least increases the longevity, for the individual resistance is not impaired.

During the past six years we have been using radium almost daily, with more or less success. Our follow-up system, which is detailed, has given us the opportunity to see the results, modify our indications, and limit the forms of application.

*Read before the New York Physicians' Association, May, 1921.

First of all, let me say, that there is a decided difference in the application, as well as the results where the radium element is used and where the emanations are used; also let me say that intensive radium treatment, with one or two grams of radium element, does not enter into this discussion. Our results have been obtained, and what I have to say will apply to the man who has at his disposal from fifty to one hundred and fifty mgms. of radium element. The results which we have obtained can be had by the intelligent use of this amount.

While it is impressive to see the wonderful cures presented at the weekly conferences at the Memorial Hospital, these results have little clinical or practical bearing on the cases you and I will treat with our 100 or 150 mgms. of radium.

Myopathic Hemorrhages in Young Girls.—These bleedings are frequently excessive, some yield to the internal administration of endocrines and regulation of the lower bowel. When the bleeding has continued for any length of time, the endometrium becomes hypertrophied, and the uterus large and soft, and the os is very likely to be open. These cases were formerly curetted after all other forms of internal medication had failed, and a secondary anemia had been induced. After curetting there was usually an amenorrhea for a month or two, when this was followed again with a metrorrhagia. This same case treated by radium, for from 300 to 600 mgm. hours with the radium properly filtered with glass, silver, and brass, and this covered with rubber, which practically cuts out all of the alpha and beta rays, will establish a normal menstruation after one séance. Once only have we had occasion to repeat the exposure. In this class *there were* 31 *cases treated, the average dosage was* 400 *mgm. hours, and only one application was given in* 30 *of this series.* The results show that the quantity of the menstruation was regulated in every instance, except one, which required two subsequent applications. The last was followed by amenorrhea for one year, when the menses were reestablished and recurred regularly. Six of these girls are now married, and two have become pregnant, a fact which answers some of the criticisms which are made of using radium in young girls.

Radium in Myomata.—Radium will control the hemorrhage of uterine myomata and in a large number of cases will reduce the size of the tumor, provided the tumor is intramural or submucous, and not pedunculated. Nevertheless, operation is still the procedure of choice in most myomata, for the indications for radium are limited and it has certain definite *disadvantages*, such as: First: While it controls bleeding, and in the majority of cases reduces the size of the tumor, nodules outside of the uterus may be left without a blood supply and consequently are more likely to give trouble.

Second: Malignant complications, already in the tumor, may be overlooked, for it has been shown that sarcoma is found in serial section in about 9 per cent. in submucous tumors—consequently we can lay down the dictum that radium is never permissible in submucous growths or unless a diagnostic curettage is possible, for while remarkable results have been shown following radiation of cervical cancer, body carcinoma is not amenable to the effects of the rays.

Third: About 54 per cent. of all fibroids are complicated by some form of tuboovarian disease, consequently many of these intrapelvic complicating lesions are missed, and while the tumor is shrunk, and the hemorrhage controlled the associated lesions help to keep up the patient's invalidism.

Fourth: Radiation, when applied in sufficient dosage to check hemorrhage and shrink the tumor, will seriously impair the reproductive functions in young women, and therefore should not be used as a procedure of choice in this class of cases.

Fifth: One of the symptoms of fibroid which requires treatment is the pressure symptom—here the effect of radium is too slow to relieve the conditions which intraligamentous growths produce on the ureters and blood vessels.

Sixth: The immediate effect of radium is the production of edema and excitation of inflammatory reaction; hence, in the presence of old inflammatory adnexal lesions, this reaction becomes more marked.

Finally: Radiation will increase the necrosis in tumors which are already necrotic, and by added acidosis increase the toxemia of the patient.

Against these disadvantages radium has certain definite advantages in the treatment of fibroid tumors, particularly if proper selection is made. These *advantages* are: First: There is no operative mortality. There is no general anesthetic. There are no postoperative complications, and there is prompt control of uterine hemorrhage.

Second: Should radium fail, operation is always possible.

Third: The menopausal symptoms are not so marked.

Fourth: In intramural tumors we can not only expect absolute cessation of the hemorrhage, but shrinking in the tumor in over 65 per cent. of the growths.

Fifth: Radium is the procedure of choice in myomata complicated by heart disease, extreme anemia, diabetes, and chronic nephritis.

We have confined radiation in fibroids to those tumors which are not larger than a four months pregnancy, where the growth is definitely intramural, and there are no subperitoneal nodules of any considerable size; and to those submucous tumors which, after careful examination under anesthesia, are shown to be sessile.

In all we have treated 106 of these growths by radiation. These patients have had from 2,000 to 3,000 mgm. hours; the radium element has been applied directly to the interior of the uterus, the alpha and beta rays have been excluded by proper filters. I have the follow-up records of all of these cases, and only two have needed subsequent operation; in these, both large submucous tumors, the bleeding recurred, and on operation it was found that the tumors had undergone a marked edema.

In 104 the bleeding ceased and has never recurred, after the first menstruation, which was more profuse in a number of instances than some of the previous bleedings. This, in turn, was followed by a serosanguinous discharge, which persisted for several weeks. In 80 of these tumors the growth had shrunken to less than half of the original size, and in 20 it has entirely disappeared.

The largest class of cases which come to us for relief are the bleedings resulting from subinvolution and fibrosis of the uterus without lateral or posterior parametritis, or a history of pelvic inflammation.

My associates and I have seen and applied radiation to 260 women, who can be included in this class. There have been no failures to check the bleeding, and the majority of these uteri have, after a period of several months, become senile in character, and menopausal symptoms have appeared. Several in this class which were associated with prolapse have subsequently been operated upon, and the uterus interposed under the bladder with resulting cures of the descensus.

EPIDEMIC ENCEPHALITIS SIMULATING BRAIN TUMOR.*

By IRVING J. SANDS, M.D.,

NEW YORK.

ASSISTANT ALIENIST, BELLEVUE HOSPITAL; INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY

The more one studies the different types of epidemic encephalitis, the more fully one realizes the marked protean nature of the symptomatic manifestations of this disorder. Syphilis alone rivals this disease in producing so many different clinical pictures. Brain tumor has been regarded as a disease which, though at times escaping detection, is, as a rule, readily diagnosed by the average clinician, especially when it is advanced to the stage of producing general symptoms such as choked discs, projectile vomiting and intense headache.

The following cases of epidemic encephalitis are reported because they have simulated closely the clinical course of brain tumor cases. In two of the cases operative interference was decided upon, but the operations were not performed because permission was refused in one instance by the patient and in the other by a relative. The third case terminated fatally, and although no necropsy was performed, the consensus of opinion of the men who had closely followed the case was that it was a true case of epidemic encephalitis.

Case I.—I. M., admitted to the psychopathic service of Bellevue Hospital on July 22, 1920, referred by the neurological department of the Vanderbilt Clinic. Male. Twelve years of age. White. Born in New York City. Schoolboy.

Family History.—His parents are Russian Hebrews, of normal intelligence. One sister is supposed to be mentally deficient. There are three brothers and four sisters living. The mother died following childbirth. There are no nervous or mental diseases in the family.

Personal History.—The boy was born at full term and labor was normal. He began to walk and talk at the usual age; his development was normal. He attended school from the age of six and was in Grade 6A at twelve years. He was considered a good student, was never left back in any of the grades, and had never shown anything to stamp him as an abnormal child. He had diphtheria at four and a left mastoid operation at six years of age. He had influenza at ten. In April, 1920, he was struck on the head with a broomstick, but no significance was attached to this, as he had no loss of consciousness nor anything of an unusual nature; but this incident was related by the sis-

*From the Psychopathic Service of Bellevue Hospital. Acknowledgment is made to Dr. M. S. Gregory, Director of the Psychopathic Service, for kindly criticism and permission to report these cases. Read before the New York Neurological Society, May 5, 1921.

ter in her effort to find the possible cause of his disease.

The present illness dates back to the early part of June, 1920. It was then noticed that the patient was losing interest in everything; that he did not play with the children of the neighborhood; would not go in the street; preferred to stay at home. At school he became rather inattentive and did not seem to take as much interest in his work as formerly; he was now slow in his studies, but whatever he did was fairly satisfactory; he was promoted at the end of the term because of the good record he had made in the early part of his school year. About the middle of June he began to show incoherence in speech and it was often difficult to understand him, as his speech was slurring and at times fairly thick. At the same time he began to drop things from his left hand. He had a few vomiting spells while at the dinner table and the vomiting was projectile in type and apparently without preceding nausea. There was no history of any complaint of diplopia or headache or of sphincteric disturbances.

Upon examination at Bellevue he showed the following: Well developed, somewhat pale boy, showing a dull and apparently expressionless facial appearance. He walked into the examining room, dragging the left foot and holding the left arm at his side in a limp fashion. There was a definite flaccidity in the left lower extremity. The equilibritory coordination tests were normal on the right side, but awkwardly performed on the left, on account of the flaccid paralysis. No adiadochocinesia, no dysmetria. The Romberg was negative. His skilled acts were performed well in the right hand, but awkwardly in the left. Speech was definitely monotonous, slurring and thick. No abnormal involuntary movements were seen at that time.

Reflexes.—Corneals and conjunctiva were equal and active on both sides. Upper lateral abdominal and lower lateral abdominal showed* 2 plus on the right side and 1 plus on the left; cremasterics were 2 plus on the right and only 1 plus on the left.

Biceps and triceps were 1 plus on the right and 2 plus on the left. Patellars showed 2 plus on the right and 4 plus on the left. The Achilles were 2 plus on the right and 3 plus on the left. There was a transient ankle clonus on the left and none on the right. Babinski was present on the left and absent on the right. Chaddock was absent on the right and present on the left.

His muscle strength showed that there was definite weakness of the left extremities as compared with the right. There was also definite weakness of the left side of the face. His general sensory examination could not be performed satisfactorily, as it was very difficult to get the patient's attention and also difficult to hold it. He seemed to experience difficulty in perception and in association. He responded, however, to most of the pain stimuli and recognized cold and warm sensations as well as tactile and vibratory sensations everywhere on the body. From the examination one gained the impression that there were no sensory disturbances.

Cranial Nerves.—His olfactory nerves were apparently intact. The vision was good in both eyes, and, although it was impossible to get the cooperation of the patient for proper perimetric tests, his visual fields seemed to be intact. Ophthalmic examination (attending ophthalmologist) showed the following: Right eye—Discs pink with blurred margins and radially striated. No exudate seen; disc elevated 1½ D. Left eye—Disc margins blurred and radially striated. No exudate nor hemorrhage seen. Veins over full. Disc elevated 0.5 D. Impression bilateral optic neuritis (this may be an early choked disc or of the inflammatory type). The pupils were equal, regular in outline and reacted promptly to light and to accommodation. There was no nystagmus, no extra ocular palsies. The corneals were present and active on both sides. There was a definite left facial weakness of the central type. Speech was definitely slurring and thick; tongue protruded to the midline and moved freely, though sluggishly, in every direction. The other cranial nerves appeared to be intact.

*1 plus = weak response; 2 plus = normal response; 3 plus = very active response; 4 plus = with transient clonus; 5 plus = with permanent clonus.

Mentally, the patient was quiet, did not complain of anything; appeared somewhat dazed, stupid, and apparently indifferent to his situation. He answered questions very slowly, but his answers were quite adequate, although slowly drawn out. While apparently in a state of utter indifference, further observation made it quite evident that patient was very bright; observed what took place on the ward and answered all questions quite relevantly and satisfactorily. However, he appeared to have a definite retention defect and association of ideas was somewhat retarded. He showed no delusions or hallucinations; his emotional reaction was quite adequate, and consistent with the stimulus eliciting it. His mood appearance was that of considerable tension. He seemed to have slight insight into his condition and whenever he would wet or soil himself he would burst into tears. He always recognized the examiner and nurses when visited, although he would soon relapse into an apparent state of lethargy and indifference. His heart and lungs were negative. Blood pressure 118/75. Pulse 80, respirations 20, temperature 98.6. Spinal fluid examination made July 29, 1920, showed 2 plus pressure; 1 plus globulin; 4 cells; negative Wassermann; colloidal gold was 0000100000; there was no growth obtained in any of the media after twelve days.

Blood Wassermann was negative. Blood count showed the following: Red blood corpuscles, 4,950,000; white blood cells, 11,000; polymorphonuclears, 75 per cent.; large lymphocytes, 15 per cent.; large mononuclears, 8 per cent.; eosinophiles, 2 per cent.

The patient continued to show a gradually increasing paralysis of the left side of the body with beginning involvement of the right. At the end of a week's residence he began to wet and occasionally to soil himself: he began to experience difficulty in swallowing solid food. A note dated July 31, 1920, states: "Slight drooping of left eye; right pupil does not react as well as left; left facial weakness of the central type; left arm flaccidly paralyzed; left lower extremity spastically paralyzed. Gait is hemiplegic, tendency to fall to the left. Left Babinski and a left Chaddock. Left inexhaustible ankle clonus; left exhaustible patellar clonus. Left knee jerk is 4 plus, while right is 3 plus; left abdominals are not elicited; right are present; left cremasteric is gone, while right is present. Pulse 96, regular, no respiratory difficulties." Eye grounds showed bilateral choked disc, the right elevated to 2 D. and the left to 1 D.

X-ray, August 3, 1920, showed "no fracture of the vault of the skull. The bones of the skull are of the usual thickness; there is no erosion of clinoid processes. Floor of the sella is well formed; no evidence of a tumor of the brain."

August 6, 1920.—Spinal fluid showed 2 plus pressure. 1 plus globulin, 5 cells; colloidal gold 0001100000; no growth on cultures. Patient continued to show apparently increasing drowsiness; his attention seemed to be somewhat clouded; he appeared puzzled and manifested obvious thinking difficulty. He never, however, was inaccessible; he tried to cooperate in examinations; would invariably recognize the examiner, showing this by smiling or nodding his head or lifting up his right arm. He found it very difficult to speak and the few words which he did utter were very indistinct and slurring and of the pseudobulbar type. His general mood was that of apparent depression. He would react to the visits of his friends and of the examiners in a natural way; would often burst into tears when his condition was discussed in his presence and his mood adequacy was that of normal reaction to his situation, although his mood appearance was that of apathy. He really showed a normal emotional response and often burst into tears when he had wet or soiled himself. When food was given to him he would begin to cry, as he apparently realized that he could not swallow it. After his recovery he explained that he knew this. At this time he began to show increasing difficulty in swallowing and would often regurgigate fluids. When asked if he had any headache, he would occasionally burst into crying and then again he would point toward his occipital region. The physical signs pointed to a steadily increasing growth in the right cerebral hemisphere, which indicated operative interference. Nevertheless, the study of the patient's mental picture led one to

doubt the presence of a new growth and strongly pointed to a condition of epidemic encephalitis. However, the consensus of opinion of the different men and the various consultants from other services seemed to be that there was a new growth present, and that the patient should be subjected to operative interference. He was, therefore, transferred to the neurological service on August 12, 1920. There the diagnosis was made of "an infiltrating glioma, starting from the right side beneath the cortex and passing to the left. The assumed extensiveness of the tumor leads to the opinion that operation is not indicated except to save sight." The parents refused to give their consent to the operation and the patient was left alone. He continued to grow physically worse. He would cry from time to time during the day, and would point to the right side of his head at such times when asked if he had any headache.

A note of September 11 states: "Pupils are both very irregular and respond to light poorly. Slight contraction at elbow of left side. Deep reflexes greater on the left side. Plantar response is definitely flexor on the right and is not so definitely flexor on the left. Abdominals are well preserved. There is a well sustained patellar clonus on the left and also an ankle clonus. The reflexes on the right are quite active and there is an exhaustible ankle clonus on that side. Except for the sudden crying at times, as noted above, the patient lies quietly in bed; both eyelids are tightly closed; the swallowing of food becomes increasingly difficult. Speech is entirely absent."

The first sign of improvement was noted on September 12, 1920, when a note was made to the effect that there was no papilloedema in either disc, and there was definite clearness of the disc arteries. The patient then gradualyy stopped crying, and swallowing had greatly improved. On September 16 the patient began to talk. A spinal fluid on September 19 was made showing 2 cells, negative globulin, negative Wassermann, and Fehling was reduced. In the early part of October he began to show definite masklike facial expression; still evidences of left residual hemiplegia; eye grounds were negative and he showed choreoathetoid movements in the left upper extremity. He began to walk on November 1, and continued to improve, so that he was discharged from the hospital on November 18, practically recovered except for residual left hemiplegia and masklike expression of the face.

The patient returned on March 4, 1921, being brought to the Out Patient Department of the Psychopathic Service by a worker of the Jewish Big Sisters. The history at that time was to the effect that following his discharge from the hospital patient was rather helpless; had to be dressed by his stepmother, seemed to show some difficulty in talking, was very awkward with his left hand, would often fly into rages, was unstable emotionally, easily irritated and could not sleep well at night. The worker stated that patient had returned to school, and was apparently getting along fairly well in his work, but that he had often shown in the classroom an irritability and distractibility which was annoying both to his teacher and the other pupils of the class.

A physical examination at that time showed rather interesting features. He walked into the examining room showing a characteristic left hemiplegic gait, the left hand being held at this side, flexed at the elbow and the hand flexed. He appeared very well developed; had gained at least fifteen pounds since his previous residence in the hospital. There was a definite slight left facial weakness. His coordination was good, all tests being performed well on the right side, but awkwardly on the left. No dysmetria, no adiadochocinesia. There was a definite involuntary movement of the left hand and forearm, and the fingers of the left hand would assume definite choreoathetoid movements on voluntary motion of any other part of the body. Skilled acts were well performed on the right, but poorly on the left.

Reflexes.—The corneals and conjunctiva were absent; the abdominals and cremasterics were present and equal on both sides. Biceps, right 2 plus, left 3 plus; wrist, right 2 plus and left 3 plus; knee jerks, right 3 plus and left 4 plus; Achilles, right 3 plus and left 4 plus. There was a definite left ankle clonus. There was a left Babinski. His cranial nerves showed left facial weakness; his pupils were unequal, the right bigger than left, and irregular in outline. The reaction both to light and accommodation was brisk. His eye grounds were clear, vessels were defined, but right disc showed definite haziness. There were no sensory disturbances whatever. Heart and lungs were negative.

Mentally, the patient appeared very pleasant and agreeable, but became easily excited and irritated. He gave a good account of his illness and recognized all the nurses who had had him in charge in the psychopathic word. He spoke fairly freely and in a coherent form. His emotional reaction was somewhat unstable, though adequate. His emotional tone was raised; his mood appearance was that of tension. His memory was good.

His orientation was correct. His retention was somewhat impaired, but this was due more to his attention disorder, which was manifested by some thinking difficulty and distractibility.

CASE II.—A. K., admitted to the psychopathic service of Bellevue Hospital on March 3, 1921. Female. White. Age, 42 years. Hebrew. Born in Austria; eleven years in the United States. Housewife; married at 25 years; had four living children; no miscarriages.

Family History.—Parents living; two brothers, one sister in good health. No nervous or mental disease in the family.

Personal history was uneventful; she was a housewife; no history of any trauma; has never been in any other hospital; very temperate in her habits.

Present illness dated back to February 18, 1921, when the patient began to complain of general malaise, headache, pains in chest, occasional cough and of gradually increasing weakness so that it was found necessary for her to go to bed during the day. On March 1, 1921, she suddenly complained that she could not eat any more, refused to talk to anyone, took to bed and would answer no questions and would speak at no time other than when she complained of being weak and of being unable to walk. At Bellevue on admission the patient appeared quiet and somatically ill, although her appearance showed a well nourished and well developed physical state. Her face was flushed, oily and greasy; pulse was of a low, weak type, and responses to questions were very slow and in a thick, weak, pseudobulbar monotonous manner. It was very difficult to elicit any equilibritory tests because the patient would not cooperate sufficiently to enable one to arrive at proper deductions. The impression gained, however, was that while awkwardly performed on the right side and fairly well on the left, there were no real abnormalities noted in this test. There were no abnormal involuntary movements. Regarding the muscle strength, it was found that the patient was unable to move the right side of the body, due to paralysis. Muscle tonus was increased on the right side of the body. The reflexes showed equally active corneal and conjunctival reflexes. Abdominals were bilaterally active. The biceps were 3 plus on the right side and 2 plus on the left. The triceps was 3 plus on the right and 2 plus on the left. The wrist jerk was 2 plus on the right and 1 plus on the left. Knee jerk was 3 plus on the right and 2 plus on the left. Achilles jerk was 4 plus on the right and 3 plus on the left. There was a definite right Babinski and right Oppenheim and Chaddock. There was a right exhaustible ankle clonus. The sensory examination was difficult to elicit on account of lack of cooperation, but there seemed to be no gross anesthesia to touch or pain.

Cranial nerves showed the following: Pupils were unequal, irregular in outline and reacted very sluggishly both to light and accommodation. Ophthalmological examination showed a definite elevation of the left disc to 1½ D.; the vessels were somewhat congested. The right side of the face was definitely flattened. The tongue pointed to the right when protruded in the midline. Other cranial nerves were intact. Heart and lungs were negative. Pulse, 80; respirations, 20; temperature, 98.0; blood pressure, 125/75. Urine was amber in color; specific gravity 1031; no albumen; no sugar; and showed occasional epithelial cell.

Blood chemistry on March 16, 1921, showed the fol-

lowing: Nonprotein nitrogen, 36 mg. per 100 c.c.; creatine, 1.4 mg. per 100 c.c.; uric acid, 1.2 mg, per 100 c.c.; alkaline reserve (CO_2 vol. per cent.), 58. Spinal fluid showed 2 plus pressure; 1 plus globulin; 3 cells; negative Wassermann and colloidal gold curve of 0012221100.

Mentally, the patient appeared rather irritable, accessible only with difficulty; ate insufficiently and was quite restless and somewhat resistive, and very uncleanly. Did not speak spontaneously, although would groan and moan at night. It was difficult to understand what she spoke, as speech was quite indistinct and patient would not cooperate. Her physical activity was that of restlessness and gestures. Her mood appeared to be unstable; she would occasionally cry, but as a whole appeared somewhat depressed. It was impossible to get her cooperation for any intellectual tests; she seemed to be somewhat confused, although it was really difficult to get her to answer to any of the usual questions given for memory and orientation tests.

The impression gained was that the patient was suffering from an organic brain lesion, which affected chiefly the left hemisphere, causing elevation of the left disc, and compromising the opposite pyramidal tract, giving her a right hemiplegia and a mental picture resulting from this organic disease.

Clinical Course.—Patient continued to show an increasing lack of attention, drowsiness, irritability, and apparent retention defect. She would sleep very little during the night and would moan and groan at times. Efforts to get her cooperation or to elicit any definite complaints were usually fruitless. When asked if she had any headache she would occasionally point to her forehead, but most of the time she would answer "No." She never spoke spontaneously. She would obey commands very slowly; when asked to protrude her tongue she would do so after an interval of about 30 to 60 seconds, and when asked to hold her eyes fixed in one particular place she would do so after an interval of one to two minutes. She would occasionally grasp the hands of the nurse or examiner and hold them tightly for a few minutes. Her general mood seemed to be rather that of depression and anxiety. When visited by her brother she would show her emotional reaction by tears. Her mood appearance was that of apparent apathy. She never appeared to express any delusions or hallucinations. At one time it was possible to get the patient to name correctly the day of the week, time of the season and the year. She seemed to know that she was in a hospital. She readily identified the examiner as a doctor and the nurse as such. She could never give any account of the onset of her trouble. At one time it was possible to get her to remember the examiner's name, but this was only for a few minutes.

An eye examination on March 15, 1921, by the attending ophthalmologist stated: "Eye examination: Dilated pupil, optic neuritis of right disc; choked disc of left."

About March 30, 1921, the patient began to show considerable improvement; she slept fairly well during the night; she did not groan as much as she had previously; she appeared stronger, pulse was better. She was able to retain liquid food, and without regurgitation. She seemed to take more interest in her surroundings, answering a few questions. She complained of pain on moving the right side of the body. She showed irregular and unequal sluggishly reacting pupils; weakness of the left external rectus muscle. There was a definite weakness of the right side of the face, and all movements on the right side of the face were impaired; there was a drawing of the left angle of the mouth, and the tongue protruded to the right. There was a definite right hemiplegia of the flexor type; the reflexes showed the following: Corneal and conjunctival present and equal on both sides; abdominals, right 2 plus, left 2 plus; biceps, right 2 plus, left 1 plus; triceps, right 2 plus, left 1 plus; wrists, right 2 plus, left 1 plus; knee jerks, right 1 plus (?), left 3 plus; Achilles, right 2 plus, left 3 plus. There was a right Babinski. She would begin to cry whenever her right extremities were moved.

On April 5, 1921, she suddenly began to get markedly lethargic; would answer questions only after great difficulty, and then in a very unintelligible manner. She became very restless; kept groaning at night and kept all the other patients awake. She took food very well and did not regurgitate. She had incontinence of urine and feces. She showed a bilateral Kernig. Pulse was 80, respirations 20, temperature 98.4. A spinal fluid examination showed the following: Pressure, 2 plus; globulin, 4 plus; cells, 45; colloidal gold curve, 0122322100; Wassermann, negative.

Eye grounds examined April 6, 1921, by attending ophthalmologist, who said: "Marked choked discs of both sides; unable to determine if hemianopsia is present or not; from the fundus picture one would suspect a brain tumor. When I saw this patient on March 15 she had an optic neuritis in the right eye, but at the present time she has a marked choked disc. The fundus picture also in the left eye is much more marked than when I saw her before."

On April 8 the patient developed a ptosis of the left lid. Blood pressure was 115/85. At this time there was choking of the right disc to 3 D and left to 2 D. There were hemorrhagic areas in both discs, more marked in the right, with overflowing of the veins of both discs, but more marked in the right.

X-ray examination on April 12 showed the following: "The skull is of moderate size. The bones of the vault are of moderate thickness. The groove of the meningeal vessels are slightly deepened. The sella turcica is of moderate size, concave. No evidences of intracranial pressure."

On April 10 she became very restless and resistive, took no nourishment and kept moaning and groaning during the night and screaming during the daytime. On the 11th she became much quieter. On the 12th she hardly made any noise at all, and it was difficult to arouse her from her apparent sleep. When she was aroused, it was found she could swallow fluids only. She became very weak during that same evening, when she sank into a state of stupor. Spinal fluid examination done at this time showed 3 plus pressure, 10 cells, 1 plus globulin, and colloidal gold curve 0000000000. On April 13 she developed pulmonary edema and died on the following day.

CASE III.—A. B., admitted to the psychopathic service of Bellevue Hospital on January 25, 1921.

Personal History.—Female, single, age 46 years. Swedish, twenty-five years in the United States. Laundress of moderate habits. No known previous illness.

Family History.—Father died of pulmonary tuberculosis at 58; mother living at 77 and in good health; two brothers and five sisters in good health.

Present Illness.—Informant, a Bellevue Hospital nurse, who had known patient for a number of years, stated that one month ago the patient suddenly became confused, dizzy, laughed and cried a good deal and could not speak clearly. The people living in the same house complained of her actions and said that she was mentally upset. One week before admission she became very noisy at night, would vomit at the least exertion, became very irritable and impulsive, would fall on all fours when in her room, and had to be looked after like a child. The day prior to admission to hospital she had a spell of confusion, fell on the floor, and, when she regained her senses, it was found that she could not move the left side of her body.

At Bellevue, patient was in bed and showed a greasy appearance of face, emotionless expression, and, when walking, she dragged her left foot in a manner suggesting a hemiplegic condition. Coordination tests were carried out very well in the right extremities but very awkwardly in the left. There was no real adiadochocinesia, no dysmetria. Skilled acts were performed well in the right hand and awkwardly with the left. There was no aphasia and no dyspraxia. Speech was somewhat drawling.

Reflexes showed the following: Biceps, right 2 plus, left 3 plus; triceps, right 2 plus, left 3 plus; radial, right 1 plus, left 2 plus; ulnar, right 1 plus, left 2 plus; patellar, right 2 plus, left 3 plus; Achilles, right 2 plus, left 4 plus; Babinski, right absent, left present; ankle clonus, right absent, left exhaustible; abdominal, right 2 plus, left 1 plus. There were no abnormal involuntary movements noted.

The muscle strength was definitely increased in the left extremity. General sensory examination was not satisfactorily carried out as the patient would object

to the application of the different stimuli, but there was no definite sensory disturbance noted.

Cranial nerves showed the following: Pupils were unequal, the right bigger than the left, and irregular, and reacted sluggishly both to light and accommodation. Visual acuity was very difficult to test on account of lack of cooperation. Right disc was raised to 1 D and showed distention of the veins. Left disc was normal. Both eyes appeared directed straight forward and both eyes were moved rather slowly in looking in any direction. There was no diplopia. There was no other abnormality noted in any other cranial nerve.

Heart showed normal outline; no murmurs and was regular in course and rhythms; lung showed normal resonance, breath, and voice sounds. Pulse was of low tension, 80; respiration 18, temperature 98.6. Blood pressure, 120/75. Blood, Wassermann plus minus; spinal fluid, Wassermann negative; cells, 18; 2 plus, globulin.

X-ray examination of the skull showed that the cranial vault was normal; cranial cavity was not enlarged. The sella turcica was small but well formed. There was no evidence of increased intracranial pressure.

Mentally the patient was dull, disagreeable, would interfere with the other patients, and was quite untidy in her personal appearance. Her speech was incoherent and at times rambling. Her general mood was changing; she was impudent at times, then again she would become fairly agreeable. Her emotional reaction was adequate. Her mood appearance was that of tension and irritability. She was unable to give any account of her difficulties. She denied any hallucinations, nor would she express any delusions. She was, however, often seen talking and laughing to herself, but would offer no explanation for her actions. She was confused and was unable to give any correct answers to the usual orientation tests. Her attention was poor and cooperation tests of memory and retention was poor.

The clinical course was characterized by paroxysmal attacks of restlessness, irritability, intense headache and vomiting, and by steadily increased pressure in the right eye grounds, with the occurrence of hemorrhages in the right disc. During these paroxysmal periods she would groan and scream at the top of her voice, and the pain would not be relieved by the ordinary sedatives. These paroxysms would last from three to ten days. On March 3, 1921, she showed unequal, irregular, sluggishly reacting pupils. The right disc showed linear hemorrhage along the course of the blood vessels, beginning near the centre of the disc and extending outward. The disc margin was blurred. The left disc margin was slightly blurred but not so much as the right. No hemorrhage was seen. The opinion was that it was a neuroretinitis of general or systemic origin. The left side of the face moved very slowly and there was a suggestion of a left facial paresis of the central type. Left abdominals could not be elicited. Deep reflexes were more active on the left side of the body than on the right. There was a left Babinski. Vomiting continued without nausea. Patient wet and soiled herself. Mentally she was moderately confused, but complained of intense headache. The diagnosis made at this time was of a neoplasm in the right cerebral hemisphere. She was then transferred to the surgical service for operative interference. When all arrangements for her operation had been made, the patient refused to give her consent. Strangely enough, she began to show great improvement on March 18. She became much quieter, was more amenable to care and to attention, would no longer wet herself, and the headaches were apparently greatly relieved. On March 24 the eye grounds no longer showed any papilledema and the hemorrhagic areas in the right disc had gradually been absorbed. There was still a moderate left hemiplegia with pyramidal tract signs. She continued to improve so that it was possible to discharge her from the hospital on April 8. She then showed left pyramidal tract signs with but slight haziness of the right eye ground.

COMMENT.—In CASE I we have a young boy who showed steadily increasing paralysis of the left side of the body with choked discs, first in the right and later in the left eye, and the symptoms of paralysis eventually spreading to the right side of the body, and in whom there was great difficulty in swallowing. The mental picture strongly presented the type of reaction usually seen in ordinary lethargic cases of epidemic encephalitis, rather than the mental picture associated with a steadily increasing intracranial neoplasm. The serological examinations excluded the possibility of syphilis. He eventually made a favorable recovery from the active period of the disease, and was left with a residual left hemiplegia and abnormal involuntary movements of the left hand, and a mental disorder strongly suggesting the type of reaction which has been described in a former paper.[1] The refusal of the parents to give consent stood in the way of having patient subjected to operative measures.

In CASE II we have a middle aged female who showed evidences at first of a right hemiplegia with choking of the left disc and later a process extending to the right side of the brain giving greater choking in the right than in the left disc, with hemorrhages in both discs and subsequently showing considerable meningeal irritation, in whom the serological examinations excluded the probability of a syphilitic process; and whose mental picture was that of steadily increasing drowsiness, lack of attention, inability to answer questions properly, and who finally died.

The last case, from the very beginning, showed evidences of a growth in the right cerebral hemisphere, which gave periodic attacks of intense headache, vomiting and choking of the right disc, and a left hemiplegia. In this patient the mental picture was characterized by marked irritability and confusion, and serological examinations strongly pointed against the possibility of syphilis. The general course of the disease did not suggest the possibility of encephalitis, as everyone seemed to be convinced that the reliability of the symptoms pointed to a clear-cut neoplasm. She refused to give consent to the operation, but made a complete recovery. She was finally discharged as an encephalitis lethargica case.

These cases presented many unusual features. In the first place, a perusal of the literature of all the reported cases leads one to believe that the optic discs are not, as a rule, involved in the disease process; and choked disc, as such, is indeed an unusual occurrence. Thus Bramwell,[2] in reporting a group of 57 cases of definite encephalitis lethargica, says, "Changes in the fundi oculi are seldom met with, although in several cases I have seen engorgement of the veins." Barker[3] and his coworkers in their extensive study say, "Outspoken choked disc was not present in any of the cases of my series and judging from the reports, is not met with, although a slight optic neuritis may occur." In reading through the work of Tilney and Howe,[4] one is left with the impression that the changes in the optic discs is not the usual rule. There are, however, isolated cases reported in the literature of choked discs and neuritis. Thus, Urbantschitsch[5] reported a case in which there was intermittant bilateral choking of disc with a left sided abducent paralysis in a boy of fifteen years. The periods of choked discs and abducent paralysis lasted 13 days, 19 days, and 6 months, respectively, the discs clearing up in the interval, and the patient finally

making a complete recovery. Symmonds[6] reported four cases of epidemic encephalitis in which optic neuritis was associated with widespread lesions of the nervous system.

Regarding the explanation for the choked disc, one need mention only the usual theories offered for such phenomena, namely the Leber toxic theory, the Schmidt-Rimpler mechanical theory, and, in addition, the anatomical explanation lately offered by Tilney,[7] who describes a canal which extends laterally over the chiasm and optic nerves from the cephalic extremity of the third ventricle for a distance varying in different subjects. Its lining is formed by ependymal extension of the third ventricle. This canal he calls the supra-optic canal. Any interference which might produce distension of this supra-optic canal or affect its drainage, might cause pressure upon the optic nerves and chiasm obstructing the drainage canal of these structures and causing choked discs. A small amount of exudate might well block these channels; furthermore, if properly localized, it might cause some internal hydrocephalus with resulting choked disc. The hemorrhages could be best explained by the distension of the veins and their subsequent ruptures. The headache and vomiting could best be explained by the increased intracranial pressure. The paralytic phenomena in this disease have been fully described by other observers, and need no further comment.

Regarding the treatment of these cases, we have nothing to offer, except the ordinary symptomatic measures. Operative interference is hardly abvisable. Buzzard[8] discusses a group of four cases in which there was considerable difficulty in the diagnosis, especially in regard to the possible presence of a cerebral tumor, cerebral abscess or cerebral hemorrhage, and in those cases in which operative measures were instituted, death invariably resulted.

Remarkable Recovery from Sarcoma.—A subject had been operated on for sarcoma of the face twenty-two years before he noticed a recurrence. The latter, whether a bona fide recurrence or not, was seated in the superior maxillary bone and was not operable. It was treated with four hours of the most powerful *x*-rays, and in thirty-three weeks but a trace remained. An abundant fetid suppuration had, however, been established, probably in connection with fistula formation, and was treated by large doses of an autovaccine. The lack of definite bounds and the osseous adhesions made operation out of the question.—*Le Progrès Médical.*

A NEW DUODENAL TUBE.

By L. Winfield Kohn, M.D.,

New York.

In a recent article,[1] the author made a preliminary report of a new duodenal tube devised for the purpose of making more detailed studies of the upper portion of the small intestine and the biliary tract. Since that time additional experiments have been performed with this tube but to say more than that the work is encouraging would not be warranted at the present time. However, numerous inquiries regarding this tube and a desire to satisfy those interested, impels the publication of this article with the illustrations and description of the instrument and its modifications.

As brought out in a previous paper, the tube, it is hoped, will serve many purposes:

1. Through the medium of the air-bag arrangement, we are enabled to create a temporary blockade either in some portion of the duodenum or jejunum, depending upon the discretion of the investigator. If the duodenum alone is to be studied, the distance of the tubing between the air-bag blockade and the perforated olive is comparatively short, whereas if jejunal studies are desired the tubing between the air-bag blockade and the perforated olive must be longer. This instrument can be made adjustable to

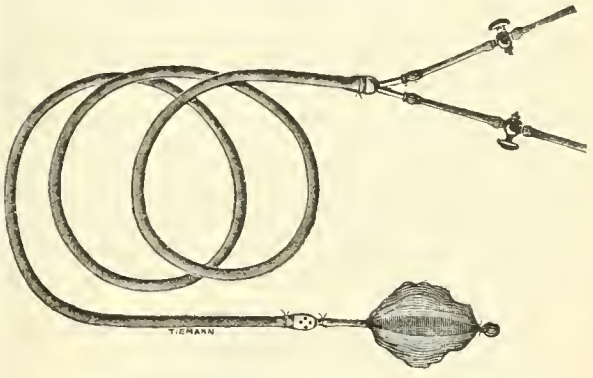

Fig. 1.

the occasion. We believe that fluoroscopy and roentgenography, through the medium of this device, may outline more adequately the duodenum or jejunum. As a result, we may be able to differentiate more definitely gastric, duodenal, jejunal, biliary, pancreatic and colonic diseases.

2. We may attempt to demonstrate or outline the gall bladder and biliary ducts by filling these tracts with a shadow-producing substance. Up to the present time, a demonstration of this kind has been more or less accidental. Beall and Jagoda,[2] and more recently Tenney and Patterson[3] demonstrated the bile ducts in roentgenograms. Why not make a purposive effort to fill these organs? This is just what we are about to attempt and preparations in this direction are now being made.

3. With the principle of blockade of the intestine in mind, we may be able to isolate more definitely the uppermost portion of the intestine and control it in such a manner as to enable us to collect in more accurate quantity and quality the biliary material from the liver and bile tracts, as well as the digestive fluids from the duodenum and pancreas. Thus, diagnosis and treatment of these parts may become more definitely improved.

Since the author's first paper was published, Van Nuys' also has made a preliminary report of a tube for the purpose of obtaining the results we have aimed at by our instrument.

We have devised, in all, three different types of

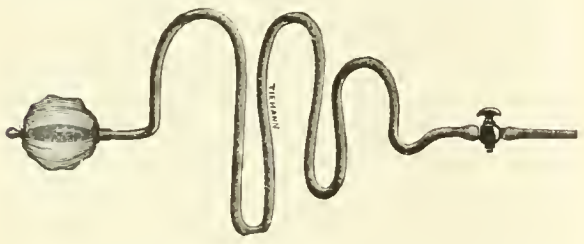

Fig. 2.

tube. The instrument being employed at present is No. 1 of the illustrations. These instruments consist of hard rubber stop cocks, a silver Y, rubber tubing, size 16 or 17 French, perforated olive body with a double channel, inner tubing of 12 French size, olive weight brass tip, 23 French size, thin tissue or glove rubber (for air-bag), with fine silk chiffon surrounding it as a retentive or supportive agent. The rubber air-bag, when it is blown up, should be circular or as near circular in form as possible. The rubber connections are securely tied with waxed silk thread. The instrument must be practically airtight or else the air-bag will quickly collapse. In instrument No. 1, one avenue communicates with the air bag which is filled up with air and serves as a blockade, whereas the other avenue serves to convey the shadow-producing medium to the duodenum or upper intestine above the blockade. Instrument No. 2, after it has entered the duodenum and while the patient is under the fluoroscope, may be blown up with air and as soon as the blockade has been created, the patient is instructed to drink the shadow-producing medium. Small portions of this medium may then be seen to

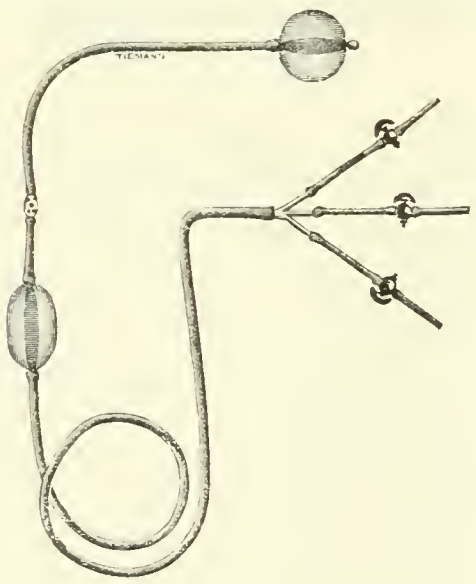

Fig. 3.

enter the duodenum and accumulate above the blockade. Up to the present, work with this device has been mainly speculative and the same may be said of instrument No. 3, which has a double blockade arrangement for the purpose of isolating special portions of the alimentary tract, particularly separating the duodenum from the stomach.

In conclusion, the author desires to express his appreciation of the work done by others during the past in the direction of creating devices for the purpose under consideration. Every instrument or idea of the past serves to create new ideas and instruments for the present. It is to be hoped that our efforts may be fruit bearing.

The instruments here described may be secured from Geo. Tiemann & Co. of 107 East Twenty-eighth Street, New York City.

THE DIAZO REACTION WITH A NOTE UPON THE INCIDENCE OF POSITIVE REACTIONS IN A SERIES OF 2017 TESTS.*

By Robert A. Kilduffe, A.M., M.D.,

Pittsburgh, Pa.

Director, Laboratories, Pittsburgh Hospital; Director, Laboratories, McKeesport Hospital; Serologist, Providence Hospital.

The history of medicine moves in cycles and this is often well illustrated, as any observer of the literature can testify, by the ebb and flow in popularity of the various procedures introduced from time to time as methods of value in the accumulation of data leading to that "consummation devoutly to be wished for"—a diagnosis.

A striking example of this inconstancy in popularity is seen in the so-called diazo reaction in the urine, originated by Ehrlich in 1883. The simplicity of the technique, resulting in its widespread application, soon gave rise to a multiplicity of reports many of which are at wide variance, so that one searching for information as to its possible value as a part of a routine uranalysis, is at once confronted, on the one hand, with numerous reports in which the test is widely extolled as a valuable procedure, and, on the other hand, equally numerous observations as a result of which it is as vehemently decried as worthless and misleading.

In a cursory review of available literature one is at once struck by the fact that there are many absolutely contradictory statements with regard to the occurrence of the reaction and also that there are many variations in the technique used by different reporters, a fact which may be of importance as tending to explain some of the varying results. Thus the reaction is said to have been positive—or negative—in measles, typhoid fever, tuberculosis, trichinosis, gonnorheal septicemia, meningococcus infections, acute rheumatic fevers, and after the ingestion of naphthalin, chrysarobin, opium, and

*From the Laboratories of the Pittsburgh Hospital.

phenol derivatives; tannic acid, gallic acid, and iodine compounds interfere with the production of the reaction, probably because of the action of the drugs on the reagents in the test tube rather than because of any effect within the body.

No adequate explanation of the mechanism of the reaction has ever been advanced. All that is known is that, in positive reactions, there is a chromogen in the urine which, when treated with diazo-benzene-sulphanilic acid and ammonia, will give rise to a red color, the nature of the chromogen being unknown. As the preparation of chemically pure crystalline diazo compounds is a matter of great difficulty, the formation of diazo-benzene-sulphanilic acid is accomplished by the action of nascent nitrous acid on sulphanilic acid just prior to the test.

The two conditions in which the occurrence of the reaction is more or less unanimously granted are tuberculosis and typhoid fever. Its exact significance in the latter condition is a matter of doubt; in tuberculosis by many observers it is held to be indicative of a very extensive process, a rapid progression, and of sufficient gravity to warrant a grave prognosis. In typhoid fever the reaction may be looked for from the second to the sixth day, lasting until the fifteenth or twentieth day when the intensity gradually fades until the reaction disappears entirely. It is prone to reappear with fresh rises of temperature but only when these are due to a relapse, thus serving to differentiate between relapses and complications in which it does not appear. In paratyphoid fever the reaction is inconstant.

According to Todd[1] its early disappearance in typhoid fever is a favorable sign while Green,[2] one of the most ardent advocates of the test, believes that, though a positive diazo reaction does not of necessity indicate typhoid fever, a failure to obtain the reaction during the proper stage of the disease renders the diagnosis dubious, while a persistent failure to obtain it at any time absolutely negatives the diagnosis.

According to the same observer, when the test is made according to his modification of the technique, the reaction will be found negative in malaria, pneumonia, and early miliary tuberculosis, and positive in many of the acute exanthemata though transient.

Because of the varying statements encountered and as an aid in determining whether or not the reaction should be included as a part of the routine uranalyses of these laboratories, the test was applied to 2,017 consecutive urines, the purpose of the investigation being to determine the incidence of positive reactions rather than to gather statistical data concerning the value of the test as a diagnostic or prognostic aid. Obviously if a high percentage of positive reactions was obtained in routine specimens from the medical, surgical, and gynecological wards of a general hospital, the importance of the test was automatically decreased; conversely the occurrence of positive reactions in limited numbers or in a restricted group of pathological conditions would serve as an indication of the utility of the test in general.

Owing to the unselected character of the cases admitted during the period of investigation it was not possible, nor was it attempted, to secure a large series of any one disease and the results are, therefore, reported without comment.

The technique used was that advocated by Greene, and follows:

Reagent: Solution A:
Acid hydrochloric concentrated..... 50 c.c.
Water distilled .....1000 c.c.
Acid sulphanilic C.P. q. s. *to saturation.*
Solution B:
Sodium nitrite .....0.5 gm.
Water distilled .....100 c.c.

(N. B. The sodium nitrate solution was freshly made each week and kept in a dark colored bottle).

The Test: To 100 parts of solution A add one part of solution B by volume. This solution constituted the reagent used in the test. Equal parts of this solution and of clear, filtered, fresh, acid urine were mixed in a test tube. After mixing, 5 cc of concentrated ammonium hydroxide solution were stratified upon the mixture. The reaction was looked upon as positive only when the following criteria were achieved: (*a*) The color produced must be a distinct *red*; (*b*) when shaken the foam must be pink; and (*c*) when diluted with a large quantity of water in a porcelain evaporating dish the pink color must be plainly evident.

Performed in this manner in 2,017 tests a positive reaction occurred 28 times, an incidence of 1.4 per cent.

The diagnosis in the cases giving positive diazo reactions follows:

Pneumonia, lobar	6	Following neosalvarsan injections	2
Typhoid fever	5	Chronic nephritis	1
Tuberculosis (sputum positive)	2	Pelvic peritonitis	1
Tuberculosis suspected but not proved	3	Diabetes	1
Abortion	2	Empyema	1
Acute rheumatic endocarditis	1	"Blood stream infection"	1
		Not made	2

With this technique the reaction was positive in every case of pneumonia tested and was constantly found positive at some time or another in every case of typhoid fever. Both of the known cases of tuberculosis were actively progressing and in the suspects the history and clinical picture were very suggestive although a positive sputum was not obtained during the period of examination reported. The occurrence of a positive reaction following the injection of neosalvarsan is of some interest though without adequate explanation.

The result of the series suffices to indicate that with the technique used the reaction certainly does not occur promiscuously.

New York, March 25, 1922.

SUGGESTED REMEDIES FOR CERTAIN DEFECTS IN MEDICAL ORGANIZATION AND SERVICE.

SUGGESTIONS for the modification of medical practice for the purpose of giving still greater emphasis to the prevention of disease, and which at the same time, might solve some of the pressing problems confronting the profession, are commended to the consideration of medical organizations and physicians in an article by Dr. Louis I. Harris published in the *Monthly Bulletin* of the Department of Health of New York City. Dr. Harris points out that we are compelled to recognize, dislike it as we may, that new social demands are being made upon the medical profession throughout the world. To ignore these demands and merely to disclaim and protest against them is to challenge various lay groups to take entirely into their own hands the reorganization and the control of medical service.

The plan suggested by Dr. Harris would include the restoration of the family physician to the state which he previously occupied, presupposing that he must equip himself with wide knowledge, study, and skill, to assume the general direction of the treatment of patients and responsibility for securing the help of specialists when needed. Dr. Harris comments on the helpless and pathetic attitude of the general practitioner who seems to forget that, if a new method finally receives scientific approval, if it is a method which does not require unusual technique or equipment, he, like his confrère, the specialist, may acquire competence in the new procedure. Believing that any satisfactory reorganization of medical service must come from within the profession and not from without, Dr. Harris bases his plan on the fact that what an individual may not do without incurring reproach and ostracism a society as an organization can do with propriety. For example, a county or well-organized district medical association could establish itself as the neighborhood medical service agency for its district. It could select a committee to prepare a form or circular written in forceful and clear style, to be distributed, posted, and otherwise brought to the attention of the patients of each of the medical members of the association that it is the collective judgment and counsel of the association that all persons should submit to a periodic health examination for their protection and benefit. Such a campaign of publicity would eventually mean that every physician would be carrying on at a reasonable fee a large life extension service. In the same way the residents of a community could be warned of a threatened typhoid fever epidemic and advised to avail themselves of antityphoid inoculation, or a campaign could be carried on calling attention to the need of a Schick test. The examination of food-handlers and many other forms of public service attempted by tuberculosis clinics, venereal disease clinics, cardiac clinics, etc., could revert to the private physician. In this way a new relationship would be established between the general practitioner and his patients. The doctor would not be a figure whose presence always suggests tragedy, and the conflict between life and death. He would become the advisor and counsellor of his patients in the fullest sense of the term. If this plan were adopted it would be the business of the County Society to see that members who pledged themselves to preventive medical work would employ the most approved methods and conform to high standards in their medical work.

Another fact emphasized by Dr. Harris is that physicians, through their county medical societies, must take over the control of philanthropic organizations doing medical work and exercise an aggressive unselfish censorship upon those which threaten the public welfare, or which are unnecessary, or which add to the general confusion. These things can be done, if medical men, under strong and wise leadership, cooperate not only in a business spirit, but on a fraternal basis hitherto undeveloped. If such a spirit could be developed the medical profession might inaugurate an economical system of practice whose benefits might be enjoyed by the poor and those of moderate means, which might enable it to forestall Health Insurance or some other system of nationalization of medical practice.

In closing, Dr. Harris says: "It is to be hoped that this communication will cause the members of the medical profession to make a searching inquiry into the weaknesses, the pettiness, and the lack of objective and leadership, which characterizes the conduct of our medical and public health societies, and that they will adopt vigorous and drastic measures for the correction of these things, to the end that these societies may become the instruments of cooperative, well-organized effort to correct the defects of medical organization and service, and to rout and banish the small politicians who divert such societies from their higher duties to the public and to their own membership." Even though one may not endorse Dr. Harris' critical comments in their entirety, his plan is well worthy of thoughtful consideration and if it did not solve all knotty problems confronting the profession it would at least do away with the antagonism sometimes in evidence between private practitioners and public health organizations, enlarge the scope of preventive medicine, and be a step toward restoring the general practitioner to a place in the sun.

RADIUS CURVUS.

RADIUS curvus is more frequently unilateral than bilateral and is an affection of adolescence. It is much more common among females than males. Of all the numerous theories which have been emitted for explaining its pathogenesis, late rickets is the only one worth consideration. There are several varieties of this deformity, according to whether the degree or the direction of incurvation is considered. The lower third of the radius is alone deformed in some cases, in others the upper two thirds of the bone is the site of the deformity, while the concavity may be anterior and external, or posterior and internal. The symptoms of radius curvus are a deformity of the diaphysis of the radius with perfect integrity of the ulna excepting at its epiphysis, which may be hypertrophied, thus changing the direction of the articular surface of the radius; an ulna-pyramidal dislocation, but the connection of the radius with the semi-lunar and pyramidal bones is always preserved; hyperextension of the hand; limited movement of flexion or extension, according to the direction of the incurvation; intact ligaments; no changes in the muscles or of the sensibility, and sometimes shortening and decrease in size of the forearm. The diagnosis is made with radiography. The condition is to be differentiated principally from Madelung's subdislocation, which in the majority of cases has the same pathogenesis, but in radius curvus the lesion is in the diaphysis, while in the process described by Madelung it is seated in either the bones of the carpus or the ligaments. It has the same subjective symptoms, but the objective symptoms are entirely different; there is unquestionably deformity of the wrist and dislocation of the ulna. but even in the most accentuated cases the most that will be noted is an incurvation of the styloid apophysis of the radius. Finally, in certain cases there is dislocation of the ulna-pyramidal joint as well as the mediocarpal, and the radius is absolutely intact.

The evolution varies with each case; in some it progresses regularly for several years, in others it attains a rather advanced degree in a year or even in a few months. As in the case of genu valgum, this process may present an acute or a chronic form and several phases in the evolution can be made out. In the first place, the pain ceases when the limb is at rest; in the second, the deformity appears, but disappears on resting, while in the third the pain will have ceased, but functional difficulties arise; in some cases, however, a kind of accommodation occurs which allows the functions of the limb to continue; in the fourth phase of the process the deformity is evident and attains such a degree that it becomes a real infirmity. But such cases are rare, as most frequently the deformity stops before having reached such an advanced degree.

The prognosis is good if the lesion does not go beyond the first phase, but it is generally rather serious because the patient, being deceived by the temporary character of the pain, at the onset does not usually consult his physician until the deformity has become established. This is all the more unfortunate because the process is more prone to arise in young girls and results finally in great disturbance in the use of the hand, preventing the execution of daily work. Therefore, the gravity of the lesion differs according to the time in the evolution when the patient is first seen, but need be taken into consideration only from the time that the carpus has become involved, preventing movements of the hand and wrist. When the movements are still relatively good, the treatment by massage and electricity will usually be sufficient, but when the second phase is reached, the pain having given place to functional disturbances, forced correction of the limb should be attempted by the use of a plaster cast. If this treatment is insufficient, the only procedure of any value will be osteotomy.

SLEEPING SICKNESS AND SYPHILIS.

THERE is a certain amount of similarity between sleeping sickness and syphilis, although there is not enough evidence to justify the theory of Schaudinn that there is a close biological relationship between trypanosomes and spirochetes. It may be pointed out, however, that there are some suggestive analogies between sleeping sickness and syphilis. For example, each has a primary and secondary phase, the former in which the disease is mainly an affection of the blood, responding to treatment, while the latter, in which the parasite has attacked the central nervous system, is recalcitrant, in the case of sleeping sickness entirely so. In the Bulletin of the Alfonso National Institute of Hygiene, several years ago, was an article on this subject by Dr. Edward Reichenow describing the parallelism between sleeping sickness and cerebrospinal syphilis. In this article attention was drawn to the fact that the non-success of atoxyl in one and of salvarsan in the other infection was because the parasite multiplied in the cerebrospinal fluid and that the drug injected did not penetrate the meninges. Of course, intraspinal injection has been suggested and tried, but with no success. F. S. Arnold, writing in the *Tropical Diseases Bulletin* for February, 1922, notes that in this connection the observations of Tuszewski, made in 1914, are significant. He found that in animals injected intraspinally with trypan blue, the coloring matter spread in the cerebrospinal fluid up to the base of the brain and as far as the frontal lobe, tinging the mininges deeply. It did not, however, spread to the convexity of the brain, nor to the ventricles or their fluid. Reichenow suggested the use of drugs which have the power of penetrating the meninges and so reaching the central nervous system. He had himself experimented with alcohol and urotropin and gave a brief résumé of the experiments with the latter drug. The patients, in all of whom the existence of trypanosomes in the cerebrospinal

fluid has been proved, were given 6 gm. of the remedy at intervals of two weeks until 48 gr. had been given. The effect on lymphocytosis in the cerebrospinal fluid was in all the cases, four in number, very marked, the fluid in one case being normal in that respect at the expiration of the treatment. This patient, who, in spite of the presence of parasites in the cerebrospinal fluid, was free from nervous symptoms, remained so after treatment. In the other three, in whom the disease was clinically very advanced, with ataxia, somnolence, and psychic defects, definite improvement was observed in one only. Reichenow considered that his results should encourage to a further and more extended trial of the drug in cases in which no grave damage had yet been done to the nervous tissue.

There assuredly is a parallelism between sleeping sickness and cerebrospinal syphilis, but there is lacking evidence as to an intimate biological relationship between trypanosomes and spirochetes. The poison of both infections profoundly affects the central nervous system, but it is impossible to treat sleeping sickness with any measure of success, while syphilis is amenable to treatment to some extent, although both diseases, after they have reached the stage in which the central nervous system is attacked, are as yet incurable. Both are progressive, and the only favorable remark that can be made is that, while the progress of sleeping sickness is made inexorably without any lagging, the advance of syphilis may be stayed by proper treatment.

Pulmonary Complications of Influenza in Pandemic Times and During the Grippe of 1921-2.

Papers were read on these subjects at the Academy of Medicine, Paris, during January last (*Le Bulletin Médical*, February 1-4, 1922, xxxvi, 6). While grippe pneumonia has become a very trite theme it possesses perennial interest. In 1918 the presence of congestion, edema, and hemorrhage was a feature in the pulmonary lesions. According to Letulle, lobar pneumonia is practically devoid of any element of congestion despite the widely held idea that congestion of the lungs stops short of and passes into it. Lobar pneumonia is hardly more than an intra-alveolar clotting which follows the pouring out of a fibrinous exudate. In influenza this fibrinous alveolitis is something which most decidedly does not take place. Instead we see intense vascular congestion, intraparenchymatous hemorrhage, intraalveolar serous exudate, epithelial desquamation, and leucocytic diapedesis. The latter, being usually intense, leads to the formation of multiple abscesses which may cause extensive parenchymatous destruction. Naturally influenza-pneumonia is diffuse. In the present seasonal influenza several prominent practitioners had seen no clean-cut pneumonia. What was seen was a diffuse generalized bronchitis with pleuropneumonia of the sort which causes posterior percussion dulness, bilateral, extensive, and silent. Puncture of the pleura is positive. The sputum is non-pneumonic, abundant, mucopurulent, suggestive of edema of the lungs, but nonalbuminous. There has been no hemoptysis. Recovery is the rule and is preceded by lysis. The pneumococcus has especially been present; Pfeiffer's bacillus in a less degree. There were a few positive blood tests for the pneumococcus.

The Drama as an Instrument in Medical Education.

In olden times poetry was used in teaching medicine and there was academic recognition of its utility. Dr. Æmilius Macer sang about the virtues of herbs, Dr. Ægidius sang about the pulse and heart and urine; Dr. Carolus Spon described the muscles of the body in lyrical measures, and Fracastorio sang of syphilis in classical Latin verse. This use of poetry had mnemonic rather than esthetic value, though sometimes the writers touched the higher notes. The drama, however, has not been used for purposes of technical medical instruction. In the eighteenth and early nineteenth centuries it was the fashion sometimes to describe diseases and treatment in the form of "conversations." Thus in "Dialogues About Diseases," Dr. Lobstein, in 1830, presented the doctor and his patient with much theatrical realism. The dramatic form of writing true to experience may sometimes be made an agreeable substitute for the clinical lecture and especially for realistic instruction in the art and methods of practising medicine. The drama is a dynamic, the clinical lecture a static affair, and the world is craving for the dynamic just now. A venture of this kind of medical writing is given elsewhere in this issue under the head of "The Stepfather—A Medical Comedy."

News of the Week.

Smallpox in New York and Connecticut.—Seven cases of smallpox have been reported to the State Department of Health since the first of January of the present year. This refers to the State of New York, outside of New York City, where four additional cases have been reported in the same time. Of the upstate cases, four have occurred in Niagara Falls, one in Norfolk, St. Lawrence County, and two in or near Northport, Suffolk County. There is strong suspicion that the cases in the northern and western parts of the state arose from communities across the Canadian border, where smallpox is said to have been prevalent in a mild form for some time past. There appears to be a suspicious connection between the Long Island cases and the occurrence of smallpox in Connecticut. Smallpox has also appeared in Bethel and Danbury, Connecticut, some 150 cases having been reported from Fairfield County, which includes Danbury, and the health authorities of that State are cooperating actively with the New York State and local health officers to prevent the introduction of the disease into Dutchess, Putnam and Westchester Counties. The New York State Health Department is urging vaccination of the inhabitants in all localities along the Connecticut border. Of the seven cases in other upstate counties six had never been vaccinated, and the seventh was a girl who had not been vaccinated since she was a small child, ten years ago.

Coyotes Spread Rabies.—An outbreak of rabies

is raging in the eastern section of the State of Washington, according to the Department of Agriculture. Reports from field agents indicate a similarity of the epidemic to that of 1915 during which 2,100 persons in five Rocky Mountain States were bitten by rabid animals. Spread of the disease was attributed in the department's reports to infected coyotes. In a number of cases, it was said, these animals have attacked people in their dooryards and in the streets of the smaller towns.

Dogs Quarantined in Twenty-five Connecticut Towns.—Connecticut is threatened with an epidemic of rabies, according to Cattle Commissioner J. M. Whittlesey, and to prevent its development he has extended the dog quarantine to twenty-five towns.

Clinics to Study Juvenile Delinquency.—A scientific study of juvenile delinquency with clinics in each of the 2,391 juvenile courts in the country is planned by the National Committee for Mental Hygiene. Very few of the courts now have facilities for any such study, the committee finds, and even those that are equipped for the work are handicapped by lack of funds. The work will be financed by a gift to the committee from the Commonwealth Fund. The services of psychiatric clinics will be offered by the committee to the juvenile courts, either free or on a cost-sharing basis. Each clinic will be composed of a psychiatrist, a psychologist and a psychiatric worker, and it is hoped that as a result of these clinics the entire problem of handling the maladjusted child for his own good and the good of society will be facilitated. A new organization, to be known as the Prevention of Delinquency Division, has been formed by the committee with Dr. V. V. Anderson in charge. Dr. Thomas W. Salmon, Dr. Arnold Gesell and other well known psychiatrists will assist in the work.

New Psychiatric Clinic in Philadelphia.—To aid in the prevention of mental diseases the department of public health has established a neuropsychiatric clinic at the Philadelphia General Hospital, Thirty-fourth and Pine Streets. The clinic will have a double function—the treatment and observation of patients who are not classed as insane and are discharged from the psychopathic wards of the hospital, and the examination of patients for early manifestations of mental diseases. A "flying clinic" is also being conducted at the Lee Special School, where a complete examination of children is made by staff doctors and nurses weekly.

Dubuque County Medical Society Assumes Care of Poor.—The Dubuque County (Iowa) Medical Society and the County Board of Supervisors have entered into an agreement whereby the medical men of Dubuque County agree to render aid to the indigent poor of the county for a year at the stipulated price of $3,250. The doctors have agreed to each serve the county for a period of ten days—during which times they attend all persons who are county charges free of cost to the individual. This service only applies to the indigent poor. The specialists of the city are allotted specific times when they are subject to call for the care of indigent poor. The money received in payment for this service does not go to the individual physician. A part of it is used by the Society to purchase equipment to make more interesting their monthly meetings, and to pay the expenses of experts who may be brought from a distance to address the society.

Protest Against Sending Fox Hill Patients Out of State.—The American Legion, through State Commander Major William F. Deegan, is protesting against the scattering of tuberculous ex-soldiers at Fox Hills Hospitals to institutions all over the country. The Legion is in agreement with the Government's plan to close Fox Hills Hospital, but thinks the men should be kept inside the State. They are demanding that New York Congressmen and Senators take the matter up at Washington. They complain that, with the closing of Fox Hills, the Government has no hospital for the care of ex-soldiers in this State, except an institution for the insane, still under construction at Kingsbridge. A late report states that the Government is about to contract for the care of 400 patients in Sea View Hospital, Staten Island.

Medical Service by Wireless.—American sea captains have not been slow in availing themselves of the medical wireless advice offered by the U. S. Public Health Service. Hospital No. 70 (Hudson Street, New York) reports the arrival at 10 o'clock at night of a message from the steamship Chester Valley saying that a man on board was suffering from pain in the abdomen, persistent vomiting, and inability to lie down owing to the pain. The officer of the day promptly prescribed treatment; and the next morning the ship wirelessed thanks, saying that the patient was much improved.

Foreign Mails To Be Inspected for Typhus.—The health commissioner of this city, according to the daily papers, has ordered that all mail matter reaching New York from European countries infested with typhus shall be subjected to examination by the Health Department officials. When the ships dock health inspectors will go aboard and inspect the mail. What they expect to find passes one's comprehension, unless the letters contain cooties by way of remembrance.

The Importance of Eye Care.—The Eye Sight Conservation Council of America has recently made public the results of a survey of school children and adults which show alarming conditions. Statistics covering many years show that nine out of every ten persons over 21 usually have imperfect sight. At 31 the proportion is larger. Above 40 it is almost impossible to find a man or woman with perfect sight. It was learned some years ago by the examination of several thousand school children in one of our large cities that 66 per cent. of them had defective vision of such a degree as to warrant the wearing of glasses. Quite recently the examination of more than ten thousand employees in factories and commercial houses showed that 53 per cent. had uncorrected faulty vision, 13 per cent. had defects which were corrected, making a total of 66 per cent. with defective eyes. These two surveys were made under different auspices several years apart. They mean that a very large majority of the public have eyes defective to such a degree as to require glasses to make them happier and more efficient members of society. The Eye Conservation Council of America is organized for the purpose of fixing the attention of the public on the importance of all factors that contribute to the conservation of vision and the relief of ocular defects.

Dr. Hans Zinsser, formerly in charge of sanitary inspection successively in the First and Second Army Corps, A. E. F., received the Distinguished Service Medal at Governors Island, on March 17, for his successful operation of a plan of military sanitation and control of epidemic disease while serving with the Second Army Corps.

Dr. H. W. Hartman of Keyport, N. J., has been appointed county physician. His appointment took effect on March 1.

Dr. R. MacMurran Shepler of Carlisle, Pa., has been appointed physician to the Cumberland County Home and Hospital.

Dr. M. L. Werner has been appointed health officer of Red Wing, Minn.

Dr. J. E. Hull of Pond Creek has been appointed health officer of Grant County, Okla.

Gifts and Bequests.—The will of James H. Ottley bequeaths $10,000 each to the Nassau Hospital Association, Nassau, L. I., the New York Infirmary for Women and Children, the New York Eye and Ear Infirmary, Knickerbocker Hospital, and New York University for its dispensary.

The Woman's Hospital, New York, is the recipient of a bequest of $15,000 under the will of the late Mrs. Rosina E. Hoyt. Mrs. Hoyt also provided a bequest of $5,000 for her physician, Dr. W. J. Murray.

Opportunities for Service in Venereal Disease Clinics.—The Associated Out-Patient Clinics announces that it has received many applications for assistants in venereal clinics. These positions are for both men and women, graduates and students. In most instances physicians with no special training in venereal disease will be considered. Any physicians who desire an opportunity to learn this specialty, should communicate with Dr. Alec N. Thomson, Secretary of the Section on Venereal Distases of the Out-Patient Clinics, 15 West 43d Street, New York City.

Physical Training in Pennsylvania Schools.—Henry R. Allen of the Bureau of Public Health Education, Department of Public Instruction, Harrisburg, claims that physical training courses in the schools are not producing the results hoped for. He recommends the following changes in physical training methods: That more time be given to physical education in both elementary and secondary schools; that more adequate training be given not only to regular class teachers but also to special physical instructors; that a standard course of study be prescribed; that greater facilities and equipment be provided and that less time be devoted to interscholastic athletics and an effort be made to promote interest in intramural sports.

Public Health Lectures in the Bronx.—Under the auspices of the Bronx County Medical Society, a public symposium on "Tuberculosis—Its Prevention, Signs, and Care," was held in the Concourse Community Council on March 21. This was the first of a series of lectures arranged by a committee of the society with the aim of safeguarding health by instructing the public in the principles of disease prevention. The speakers at the opening meeting were Dr. Henry Schweitzer, Dr. J. B. Cohen, and Dr. Nathan B. Van Etten.

Hospital Notes.—The Board of Managers of the Hospital for Ruptured and Crippled, New York, announce that, owing to the demand for private rooms, they are going to build an addition on the present site of the hospital, 321 East Forty-second Street, for the accommodation of private patients. The estimated cost of the building is $300,000.

The new private pavilion, children's building and auditorium of Mount Sinai Hospital, New York, will be opened to the public at dedication ceremonies to be held April 9. The new structure raises the plant investment of Mount Sinai Hospital to a total of $8,000,000. Last year the hospital cared for 9800 patients and the dispensary for 196,000 patients.

The new addition to the Bethesda Hospital at Hornell, N. Y., erected at a cost of $45,000, is completed and will be open to the public in a few weeks.

The Washington County Memorial Hospital at Bartlesville, Okla., erected as a monument to the soldiers who lost their lives in the World War, has been opened for the reception of patients. The building and site cost the county $200,000.

The Polyclinic Hospital, Harrisburg, Pa., plans to remove to a new location in the upper end of the city where there will be plenty of ground for convalescent patients and ample room for expansion.

The entire second and third floors of the new McCormick Hospital at Moberly, Mo., were recently destroyed by fire.

The Baptist State Hospital, Little Rock, Ark., is ready for the reception of patients. The directors have voted to open the hospital to students of the medical department of the University of Arkansas.

An additional appropriation of $100,000 for immediate building of a forty-room addition to the nurses' quarters, the erection of three sets of double quarters for medical officers and other buildings at the National Military Home, Dayton, Ohio, has been announced.

Ground has been broken for a new hospital at San Jose, Cal., which will cost about $275,000.

The contract has been awarded for the construction of an additional building to State Hospital No. 2 at St. Joseph, Mo. The new building will be known as the Hadley building and will cost $64,000.

The River Drive Hospital, located between Harrisburg and Coxestown, was opened for the reception of patients on March 10.

A city hospital to cost about $45,000 is being erected at Pawhuska, Okla.

Ground has been broken for a new City Hospital for contagious diseases at Dallas, Tex.

The contract for another unit of the American Legion Memorial Sanatorium at Kerrville, Tex., has been awarded. The cost of the new unit will be $25,000.

The new Municipal Hospital at Youngstown, Ohio, is practically completed, but cannot be opened until money is provided for its operation.

El Paso, Tex., will be recommended as the site for the $1,000,000 tuberculosis sanatorium which the Brotherhood of Locomotive Firemen and Enginemen plans to build.

A contract has been signed between the city of San Francisco and Alameda County whereby fifty San Francisco tuberculous patients will be cared for at the Livermore Sanatorium, owned by Alameda County. The contract runs for twenty-five

years. San Francisco will advance Alameda County $100,000 for the construction of an addition to the hospital sufficient to care for fifty patients.

The St. Louis Meeting of the American Medical Association.—The American Medical Association calls attention to the fact that the arrangements of the St. Louis profession for the meeting places for the Session of the A. M. A., which is to be held in their city May 22-26 next, are singularly fortunate and convenient; never has the Association been so well favored in this respect. The district in which the meeting is to take place is at the west edge of the business section of the city, easily accessible from all directions by street car or otherwise and not more than fifteen minutes street car ride from the most distant hotel. The grouping of the meeting places is so compact that should one walk from the Registration Building (Moolah Temple) to the farthest hall it can be done in ten minutes or less; from section to section is a matter of from one to five minutes. The convenience of the location and arrangements of the different halls is more outstanding than in any other city in which the Association has met, and a decided improvement over the accommodations which were had at the meeting in St. Louis, 1910.

The International Otological Congress will hold its tenth meeting in Paris, July 19-22, 1922, under the Presidency of Professor Pierre Sebileau. The Secretary General is Dr. A. Hautant, 28 rue Marbeuf, Paris. Dr. Thomas J. Harris, 104 East 40th Street, New York City, is the Secretary of the American Continuation Committee.

The Pennsylvania, Delaware and New Jersey Section of the American College of Surgeons will hold a meeting in Allentown and Bethlehem, Pa., on April 3 and 4, 1922. Dr. W. L. Estes of Bethlehem will preside at the meetings.

The California State Homeopathic Medical Association will hold its annual meeting at Santa Barbara, May 10, 11 and 12, 1922, under the presidency of Dr. Hovey L. Shepherd of Los Angeles.

Medical Society Elections.—The New York Electrotherapeutic Society, at its annual meeting held March 1, 1922, elected the following officers for the ensuing year: *President*, Dr. Victor C. Pedersen; *Vice-Presidents*, Drs. Harry Eaton Stewart and Sinclair Tousey; *Treasurer*, Dr. J. Willard Travell; *Secretary*, Dr. Richard Kovacs; *Members of the Executive Committee*, Drs. Frederick de Kraft, A. Bern Hirsh, Byron S. Price, and William B. Snow.

Obituary Notes.—Dr. Frederick L. Johnson of Stanton, N. J., died of pneumonia on March 8, at the age of fifty-seven years. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1889. He was a Fellow of the American Medical Association and a member of the Medical Society of the State of New Jersey.

Dr. Alvin Elizur Barber of Bethel, Conn., died on March 15, at the age of ninety-one years. He was graduated from the Berkshire Medical College, Pittsfield, Mass., in 1854.

Dr. Harris Graham died recently in Beirut, Syria, where he had been connected with the University of Beirut for thirty-two years. Dr. Graham specialized in tropical diseases.

Dr. Ida Clarke of Youngstown, Ohio, died at Atlantic City on March 9, at the age of sixty-nine years. She was graduated from the Women's Medical College of Pennsylvania, Philadelphia, in 1878, and was a Fellow of the American Medical Association.

Dr. Joseph Evan Brunson of Ninety-Six, S. C., a graduate of the Southern Botanical Medical College, Macon, Ga., in 1902, died Feb. 19, at the age of seventy-two years.

Dr. Bennett Bernard Browne, since 1882 professor of gynecology at the Women's Medical College, Baltimore, Md., and since 1885 professor of gynecology at the Polyclinic and Post-Graduate Medical School, died on March 10, at the age of seventy-nine years. He was graduated from the University of Maryland in 1867.

Dr. Arthur J. Richer of Montreal, a graduate of the University of Bishop College Faculty of Medicine, Quebec, in 1892, died on Feb. 25, at the age of fifty-four years.

Dr. Frederick L. Johnson of Stanton, N. J., died at his home Feb. 8, of lobar pneumonia, at the age of fifty-seven. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1889, and practised medicine at Stanton for thirty-two years. He was a member of the Hunterdon County Medical Society.

Dr. George Alexander Ramseur of China Grove, N. C., a graduate of Jefferson Medical College, Philadelphia, in 1880, died on March 4, at the age of sixty-five years.

Dr. Henry D. Wells, a retired physician of Middleburg, N. Y., died on Feb. 25, at the age of ninety-two years. He was graduated from the Albany Medical College in 1857 and was a Fellow of the American Medical Association.

Dr. John Clinton Shuman of Akron, Ohio, a graduate of Jefferson Medical College, Philadelphia, in 1890, died of apoplexy on March 4, at the age of seventy years.

Dr. Winona E. Long of Battle Creek, Mich., a graduate of the University of Arkansas Medical Department, Little Rock, 1909, died on March 11, at the age of thirty-four years.

Dr. Elannus R. Birch of Denison, Tex., a graduate of the Miami (Ohio) Medical College, in 1879, died on February 28, at the age of seventy-two years.

Dr. William S. Maxwell of Chicago, a graduate of the Cleveland College of Physicians and Surgeons in 1891, died of pneumonia on March 9, at the age of sixty-three years.

Dr. Lewellyn G. Klepinger of Dayton, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1909, died on March 11, at the age of fifty-two years. He formerly held the position of county health officer.

Dr. William Virginius Brockington of Kingstree, S. C., died at his home on March 9, after a brief illness. He was graduated from the University of Georgia Medical Department, Atlanta, Ga., in 1888. He was a Fellow of the American Medical Association, and the local surgeon of the Atlantic Coast Line Railroad Company.

Dr. Samuel I. Myers of Bayonne, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1878, died on March 5, at the age of seventy years.

Dr. JAMES G. SINCLAIR of Chicago, Ill., a graduate of the University of Illinois College of Medicine, in 1888, died of heart disease on March 12, at the age of sixty-seven years.

Dr. JOSEPH LANE HANCOCK of Chicago died of heart disease on March 12, at the age of fifty-eight years. He was graduated from the Northwestern University School of Medicine, Chicago, in 1888. Dr. Hancock was a well known naturalist as well as a physician. He was a member of the Entomological Society of London and was a recognized authority on *Tettigidæ*.

Dr. CLARA M. SWEET, a graduate of the Boston University School of Medicine in 1894, died of apoplexy at her home in Springfield, Mass., on March 14, at the age of sixty-three years.

Dr. W. D. JENNINGS, Sr., a graduate of Emory University School of Medicine, Atlanta, Ga., in 1868, died of pneumonia on February 28.

Dr. GEORGE MACMURPHY died at his home in Ortonville, Minn., on March 11, at the age of seventy years. He was graduated from Bellevue Hospital Medical College in 1878.

Dr. RALPH E. CONGER of China Springs, Tex., a graduate of Tulane University, New Orleans, 1897, died suddenly of heart disease on March 1, at the age of fifty-nine years.

Dr. REGINALD HUBER MEADE of Kansas City, Mo., died suddenly on March 10, at the age of forty-seven years. He was graduated from the Beaumont Hospital Medical College, St. Louis, in 1896. He was a former president of the Kansas City Academy of Medicine, a Fellow of the American College of Surgeons and the American Medical Association, and a member of the Southwest Medical Association. He was attending physician to St. Joseph's, St. Margaret's and St. Luke's Hospitals. Dr. Meade was a veteran of the World War and president of the Medical Officers' Society of the 89th Division.

Dr. FRANCIS FENELON ROWLAND, formerly of Media, Pa., died at Pasadena, Cal., on March 12 at the age of seventy-five years. He was graduated from Jefferson Medical College in 1873.

Dr. KATRINA FREUDENBERGER died at Tamaqua, Pa., on March 9. She was graduated from the Woman's Medical College of Pennsylvania in 1898. She was a member of the Schuylkill County Medical Society, and the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

BELATED CENSURE BY A SOCIETY OF ANESTHETISTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—If an author in preparing a paper for publication secures statistics from other publications, or by correspondence or personal interviews, and if it subsequently develops that one or more of those from whom he quotes made erroneous statements, can the author himself be properly charged with falsification?

The Facts.—In the MEDICAL RECORD of July 29, 1916, I published an article on nitrous oxide-oxygen as an anesthetic. In that article I reported a considerable number of deaths that had occurred in Columbus, and also referred to large numbers of deaths which had occurred in other cities and which had not been reported. In each instance I gave the name and address of my informant. Among others I quoted from a physician (giving his name, address, and date of statement) who had told me of a fatality of his own, and who had stated that in the hospital where he had had that death they had "seven or eight" deaths from the gas previous to his own. His statement was made to a number of surgeons in Grant Hospital; it was made frankly and without any manifestation of feeling, and we all accepted it as a statement of fact. Soon after the publication of my article, someone connected with the hospital in which these "seven or eight" deaths were said to have occurred, wrote me denying the deaths. I replied at once that the question was simply one of veracity between himself and my informant. I supposed that that ended the matter so far as I was concerned, but I at once wrote to my informant so as to give him an opportunity to change his statement if there had been an error, but in his reply he suggested no change in his figures. If any denial of the deaths ever appeared in the MEDICAL RECORD or elsewhere I failed to see it.

It now appears, however, that at a meeting of an organization which calls itself the "Mid-Western Association of Anesthetists," held in Kansas City, Mo., October 25, 1921, an anesthetist connected with the above hospital, as I am told, denied the occurrence of the deaths, and thereupon a resolution was "unanimously adopted" censuring me for my article, and accusing me of all sorts of falsification and unethical practice. That such action was in contemplation was kept from me, and no opportunity was afforded for defense or explanation. The fact of the censure was promptly telegraphed to Columbus papers, and I presume to others, and appeared "by request" in the *Journal of the A. M. A.*, December 10, 1921, p. 1902, and perhaps in other medical periodicals.

My paper originally secured wide circulation through the columns of one of the leading medical journals of the country, and a considerable number of reprints were sent out. The number sent out was limited, however, because so many surgeons had gone into the war. A few months ago, therefore, in mailing some other reprints the reprints of this article were sent to the profession in Ohio, and to the surgeons and others associated in surgical sciences whose names appear in the special list in

the Directory of the A. M. A. Other copies were sent out in response to requests.

The action of this little association of anesthetists was taken in direct contravention of what the Federal Supreme Court has called "a principle of natural justice," the principle that no man should be condemned without a hearing. Such action may be properly regarded as significant of the desperation of the men who are back of the movement to make high-priced "specialists" out of mediocre physicians, most of whom if left to themselves would be honest and useful members of the profession.

The Cause.—The animus back of the attack is simply this: I was chairman of a committee of three ex-presidents of the Ohio State Medical Society, appointed by the president of the society to investigate the anesthesia problems. At its first meeting the committee decided to send a questionnaire to all hospitals having a capacity of 100 beds or more, as their names appear in the A. M. A. Directory; also to send similar questionnaires to 500 leading surgeons of the country whose names appear in the directory published by the American College of Surgeons. Those questionnaires were most carefully worded so that no inkling could be conveyed to the recipient as to the views of any member of the committee. Replies were received from large numbers of hospitals and surgeons. These replies were turned over to me by the secretary of the State society, and by me forwarded to the Cincinnati member (Dr. E. O. Smith), and by him to the Cleveland member (Dr. W. E. Lower). After considerable correspondence between us, a report was finally unanimously formulated at a full meeting of the committee, and presented to the council of the State society, which ordered the same printed, and extended a vote of thanks to the committee for the thoroughness of its work. The report was as free from bias as the multiplication table. It was practically a résumé of the replies which we had received, and showed that 303 surgeons used straight ether by the open drop method; three used chloroform, and 22 used nitrous oxide.

Our report also took up the matter of the specially trained nurse anesthetist, and gave the numerical preferences of hospitals and surgeons as to her employment. Because the nurse anesthetist was in a sense an innovation the committee thought it instructive to incorporate opinions expressed by different surgeons and hospital superintendents as to their experience with the nurse in regard to efficiency, safety, etc. The committee also found, though that was not incorporated in its report, that various commercial interests connected with the manufacture of anesthetic agents and machines for their administration, were financially backing the anesthetists' association, and furnishing a large part of the money for the carrying on of its propaganda.

The promoters of the "anesthetists'" plans did not like this report; it threatened to block their efforts to secure a monopoly by legislation; *hinc illæ lachrymæ*. Just before the last meeting of the Ohio State Medical Society, and at a time when it was too late for a reply, a circular was sent out by the anesthetists' organization broadcast over the State, viciously attacking me and incidentally the committee and its report. Calling me names and abusing the committee were resorted to merely to distract attention from the demand for their death reports. I have repeatedly challenged one of their leading proponents to point out a single improper feature in the report that we made, but though he has replied promptly to my letters he has not once complied with my request.

My Effort.—I have constantly urged the anesthetists, as a part of their "research" work, to make a report of their fatalities so as to reach if possible some conclusions that would enable us to reduce that death rate; but my efforts have been entirely without avail. Several years ago Teter wrote me that he knew of 26 unreported deaths from nitrous oxide-oxygen; Miller reported 18; Rovsing 13, and Gwathmey from 20 to 40. Other anesthetists have reported to me additional deaths, so that in the aggregate I found an enormous number of unreported deaths from that agent alone. With knowledge of these many unreported deaths, why should one question the statement of the physician from Detroit that he knew of "seven or eight" such fatalities? Indeed, from the action of the Detroit anesthetist previously alluded to, I am the more inclined to think that my informant told the truth. If he was in error why was not that error promptly corrected by those who claimed to have knowledge? If a libelous statement was printed, even though in good faith, why was not attention called to it at once in the journal of its publication? In Ohio the statutory limitation for prosecution for libel, I am told, is one year, and I presume the limit in other States is about the same, but these men allowed more than five years to go by without a word of published protest, and then they come in with the Bœotian argument of calling names.

If the anesthetists are honest truth seekers, why do they not give us promptly and fully their death reports, with full histories and autopsies, so that we may reduce to a minimum that source of danger in connection with our operative work?

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, March 1, 1922.

London School of Hygiene.—The Rockefeller Trustees have donated the sum of $2,000,000 for the building and endowment of a British National School of Hygiene. There has been a good deal of speculation as to the eventual site of this school. However, no definite information is available on the point, except that the school will be connected with the University of London. In some quarters it is thought that the Earl of Athlone, brother of Queen Mary, will be invited to become the first chairman of the governors, as the report of his committee really originated the idea. The Earl of Athlone is an enthusiast on public health, and it would be a graceful compliment to America for a member of the Royal Family to be closely associated with the result of this gift.

More Concerning Cancer Research.—Lord Atholstan of Montreal and Sir William Veno have done good to the cause of medical research in

general and cancer research in particular in that their widely advertised gifts have aroused the interest of the public in a question with regard to which in this country they are lamentably ignorant, and consequently somewhat callously indifferent. Also, and this is a point to be considered, the moment is or should be propitious on account of the seemingly useless research work which has been done already in this direction. But this work has not been futile by any means, for the reason that by a process of exclusion it has drawn attention to the paths that should not be followed and has rendered more or less obvious the roads that will lead to the goal. The Imperial Research Fund and the researches in other countries have at least proved that certain paths are blind ones, along which it would be a waste of time and money to attempt to travel further. While the discovery of the origin of malignant disease would undoubtedly simplify matters and expedite the finding out of a cure, yet as mentioned in a previous letter, a cure might be evolved even if the cause of the disease continues to be shrouded in obscurity. Moreover, the specific agent, that is an agent which is specific in its action against the malignant cell, but having no deleterious effect on the normal harmless cells need not be a drug but may be some form of radiation. Both radium and *x*-rays have demonstrated their value in the treatment of some kinds of malignant growths where such growths have been situated in a position favorable to radiation treatment. The powers of radiation have not reached their limit, and it might not be preposterous to suggest that a specific treatment for cancer may be found in these agents. Again, electrical treatment may provide a successful mode of ridding the system of the poisons engendered by the cancerous process. In all events and in every event early diagnosis and vigorous treatment on approved lines should be the slogan. Some forms of cancer may be termed curable at the present time, if the well-equipped radiologist and the skillful surgeon work in unison. But money is required for research and as has been emphasized on several occasions funds are not forthcoming in this country in the manner in which they are lavished in America. Medical research here is starved and it is to the generosity of those responsible for the distribution of the Rockefeller Fund that we are indebted for much aid and to whom we look to further assistance. It is time that science should know no boundaries and that the discovery of a cure for a disease or of a means of promoting health is of benefit to the entire human race.

Mr. Gilbert Chesterton on Eugenics.—Mr. Chesterton is easily one of the most brilliant writers of the day and has the faculty of clothing common sense views in scintillating paradox. In his latest work, "Eugenics and Other Evils," he takes a tilt against the cult of eugenics, which is an old bogey of his. In the preface to the book referred to he says that he had hoped that the eugenic fad was dead, that the fierce flame of war which had burned up so much that was both good and evil had destroyed that also. He has found that such is not the case, that the craze for scientific officialism and strict social organization is as rampant as ever, that the spirit of Prussianism has triumphed in the realms of sociology and politics more decisively than it was defeated in the trenches. The passage of the Feeble-Minded Bill here, seems to show that the eugenists wield a considerable amount of influence as the bill in question is badly conceived and carelessly drawn. However, because this bill is law it does not mean that it is workable. More than one bill which has been placed on our statute book and never repealed is as dead now as Queen Anne, and this is what will happen to the eugenists' bill. Mr. Chesterton explains what the eugenists want in the following words: "They want to be allowed to find out what they want. Not content with the endowment of research, they desire the establishment of research; that is, the making of it a thing compulsory, like education or state insurance; but still it is only research and not discovery. In short, they want a new kind of state church, which shall be an established Church of Doubt, instead of Faith. They have no science of eugenics at all, but they do really mean that if we will give ourselves up to be vivisected they may probably have one some day. I point out that this is a bit thick." There is no doubt that Mr. Chesterton is on solid ground when he inveighs against eugenics being made compulsory or an affair of the State. There are such patent objections against such a course, that argument is superfluous. Who is going to decide as to who is fit to propagate the race and who is not fit? Enough is not known of hereditary diseases or, rather transmission of disease as to make such a plan feasible or reasonable. Only a few diseases are now thought or known to be passed on, or their effects passed on, to the immediate progeny or descendants of diseased persons. There are certainly a limited number of people who should not be allowed to breed, but the idea of building up a perfect race by eugenics is Utopian. The physically superior are by no means the salt of the earth, for in very many instances conspicuous brain power is lodged in a frail human tenement. Further, the question of eugenics is a social question, just as much as it is a health question. Love and affinity enter into it so largely that it must be considered from this point of view. Mr. Chesterton is right in declaiming against any attempt to make the practice of eugenics compulsory, although at the same time it is obvious that persons suffering from certain gross diseases and those afflicted with certain mental affections should be prohibited as far as is possible, for the good of the community, from marrying or from propagating the species.

Foot and Mouth Disease.—It has been more than hinted in some of the lay journals that foot and mouth disease which is now very prevalent in Great Britain is a form of influenza and that furthermore it might be transmitted to human beings. With regard to its pathological significance for human beings Mr. A. K. Cameron, F. R. C. V. S., contributed an article on the subject to the *Lancet* of February 18, last, to which editorial reference was made in the same journal the following week. It is there pointed out that it has been definitely established that the causal

agent is a filter-passing virus, but it is not yet known whether the periodical propagation is due to an increase in its violence, or to reintroduction by means of birds or other carriers, or whether it is maintained, perhaps constantly in the systems of non-susceptible animals other than cattle, which act as reservoirs. There is apparently no evidence that the disease has any relation to other epidemics alleged to be filter passing; nor has it ever been established that any relationship exists between it and the filter passing diseases of man, such as influenza or encephalitis lethargica. There are a few, but a very few diseases, which may be transmitted from animals to man, although the profits in evidence of this statement are by no means always convincing. In any event, in spite of the assertions or rather strong suggestions of lay papers that foot and mouth disease in cattle is a form of influenza and transmissible to man, the evidence in this direction is so extremely slight as to be practically negligible.

Lunatic Asylum Administration.—The question was asked in Parliament of the Minister of Health on February 14 whether, in view of the fact that the committee appointed to consider the administration of the lunatic asylums was predominantly representative of medical superintendents, the inefficiency of whose administration was the matter to be inquired into, he would favorably consider strengthening the committee by the addition of representatives of the general public and of the Asylum Workers' Union. The Minister replied that the committee in question was appointed to consider charges made by Dr. Lomax and not the general question of asylum administration. Neither of the medical members of the committee had ever been associated with an asylum provided by a local authority. It would merely prolong the inquiry to add persons with no previous experience of asylum administration, and as regarded the Asylum Workers' Union, while he regretted their refusal to give evidence, he was unable to regard this as a reason for appointing to the committee a representative of a class directly incriminated by Dr. Lomax's charges. There seems to be a good deal of difference of opinion as to the validity of the charges made by Dr. Lomax some little time ago, against the manner in which these institutions were conducted. It is to be hoped that the committee appointed to investigate the matter, and to which reference was made in a previous letter, will act impartially and report accordingly. If reforms are needed they should be introduced without delay, as if any class of sufferer should be treated with the utmost consideration, it is those afflicted with mental disease.

Obituary.—The well-known pharmacologist, Dr. Craig, died recently in Edinburgh, within a few weeks of completing his ninetieth year. He was born March 28, 1832, and first entered Glasgow University, where he graduated in Arts, and at Edinburgh University he graduated M. B. C. M. in 1868. He became M.D. two years later and then a Fellow of the Royal College of Surgeons of Edinburgh in 1868. He specialized in pharmacy and therapeutics, and was appointed lecturer on materia medica at the Medical College for Women, Edinburgh, examiner at the Royal College of Surgeons, Edinburgh, and lecturer on materia medica and therapeutics at Surgeons' Hall. He was an enthusiastic botanist and one of the oldest members of the Scottish Alpine Botanical Club and of the Botanical Society of Edinburgh. In recognition of his services to the latter society as secretary, one of the Sterculiaceae was named after him. Dr. Craig was a Fellow of the Royal Society of Edinburgh, author of a Manual of Materia Medica, and edited Milne's Materia Medica and Posological Tables.

2. The Infected Colon as Related to the Toxic Psychoses.—Dr. John William Draper. (See MEDICAL RECORD, February 18, 1922, p. 299.)

4. Two Unusual Cases of Injury to the Tibial Tubercle.—Dr. James Warren Sever reports two cases of this injury, one acute and one of many years' duration, and calls attention to the fact that the liability of the tibial tubercle to injury has been frequently overlooked and the symptoms of such trauma misinterpreted. Pain, swelling, and tenderness over the tibial tubercle do not always mean a separation of the epiphysis, unless demonstrated by *x*-rays of *both* legs. The condition of ordinary strain of the epiphyseal line at this point is not infrequently met with, and under ordinary circumstances easily dealt with by strapping, or, in the more persistent cases, by a ham splint. Operation on the tubercle for fixation of the epiphyseal beak to the crest of the tibia is unnecessary in the vast majority of cases. Many *x*-ray findings that might be interpreted as showing a lesion should not be so interpreted unless symptoms are present. The two cases reported were both of a nature that required operation. In the first the tibial tubercle pulled off, the fracture extending into the knee joint. The tubercle remained at an angle of almost 35° to 40° to the tibia. After ten days' rest in bed on a splint, the patient was operated on, the bony fragment pressed into place and held there by a mattress suture of kangaroo tendon. Only nine cases similar to this have been reported in the literature. In the second case the fragment of tibia had been separated for some time and was apparently adherent to the under side of the patella tendon. The fragment removed at operation was found to consist of bone adherent to the under side of the patella tendon. These patients made perfect recoveries. These types of cases are the only ones that really need operative procedures.

5. Arthroplasty of the Elbow Joint: A Point of View.—Harold C. Bean holds that, although, with few exceptions, favorable reports have been made by divers surgeons concerning arthroplasties of the elbow joint, and although this joint affords a unique site for experimentation, we must consider well the patient's anatomical, mental, social, occupational, and financial status before undertaking a procedure of which we can give no definite preoperative assurance of success; such success being that end-result which, in the patient's opinion, is considered worth the pain, the time, and the finances necessary for that end-result. Bean is not convinced of the advisability of arthroplasty of the elbow

joint in the majority of cases, and says he has yet to see the advantages of a few degrees of stable motion over an ankylosis in favorable flexion or an excision with the moderately flail joint. He considers the various methods of arthroplasty in general use and expresses a preference for that of Dr. W. R. MacAusland, which he describes in detail. The only objection which he raises to this method of approach lies in the question as to whether the arm can be safely placed in flexion after approximating the olecranon with kangaroo tendon. It seems like a confession of lack of faith in the operation not to be able to fix the arm in extension after operation, that is, as if the operator looked ahead with uncertainty to the period of manipulation, and, therefore, left the arm in a favorable position for reankylosis if it should form.

1. Hemorrhage as a Form of Asphyxia.—Yandell Henderson, Howard W. Haggard, et al. have made these observations because of the inadequacy of the conceptions of the effects of hemorrhage as dependent upon the circulatory mechanism. The results of various degrees of hemorrhage are recorded and the effects of some treatments. The following conclusions are drawn: (1) A standard hemorrhage has been here used under which the chances of recovery and of deaths are about equal. Several treatments, particularly infusions equal in volume to the blood lost, have been tried. The data show that, although temporarily beneficial, mere restoration of blood volume, even by a fluid approximating the physical properties of plasma, such as acacia solution, does not considerably increase the probability of ultimate recovery. Transfusion of an equal amount of whole blood, after so brief a deprivation as that here used, would result in virtual restoration of normality. The conclusion is therefore drawn that it is the loss of red corpuscles which is the critical factor in hemorrhage. (2) The symptoms and processes observable in a partially exsanguinated animal are found to be identical in many essential features with those under progressive deprivation of oxygen, and with those occurring in carbon monoxide asphyxia. They are like those occurring in the process of acclimitization to great altitudes. (3) The mere visual observation or counting of respiration is quite unreliable. But, when the volume of air breathed per minute is measured, the following important new fact appears: The amount of breathing increases progressively with the blood loss. After the hemorrhage, a decrease of breathing accompanies recovery; and a further increase is an indication of, and a factor in the approach of death. The volume of breathing is thus an index of the severity of hemorrhage and a basis for prognosis. (4) A marked decrease of carbon dioxide content and of alkali in the blood occurs coincidently with the increased respiration. It is shown, by analogy with other forms of asphyxia, that these blood changes are largely due to the acapnial, rather than to the acidotic process. Low blood alkali after hemorrhage calls for transfusion of blood or at least of oxygen inhalations. (5) The similarity of many of the phenomena of traumatic shock and exsanguination is shown to consist in large part in the occurrence of each of the acapnial processes, both thus leading to the condition formerly termed by one of the writers acapnia, now often erroneously called acidosis, and probably best denominated as a disturbance of the acid-alkali balance of the blood. (6) The circulatory conception of hemorrhage, which assigns the effects of fall of blood pressure, must be supplemented with a respiratory conception, namely, that, through the loss of red corpuscles, hemorrhage is a form of asphyxia.

2. Specific Precipitin Test for Human Semen.—Ludvig Hektoen has conducted experiments which show that the injection of rabbit's with human semen induces the formation of precipitins that are specific for human seminal proteins, and this precipitin reaction may prove of value in determining the nature of spots suspected to be of seminal nature.

7. Epidemic (Lethargic) Encephalitis: Recurrence of Symptoms One and One-Half Years After Recovery.—George E. Price reports this case because it is the longest interval or remission so far recorded, to his knowledge. The child made practically a complete recovery from the first attack, returning to school. The question is raised as to whether the child could have had a reinfection. The tendency of epidemic encephalitis to relapse, and the absence of any data regarding reinfection in the disease, point to a flaring up of encapsulated foci, rather than a reinfection from an outside source. The writer points out that the possibility of a relapse in epidemic encephalitis after an interval of a year or longer is of interest to life insurance statisticians, who already are chary of renewing health policies to persons who have had encephalitis.

10. The Etiology of Hay-Fever in Arizona and the Southwest.—Samuel H. Watson and Charles S. Kibler point out that in distinction to the Rocky Mountain region, the artemesias (wormwoods) have little if any importance in producing hay-fever in the Southwest. Amaranths are an important factor, and their pollen is very active; in fact, it will probably be shown that amaranths here are the principal cause of fall hay-fever, taking the place of the ragweeds in the East and the artemesias in the Rocky Mountain region. Some seasons *Atriplex wrightii* will probably take the place of *Amaranthus palmeri*. *Franseria tenuifolia* is probably a less important cause of fall hay-fever. *Capriola dactylon* (Bermuda grass), causing the spring, summer, and fall types, will probably prove to be the common grass causing hay-fever to altitudes up to 4,500 feet, and *Poa pratensis* (June grass) above that altitude. *Gærtneria deltoidea* (rabbit bush) and *Atriplex canescens* (shade scale) are probably the most important plants causing the spring type of hay-fever. Trees are probably not an important factor in causing hay-fever; but when they do cause it they cause a very early type of hay-fever. The principle of group reactions is not applicable to the hay-fever situation in Arizona and the Southwest. It is advisable therapeutically to administer the specific pollen or pollens responsible for hay-fever.

12. A Case of Chorea and Erythremia.—Lewis J. Pollock reports a case of chorea in a woman thirty-eight years of age, with no history of rheumatism, endocarditis,tonsillitis, or a former attack of cholera. The blood showed erythrocytes 8,100,000, leucocytes 8,500, and a hemoglobin of 115. She was given roentgen rays at weekly intervals, and at the end of a month was markedly improved. When discharged, after a sojourn of about seven weeks in the hospital, the red blood cells numbered 6,400,000. Inasmuch as the erythremia persisted after the choreiform movements disappeared, the supposition seems warranted that the choreiform movements are not produced by any change in the blood but rather by a definite pathological condition in the brain, such as hemorrhage or thrombosis. The exact nature of such a lesion, the writer of this article believes, will remain conjectural until histological study of such a case is made.

3. The Schick Test for the Determination of Susceptibility to Diphtheria. A Record of 1,200 Cases.—T. E. Dickinson presents this study, which corroborates in large measure the observations of Ker and Zingher, in that the greater number of positive tests were found in children between the ages of two and five years. This finding affords important evidence of the reliability of Schick test, since it coincides exactly with the age period at which the incidence of clinical diphtheria is most marked. In this series the percentage of pseudoreactions in those above the age of fifteen years was nearly twice as great as in those under fifteen years. The pseudoreaction was found to occur nearly twice as often among normal cases as among those with enteric fever, puerperal fever, and scarlet fever, taken as a whole. There is evidence that scarlet fever tends, very slightly, to increase susceptibility to diphtheria. There is also evidence to suggest that the previous administration of antistreptococcic serum tends to inhibit the development of a positive Schick reaction. It would seem that the previous administration of antidiphtheritic serum greatly increases the percentage of pseudoreaction, and should further experiments establish the same conclusion in the case of antistreptococcic serum, it would be reasonable to assume that in both cases the phenomenon is in the nature of a local anaphylactic response, to a foreign protein, of tissues cells previously supersensitized to a foreign protein. While no final conclusion can be drawn from the number tested, there is indication that by means of the Schick test it would be possible to demonstrate that the larger the quantity of antitoxin given, the longer would be the duration of the immunity. Diphtheria antitoxin was given subsequent to the performance of the test in one instance. This patient received 8,000 units twenty-four hours after the test. No impression was made on the definite positive reaction which had by that time developed.

4. Some Varieties of Traumatic and Toxic Ulnar Neuritis.—E. Farquhar Buzzard outlines a number of cases which suggests that the ulnar nerve is particularly prone to disturbances of function on what appear to be at first very slight provocations. Looking for a common factor in the various groups which he outlines one is struck by the fact that in the majority of cases the ulnar nerve is unprotected by any bony parapet at the end of the elbow, or so badly protected that during extension and flexion of that joint it is apt to slip in and out of its proper position. During flexion especially it may lie exposed to friction and pressure on the internal condyle. A consideration of many cases seems to justify the conclusion that movement, especially of a strenuous and frequently repeated character, is an important factor in the production of an interstitial neuritis. This moving contact with a bony surface is probably an important factor in producing the symptoms associated with a cervical rib, although so far as the writer knows it has not been shown that in the latter case the nervous tissue becomes surrounded by a definite thickening of connective tissue. In the case of the ulnar nerve, however, the nervous tissue is constantly exposed to minor injuries, and the neuromatous condition so often found must be ascribed to chronic inflammation of traumatic origin. In one group of cases one may find an additional etiological factor in the form of some toxic agent. The writer has seen fairly good results from merely dividing the connective tissue strands by means of longitudinal incisions, but he is still more impressed with the advantages of placing the nerve in front of the joint and so insuring its complete relaxation. He suggests that possibly a combination of both methods may be the ideal treatment.

6. Epididymitis and Suprapubic Prostatectomy. A Study of 50 Cases.—H. P. Winsbury White has endeavored to come to some conclusion with regard to the predisposing causes of epididymitis in relationship to previous infection, sepsis in the prostatic cavity, urethral instrumentation during the after-treatment, and two-stage prostatectomy. In 38 per cent. of the cases only, previous to operation, could the epididymes be considered normal. Of the 62 per cent. showing some evidence of pre-existing epididymitis, the most striking feature was the high percentage of the group giving a venereal history (46) which developed epididymitis following prostatectomy. In the group of cases in which a history of venereal disease was not forthcoming it was interesting to observe that the bulk of the cases gave a history of frequent catheterization previous to operation. There is, however, evidence which indicates that pre-existing infection is by no means the only factor of importance in determining a postoperative epididymitis. There is no doubt that the amount of sepsis existing in the prostatic cavity is a very important point in determining the degree of epididymitis. The rule followed in the treatment of these cases was not to pass an instrument of any kind until the tenth day, when a large metal sound was passed once into the bladder. The secret of successful use of the in-dwelling catheter is to avoid resorting to it too soon, and to leave it in the urethra as short time as possible. Acute epididymitis is easily produced by neglect of either of these rules. The value of a two-stage prostatectomy as a possible precaution against post-operative epididymitis should be realized when it is recalled that acute epididymitis may result from an infected bladder arising as a complication of enlarged prostrate previous to prostatectomy. In 9 of the 50 cases the two-stage operation was done and in none of these did postoperative epididymitis occur, while this complication occurred in 33 per cent. of the entire series.

7. The Effect of Edestin on the Mammary Secretion.—Gladys Annie Hartwell described experiments from which it is suggested that edestin is a very good protein, and that it improves the growth curve of suckling rats when the mother's diet is deficient in protein. When added to a diet containing an adequate amount of protein it has no effect, and when present in large amounts in the mother's diet (46 per cent. of the dry weight of food) the young die.

1. Remarks on Obscure Intestinal Colic.—H. Tyrell Gray reviews evidence to show that the intestine is insensitive, but that its blood supply and nerve supply are conveyed by a structure which is exceedingly sensitive to every kind of stimulus, mechanical, chemical, thermal, etc., namely, the mesentery. For many years he has believed and taught that all true visceral pain and discomfort arise from, and are primarily referred to, the mesentery, and from this source it may or may not be referred to the associated somatic nerves. Incidentally, such observations hold good also in the case of the stomach, insensitive in itself, but acutely sensitive in its mesentery (the gastrohepatic omentum). Pain referred to the gastrohepatic omentum is localized in the epigastrium, so in the small intestine colicky pain is referred vaguely to the midline—that is the situation

of the small intestine mesentery, and is not associated with cutaneous hyperesthesia. Inaccuracy of localization is thus a prominent feature of small intestine colic. The mechanism of colic consists in the natural attempt of the bowel to drive onwards a diseased or inert area, thereby inducing abnormal tension on the associated mesentery. In both the small intestines and the colon the bowel is insensitive, and colicky pain is induced through its mesentery or peritoneal attachments. There are, however, differences in symptoms corresponding in detail with the different mechanisms of the small intestines and colon. Except in the presence of obstruction, mesenteric or peritoneal involvement, colicky pain or discomfort arising from lesions in the colon occur mainly in association with powerful mass movement; it is therefore definitely related to or accentuated by taking food and the act of defecation, and occurs by reason of the drag upon the mesentery. One of the characteristic features of lesions of the colon is the ability of the sufferer to localize the site of the lesion. The wide area of mesenteric attachment of the large bowel (or of the bowel to the sensitive peritoneum) is responsible for this power of definite localization, for the mesenteric drag induced by the attempted inversion is clearly referred to the mesenteric attachment in the neighborhood of the lesion. It is this power of localization which is often responsible for colic, associated with lesions of the colon, being attributed to a gastric origin. The reference of the pain to the mesocolon may resemble fairly closely that referred to the gastrohepatic omentum, and the mechanical stimulation of mesenteric nerves in the immediate vicinity of the solar plexus evokes a reflex persistence of pyloric closure leading to flatulence and gastric distension. Thus it is not uncommon for carcinoma of the transverse colon to be mistaken for a gastric lesion.

5. Focal Infection in Relation to the Etiology of Skin Diseases.—H. Leslie-Roberts discusses his subject from a standpoint which would view focal infection as a collection of bacteria in a crypt, which, while not actively growing or multiplying, may infect the body by their cell substance, which is liberated by the action of ferments or enzymes either by autolysis or heterolysis. Clinical evidence shows that in the great majority of persons bacterial digestion in the tonsils and mouth promotes only local reactions and is not accompanied by general and remote consequences, but in not a few individual symptoms arise which must be attributed to protein poisoning. All foreign proteins, whether they be animal, plant, or bacterial, are sensitizers. Pathological symptoms accompany sensitization. The nonstriped involuntary muscles are highly sensitive to protein infection; this is indicated by spasm of the venules and vaso-dilatation, accompanied by the clinical picture or urticaria, flushing of the face, edema, and erythrodermia. In other cases the sensitization may affect the fibrous tissues, the aponeuroses, the synovial membrane of the joints, producing various forms of arthropathy. When the skin cells are sensitized in cases of chronic allergy various symptoms arise: loss of hair, either diffuse or in area; increased pigmentation and increased fat formation; in short, we have evident signs of stasis in the cutaneous tissues. Other clinical forms of disease are lupus erythematosus, lichen planus, and prurigo. These may be regarded as clinical pictures according to the particular group of cells which is sensitized. All these cutaneous diseases have been shown to disappear spontaneously after tonsillectomy. Attempts are being made to include the eczematous reactions under the head of protein sensitization. There are some eczematous vesicular reactions, which the writer believes are connected with the state of allergy, but what we may describe as the normal eczematous reactions are essentially related to physical conditions in the external environment. These are sensitized to friction owing to a defect in the physical condition of the rete and cuticle with inherited or acquired increased permeability of the capillary walls. Such cases can be cured by simply raising the pressure of the rete and cuticle over the capillaries. There are undoubtedly many conditions which affect cell irritability besides protein sensitization.

6. Bile Salt as a Vehicle for a Pediculicide.—B. A. Peters recommends the following preparation: Sodium taurocholate, 10 grams; oil of eucalyptus, 50 c.c.; water, to 1,000 c.c. The bile salt is completely dissolved in water, the oil of eucalyptus added, and the whole shaken well. During the past eighteen months this preparation has been tried on 500 patients on whose heads living lice were seen. It is well rubbed into the head until the hair is wetted. The head is wrapped in a towel and the application left on all night. The head is washed with soap and water next morning. In 23 per cent. of the cases one application was sufficient; in 63 per cent. a second application was necessary, while 14 per cent. required a third application. This preparation is not toxic, is not irritating to the skin, is not inflammable, and is elegant to use as it is easily washed out of the hair.

3. Some Causes and Some Results of Chronic Intestional Toxemia.—Allan Eustis holds that on the basis of our knowledge of physiological chemistry we are justified in the belief that the substances responsible for intestinal toxemia are amins formed by the putrefaction of several amino acids with loss of carbon dioxide; that these putrefactive basic amins have definite physiological action; that they are normally detoxicated by the liver; that when they are not detoxicated, they exert their specific, physiological action on the individual. However, a diagnosis of chronic intestinal toxemia, only, is rarely justifiable, any more than one of achylia gastrica, or tachycardia, unless the cause of the same has been ascertained; but on the other hand, severe nephritis, a supposed diabetes or a case of supposed hyperthyroidism, not to mention the large number of neurasthenics, may have their origin in a chronic intestinal toxemia. A number of cases are cited which serve to bring out the following points: (1) Certain cases of intractable intestinal toxemia may be due to intestinal stasis from an anatomical abnormality, which can be relieved only by surgical measures. (2) Some cases of chronic intestinal toxemia may present symptoms of hyperthyroidism, which symptoms are relieved by overcoming the intestinal toxemia. (3) Intestinal toxemia may be the cause of an albuminuria and even of symptoms of uremia, relief of which is complete after control of intestinal toxemia. (4) Severe pyorrhea may be the cause of an intestinal toxemia, and indirectly the predisposing cause of asthmatic attacks.

4. Diabetes and Pregnancy.—I. I. Lemann summarizes his views on this subject as follows: (1) All glycosurias of pregnancy are not diabetes mellitus. Many are innocent renal diabetes. (2) All patients, however, showing glycosuria during pregnancy should remain under constant observation during pregnancy and should be thoroughly investigated after the termination of pregnancy. (3) Abortion is not advisable as a routine. (4) The treatment of the pregnant diabetic is the same as that of the non-pregnant. (5) The danger of acidosis is to be avoided by the restriction of fats and by the choice of gas-oxygen as an anesthetic.

Pfeiffer's Influenza Bacillus.—Messerschmidt found this bacillus present in 90 per cent. of the subjects examined for influenza during the pandemic of 1918. Since that period he has found the same in tuberculosis and bronchitis, in the pus of boils and abscesses, and even in the prostatic secretions of chronic prostatitis, in subjects who had not been exposed to influenza. Apparently it is not to be found outside of human subjects.—*Schweizerische medizinische Wochenschrift.*

Book Reviews.

South America, from a Surgeon's Point of View. By Franklin H. Martin, C.M.G., M.D., F.A.C.S., Director-General, American College of Surgeons; Managing Editor, *Surgery, Gynecology and Obstetrics*. Introduction by William J. Mayo, M.D., F.A.C.S. New York and Chicago: Fleming H. Revell Company, 1922.

This most interesting little book is an account of two trips made by the author and others to various South American countries. The visits were made on behalf of the American College of Surgeons, and much of the value of the work to the physician lies in its descriptions of the hospitals and other medical institutions in the countries visited and in the illustrated biographical notes of many of the leading surgeons and other medical men there practising. But apart from this, simply as a book of travel it will be found most entertaining. The illustrations are excellent; most of them are from specially taken photographs, and they are very clearly reproduced and printed. A second section of the book, which is less interesting, but full of valuable detail, is entitled "A Summary of Facts." It contains data of all sorts—historical, geographical, political, social, and industrial, with statistics of industries and manufacture, imports and exports, population of the principal cities, hotels, hospitals, banks and shops, rates of postage and cables, etc., etc. A third section contains really good English-Spanish and English-Portuguese vocabularies, though the figured pronunciation is not always to be trusted. The work is not only an exceedingly entertaining book of travel but a complete and satisfactory guide-book as well and one that would prove serviceable to any visitor to South America, whether a medical man or not.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. By George E. deSchweinitz, M.D., LL.D., Professor of Ophthalmology in the University of Pennsylvania. Ninth Edition. With 415 text-illustrations and 7 colored plates. Price, $10.00. Philadelphia and London: W. B. Saunders Company, 1921.

A book that has passed through nine editions in twenty-nine years must be so familiar to all students of the subject of which it treats that anything more than an announcement of its new incarnation in improved form is superfluous. For more years than most ophthalmologists or general practitioners can look back to in professional life de Schweinitz's "Diseases of the Eye" has been an authoritative guide. The present edition, like recent editions of works on almost any subject, contains much new matter relating to ophthalmic problems which presented themselves, and were solved or not as the case may be, under the new conditions arising during the World War. The amount and number of titles inserted for the first time in this edition will astonish any one who regards ophthalmology as practically a fixed science. The fact that nearly thirty subjects of varying degrees of importance are treated of for the first time in this ninth edition is sufficient evidence that this branch of medicine is progressing constantly, and is still dynamic and not static.

Gout. By Llewellyn Jones Llewellyn, M.B., Lond., Governor and Senior Physician, Royal Mineral Water Hospital, Bath; Fellow of Royal Society of Medicine; Author of "Arthritis Deformans"; Co-author of "Fibrositis," etc. With a Section on "Ocular Disease in the Gouty," by W. M. Beaumont, Consulting Ophthalmic Surgeon to the Southwestern Region of the Ministry of Pensions; Author of "Injuries of the Eyes of the Unemployed, Problems in Prognosis," etc. Price, $7.50. St. Louis: C. V. Mosby Company, 1921.

Many and of varying excellence are the books on gout, but little and unreliable is the information most of them give us. This is not because the authors are not hard students and earnest searchers after the truth, but because the mystery of gout still eludes them. As the author of this most recent and on the whole most satisfactory treatise says: "Who can doubt that he who would elucidate the pathological groundwork of gout must be at once a clinical physician, a biochemist, a bacteriologist, a morbid anatomist?" And we might add a logician and a seeker after truth without prejudice and unbound by the traditions of the past. Yet each student of the subject must have a theory as a working basis, and that of Dr. Llewellyn is infection, although he admits that back of that there must be "innate tissue peculiarities reflected in corresponding obliquities of tissue function," (in other words, disorders of metabolism) through which "the general resistance of the body to invasion by infections is lowered." Whether one agrees or not with the author in his theory, the time given to a careful reading of this book will be well spent, for much food for productive thought will be found here and many useful hints in the line of treatment. There must be several forms of gout (as manifested in the accepted gouty syndrome) distinct in their etiology and therefore calling for different therapeutic management, and one inclines to the belief that Dr. Llewellyn has discovered one of these forms.

Nouveau Traité de Médecine. Publié sous la direction de MM. les Professeurs G. H. Rogers, F. Widal et J. J. Tessier, Fascicule III. Maladies Infectieuses (suite). Price, 40 fr. net Paris: Masson en Cie, 1921.

The third volume of this system contains articles on typhoid and paratyphoid by Widal, Lemierre and Abrami; colon bacillus infection by Widal and Lemierre; dysenteries by Dopter; cholera by Ruffer and Crendiropoulo; botulism by Sacquépée; Malta fever by Sacquépée; trench fever by Strong; influenza by Menetrier and Stévenin; pest by Sacquépée and Garcin; and yellow fever by Sodre. The articles on typhoid and paratyphoid fevers fill about one-half the volume. They are very complete. The other sections are also satisfactory. Strong's discussion of trench fever is classical as was to be expected. The striking difference from customs in this country is noted in the sections devoted to treatment but these differences are chiefly in the non-essentials and so far as specific treatment is concerned they are in full accord with what is generally accepted as correct. One notices at times an annoying tendency to misspell American proper names. So far as we have been able to tell in the volumes issued up to the present time this system will compare favorably with any of those recently issued in English.

A Treatise on Diseases of the Skin, for Advanced Students and Practitioners. By Henry W. Stelwagon, M.D., Ph.D., Late Professor of Dermatology in the Jefferson Medical College; Late Consultant in the Dermatological Department of the Philadelphia General Hospital, to the Howard Hospital, to the Pennsylvania Institution for the Deaf and Dumb, to the Pennsylvania Institution for Feebleminded Children, and to the Widener Memorial Training School for Crippled Children, etc. Ninth Edition, with the Assistance of Henry Kennedy Gaskill, M.D., Attending Dermatologist to the Philadelphia General Hospital and Member of the American Dermatological Association. With 401 Text Illustrations and 29 Colored and Half-tone Plates. Price, $10.00. Philadelphia and London: W. B. Saunders Company, 1921.

It is difficult to say anything new in a review of a book which appears in its ninth edition. Indeed a book that has held its own with a host of competitors in every country of the world for nineteen years speaks for itself. The illness and lamentable death of the gifted author threw much of the work of revision on Dr. Gaskill who has discharged his duty in a way that could not have failed to receive the commendation of Dr. Stelwagon, and has fully justified the choice by that author of his assistant. The characteristic of the book is the clarity of style of the writer and the simplicity of language which makes even the difficulties of diagnosis appear easy. It is a work especially for the general practitioner and non-specialist, but so complete is it and so enriched with copious references to the literature of this branch that it has always been a favorite with dermatologists. The illustrations deserve a word of praise. The book might be made more serviceable by a judicious pruning (it is over 1300 pages in length), though we admit that the task of cutting out any great amount would be one of considerable difficulty.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 23, 1922.

THE PRESIDENT, DR. ORRIN SAGE WIGHTMAN IN THE CHAIR.

President's Address.—Dr. ORRIN SAGE WIGHTMAN delivered this address, in which he said it was customary for the incoming president to outline the policy and to give a summary of the consensus of opinion on matters of importance to the Society and to outline a campaign for the coming year. It would perhaps be of interest to the members to recall that this was the 116th year of their chartered existence and the 127th year since the organization of the Medical Society of the County of New York. The membership of the Society was about 3,000 out of a possible 6,000. This was the largest county medical society in the State and paid about one-third of all annual dues paid to the State Society. The State at large looked to this Society for leadership and guidance. Dr. Wightman paid a tribute to Dr. Ward for the very excellent scientific programs presented to the Society during the past year and commended him for the success with which he had guided the Society through its first year under the new plan of organization. The new plan had had a marked influence for the better in handling the affairs of the Society. There had been some complaints as to the management of these affairs. Those who managed the Society had been characterized as a close corporation, they had been accused of steam-roller methods, and of having ruled with a high hand. It must be remembered that if one expected to get efficiency in any group power must be concentrated into the hands of a few—of men who would work. That was the method of big business and as a society they would have to adopt it if they hoped to succeed. No favor was shown in the matter of membership. The Committee on Membership considered every applicant on his merits; it made no difference by whom he was sponsored. It had been their policy to look to quality as well as quantity in selecting their membership. Looking after the affairs of the Society was not idle work, though sometimes it was thankless. Dr. Wightman said he knew of no body of men more dormant, inactive, and indifferent to their affairs than the members of the medical profession, and he made a stirring appeal urging them to awaken and take an interest in matters vital to their welfare. They could not expect others to guard their interests when they themselves were so indifferent. He had heard the Governor say the chiropractors had as good a right to practise medicine as regular physicians provided they complied with the law. Governors and legislators were interested in seeing that laws were passed sanctioned by the majority of the people and in maintaining those laws; they were not interested in the scientific and ethical standards of medicine. If these were to be maintained the medical profession must see to it themselves. Other groups of men went to Albany and looked after their personal interests; the physician was an individualist. When matters came up that threatened the welfare of the profession he felt sorry but did nothing about it. Legislators had asked him how the medical profession could expect to get the right kind of medical laws when the doctors themselves did not know what they wanted. The *New York Medical Weekly* had been called into existence largely through the efforts of the Committee on Civic Policy. Its aim was to bring before the medical body certain matters of medical interest, particularly matters having to do with medical legislation, and to conduct an open forum where every doctor had the privilege of expressing his opinion on social and economic questions affecting the profession. He hoped that it would have the cooperation of physicians and that it would assist in getting them somewhere. Dr. Wightman then spoke of the attitude of certain large foundations interested in public uplift, whose motives were no doubt good, but whose methods tended to be paternalistic and at times threatened the best interests of the medical profession. He thought they should take the medical profession into their confidence instead of telling them what to do. These interests were bringing lay control into medical matters and thus greatly limiting their usefulness. When it came to workmen's compensation the medical profession were again told what to do. If medicine was to be a state institution and if they were to be told by state and city authorities, health departments and various uplift organizations what they were to do, why not recognize the fact and act accordingly? Most men did not go into the medical profession to get rich, but surely "the servant was worthy of his hire." When a man had gone through college and medical school and had spent a couple of years as an interne in a hospital it was not fair to be compelled to compete with a chiropractor who had spent six weeks in preparing to practise. While he did not think these things would be productive or lasting wrongs nevertheless physicians had economic and social interests at stake and the members of the Society should participate actively in the work of their committees; if they did this it would spell a better County Medical Society this year.

Is Radium Worth While?—Dr. HOWARD A. KELLY of Baltimore delivered this address, in which he stated in part that he had begun his work in radium therapy about thirteen years ago. He regretted that the profession had not at that time also taken an active hold of radium therapy; his own experience with Dr. Curtis F. Burnam now amounted to about 9,000 cases treated with radium. Radium was now again under attack and it was a matter of such extreme importance that it was time to enter the lists again in its defense. In order to use radium successfully one had to be an optimist and to forget many failures. The work was difficult; it belonged to a trained specialist. If not used with care and skill radium might easily cause distressing accidents. Several things were necessary to success for general work with radium; first, one must have at least one-half a gram of radium, and considerable experience or, perhaps better, training. He considered that for the present a man of surgical instincts was the one who could best handle radium with balanced judgment, deciding for or against operation and taking advantage of the aid it offered in preoperative and postoperative treatment. Dr. Kelly related an extraordinary case which he had seen only the day before. A woman was found last fall at an abdominal operation to have a huge extensively adherent carcinoma of each ovary. The condition was clearly inoperable. The abdomen was closed. They had radiated her thoroughly and she had just returned perfectly well with a movable tumor the size of a grapefruit, which might be easily excised. He had seen other similar cases. Everyone who used radium should be a pathologist. The microscope was essential in investigating the tissue attacked and in estimating progress. At all times it ought to be at hand with instruments for local anesthesia and for taking bits of tissue for freezing and immediate examination. In radium therapy as in surgery, cases treated early in the course of disease, of whatever nature, gave incomparably better results than those seen later. The laity needed education on this point, but not so much he thought as did their medical confrères who sometimes kept and nursed a patient with a sarcoma or other interesting ailment, coddling him and exhibiting him to students when he ought to have been sent within forty-eight hours to the radium therapeutist. Another essential in the use of radium and individualization, avoiding treating patients as mere members of a group. Two cases might look alike clinically and microscopically and yet one would improve and the other would fail to be benefited by treatment; herein lay many of their disappointments. Dr. Kelly said he wished to emphasize the *palliative results;* if he could do nothing more than improve and relieve his patients, as he had been able to do, never curing one, it would still be worth his while to continue this work. If a patient remained well for a year, he talked about cure even though later he had to check up relapses, but he made it very clear that the "cure" was qualified by an attitude of watchfulness coupled with examinations. The patient should always be instructed to return the moment any change was

observed in a superficial lesion. Efficient radium therapy called for one-half, or better, one gram of radium, an emanation apparatus, a physicist with an experienced staff of radium technicians and a new man on each pumping day of the week. The blood of the technicians and nurses if they stayed over a month should be examined regularly and as soon as the leucocyte count fell one or two thousand the worker should stop. One also needed perfect clinical facilities; was advantaged by a laboratory for chemical and physical studies; a pathologist and a pathological laboratory were a *sine qua non*; various medical consultants must be within prompt reach; an *x*-ray department was imperative; a photographic department, a record room, a library and a large fund of optimism all contributed to carry on the work efficiently. Now for the gamut of radium therapy with a few remarks on each head: First of all, if radium did nothing but to *cure basal cell epitheliomata* of the face it would be well worth all our trouble, outlay, and enthusiasm; it did cure about 95 per cent. of all early cases easily. It was not so effective in the fortunately rarer *squamous cell epithcliomata* where surgery might be the best recourse. With radium one could practically wipe out all but the advanced lip lesions; here the danger was of over-radiating and destroying the lip. Incipient lesions were best excised with the cautery. If a neck was operable Dr. Kelly said he believed a block dissection was best, but whatever the results were must be shown by statistics. In *carcinoma of the tongue*, if the lesion was well localized in the front part of the tongue it was better to excise; if the lesion was in the back part of the tongue it was better to implant radium in a circumvallate way; this would usuallly wipe out any early lesion. The statistics of Dr. C. F. Burnam and Dr. Crowe with reference to the results of radium treatment of cancer of the tongue and nasopharynx showed seven cases of *angioma in the nasopharynx* cured by radium, cases with no other possible plan of treatment. *Fibromata* (juvenile polyps), tending to invade deeply in finger-like projections, gave better results when treated by radium than by operation. Some of their patients treated for lymphosarcoma of the nasopharynx were well upwards of five years after radium treatment. As to *carcinoma of the larynx*, the permanent results of radium treatment were not striking. Here it was often best to do a laryngotomy, and then to use radium. In the treatment of tubercular adenitis radium often gave remarkable results. If one could do nothing else with radium but treat tubercular adenitis it would still be worth while. A two inch exposure to a gram for two hours would often clear up such an adenitis. In *breast cases*, Dr. Kelly said he believed in surgery in a good operable case, but in inoperable cases and recurrences he always used radium. He had seen massive adherent, florid carcinomas of the breast with axillary involvement melt under radium treatment. They did not cure those cases, but the visible disease might melt down to insignificance and the patients were made immensely more comfortable. With any malignant lesion in the breast, even a small one, there might be a lesion within the chest, therefore one should make an *x*-ray examination in all cases as urged by Dr. Burman many years ago. The lenticular recurrences in the skin were easily wiped out with radium and this was true of most large discrete masses. Fixed lesions and those attached to the deeper structures were just as effectively influenced by radium as the more mobile ones. Radium would also be worth while if it only helped, as it did, mediastinal lymphosarcomata and leucemias, Hodgkin's cases, and aneurysms, in which last group occasionally great relief of pain was experienced. Again radium occasionally gave splendid relief in *bone tumors*, and in a few instances even brilliant results. In brain tumors they had seen some remarkable improvements; almost all of these cases had been operated upon; one not operated did about as well as the others. In one of these radium used at intervals prevented terrible headaches and epileptic attacks. In *testicular tumors* with abdominal metastases, while they had had many disappointments, some got well and some of these again relapsed. *Malignant bladder tumors* in women, if seen early, could be cured sometimes. Cancer of the vagina which had not invaded the deeper structures was curable almost invariably. He was about to treat all early cases which could be followed carefully with radium alone. With reference to *carcinoma of the cervix*, he was not prepared to speak with so much assurance. In borderline cases with some lateral infiltration, Dr. C. F. Burman had noted about 31 per cent. of cures over several years. In inoperable cases with extensive infiltration radium was most valuable in a palliative way and gave an occasional cure. In *carcinoma of the body* some very encouraging results were recorded in their clinic. In employing radium therapy in this region one must avoid hurting the rectum by interposing lead screens. It was important in these cervical growths that the first treatment should strike a heavy blow. The radium must not be permitted to become displaced here and to burn sound tissues; this often happened. For the *bleeding uterus* (myopathic) radium was practically specific, but in young girls of course curettage was preferable. Some 700 cases of fibroid tumors had been subjected to radium therapy and it succeeded, at a rough estimate, in about nine out of ten cases. They had treated about 78 leucemias, some 60 cases of splenomyelogenous, 21 chronic lymphatic, and 23 acute leucemias. Among these there were some in good health for three, four or five years; even then there were relapses. Such cases needed constant watching, and the leucocyte count remained up to fifteen or twenty thousand. Some had been so improved that they had been able to go back to work. They needed consultation with their medical confrères over this group. Cases of *Hodgkin's disease* showed remissions of several years and much could be done with Hodgkin's disease if seen early. Here and there a carcinoma of the rectum did well. In treating *lymphosarcoma* it was vital to radiate the entire lymphatic system. Dr. Kelly showed lantern slides illustrating the results they had been able to obtain by radium therapy. Among the slides were several showing metastases in the vertebræ greatly relieved of pains; one from being a wretched suffering invalid declared she was well, although no changes could be seen in the *x*-ray pictures of the vertebræ.

The Modern Conception of X-Ray Dosage.—Dr. WILLIAM DUANE, Professor of Biophysics of Harvard University, made this contribution to the program. He said the practising physician frequently had to ask the question, "Shall I or shall I not send such and such a case to the radiologist for treatment?" He was not a physician nor a surgeon though he had the highest opinion of the medical profession, but simply a man carrying on research on those forms of radiation which were used in radiotherapy, so he spoke only from the scientific point of view. It seemed to him that he could best employ the few minutes allotted to him if he spoke of the modern conception of *x*-rays and said a few words in regard to the dosage, comparing the amount of energy that could be sent into the tissues by means of *x*-rays with that by means of the gamma rays from radium, and conclude by making a few remarks, to emphasize in particular the great danger of these modern *x*-ray plants. As to the modern conception of the *x*-ray, firstly the *x*-ray tube itself was a tube of glass with the air exhausted. Two metal rods from a high tension generating plant caused a current of electricity to pass through the vacuum between these two pieces of metal. After defining an electron, Dr. Duane stated that the high tension generating plant caused the electrons to be thrown from one electrode to the other with great force, with nearly the velocity of light. The impact of the electron, the atom of electricity, against the atom of ordinary matter produced the *x*-ray. According to the old conception the impact sent out a wave in every direction which traveled in an ever-increasing sphere. Each *x*-ray produced by the atomic impact passed out as a spherical wave in all directions. The modern conception ways not exactly like that. It was that when the atom of electron struck the ordinary atom the *x*-ray traveled in one direction only. A certain quantity of radiant energy after the impact traveled out as a bundle of radiation in one direction. Another impact sent out a bundle in another direction so that there were a large number of bundles of

energy traveling in different directions at the same time, but each bundle was distinct. This theory was somewhat comparable to Newton's corpuscular theory of ordinary light, but one must not regard the *x*-ray as corpuscular at all, but as a little series of waves traveling in one direction. The important characteristic of these waves was the wave-length, by which was meant the distance between one wave and the wave that followed it. The wave-length and the amount of energy in one bundle were related to each other in a very simple manner. If one multiplied the energy by the wave-length one obtained a constant quantity and a very important one, the same for all *x*-rays. If one measured the wave-length, he knew, therefore, what its energy was immediately, so it was very important to know the wave-length. The effect which the *x*-ray produced depended upon the wave-lengths and upon their number. All the chemical and physical effects, the decomposition of water and of other chemical compounds, etc., all these effects depended upon the wave-lengths and their number. The wave-lengths and number were the important things to know in all estimations of dosage. Dr. Duane then exhibited slides to show that it was possible to measure wave-lengths by means of the spectrometer. To measure the relative number of waves he had curves in which the horizontal coordinates represented the wave-lengths and the vertical coordinate was proportional to the number of *x*-rays having the wave-length. Copper was, but lead was not a good substance to use as a filter. A constant voltage produced much more radiation that an alternating one. In regard to the practical application of radiation in therapy, the problem as it presented itself to the physicist was "How can I project into a tumor below the surface of the skin the largest amount of energy as compared to the amount absorbed by the skin?" As a concrete example, suppose we wished to know how much radiation would reach a depth of 10 cm. compared with the amount absorbed by the skin? The gamma rays were about one-half absorbed in passing through 10 cm. of tissue, but the amount of radiation was also reduced by the fact that it was further away from the source. If the radium was 10 cm. away from the skin and the tumor 10 cm. beneath the skin the tumor would receive only one-fourth the radiation received by the skin, even if the tissues did not absorb it all. The amount of radiation would be still further reduced by the absorption of the tissues to the extent of 50 per cent. The tumor itself would receive, therefore, only one-fourth of this 50 per cent., or 12½ per cent. of the skin dose, due to radiation traveling in a direct line from the source. With the ordinary *x*-rays as used at the present time, produced by 80 or 90 volts applied to the tube, 12½ of the total radiation was all that passed through tissue 10 cm. thick. With the new style, high voltage apparatus 25 per cent. was the greatest amount that could be forced straight through the tissue, about 75 per cent. being absorbed. The question then presented itself whether it was possible to increase the fraction of radiation that reached the depth of 10 cm. below the skin by increasing the distance of the tube from the skin. If the tube was placed 90 cm. from the skin and the tumor was 10 cm. below the surface of the skin, or 100 cm. from the source, according to the laws of physics about 81 per cent. of the radiation that passed through the skin would reach a point 10 cm. below it. After allowing for absorption by the skin and the tissues beneath the skin, about 20 per cent. of the radiation would reach the tumor 10 cm. below the surface, whereas with gamma rays only 12½ per cent. of the radiation reached that depth. One could increase the amount of radiation by increasing the distance and the amount of radium employed, but owing to the cost increase in that way was prohibitive. One point to be emphasized was that in estimating the dosage one could not base his calculations on the amount of radiation that went straight from the source to the tumor. Experience had shown that *x*-rays and radium produced secondary radiation, when the primary rays passed through matter. The importance of these secondary rays in therapy had been recognized only in recent years. That was the important contribution to this work that the Germans had made. Of the rays that reached a certain point part of the radiation came directly from the tube and part came as secondary radiation from the surrounding tissue. Of the amount of radiation reaching the point to be radiated from two to three and half times as much might come from secondary radiation as came directly from the source. In other words secondary radiation was a very important factor, and, if one did not take it into consideration, he might make an error of several hundred per cent. Again the shorter the wave-lengths the greater secondary effect. This was an additional reason why one should use short *x*-rays. Dr. Duane stated that one thing he wished to bring out was the very great danger in handling these new high power *x*-ray generators producing very short wave lengths. It was a grave question whether these high power machines should be delivered into the hands of everyone or whether they should be confined to institutions. The danger was not only to the patient and to the operator but to people in neighboring rooms. One-half of one per cent. of very short wave-lengths would pass through a sheet of copper one inch thick or through a concrete wall. Anyone working in an adjoining room or on the floor above or below such an *x*-ray generator should be protected. For the patient these high power plants were very dangerous. As was well known a great many deaths had been produced by radiation. It seemed to him that the question here was one the medical profession would have to decide by the combined weight of their individual opinions, namely, the question as to how far it was advisable to submit patients to treatment which had so much danger attached to it. This question was one which would have to be decided in the near future.

Dr. W. H. STEWART stated that the problems confronting them in deep roentgenology could be summed up as follows: (1) The introduction into deep tissue of hard filtered rays. (2) The accurate measurement of the amount of such rays which reached the deep structures. (3) The determination of the correct depth dose of *x*-ray for various lesions, both benign and malignant. Dr. Coolidge and others had at last succeeded in producing practical *x*-ray tubes which could be used with high voltage machines. With the aid of these tubes and an apparatus generating 180,000 to 200,000 volts, *x*-rays could be introduced into the deep underlying structures. They had also learned, applying the physical law of quadratics, that this introduction could be greatly facilitated by increasing the distance between the anode of the tube and the skin distance. Larger fields, permitting the more extensive use of secondary radiation had also in a great measure assisted in the solution of this problem. It had been proven that the use of heavier filters, such as ½ to 1 mm. of copper or zinc in combination with higher voltage, increase of distance, and larger fields made it possible to deliver to tissues 10 cm. below the surface 30 to 40 per cent. of the intensity of the skin dose. *The determination of the accurate amount of x-ray which reached the deeper structures had always been difficult.* Within the last two years, a number of different methods of measurement had been advocated, all of which had their special advantages The method which seemed the most practical was the use of the juntoquantimeter. A number of different forms of this apparatus were now in use, but the one which appealed to the speaker most was that modified by Freiderich of Freiburg, and which consisted of a small ionization chamber of graphited horn which could be placed on the skin or introduced into the body cavities such as the vagina or rectum. This ionization chamber was connected with a Wulf electrometer by a flexible cable in such a manner that the electrometer could be placed behind the lead protective screen where the operator could make accurate readings while the *x*-ray tube was in operation. Freiderich had established an electrical unit applicable to this juntoquantimeter, the full excursion of the indicator on the electrometer representing five such units. Experiments had demonstrated that 300 units produced death to the skin or what was known as a necrotic dose. About 150 units, or 50 per cent. of the necrotic dose, resulted in a reddening of the skin —this was known as an erythema dose. Knowing the time required for the application of five units it was

an easy matter to determine the exposure necessary to produce an erythema dose or a fraction thereof. Another popular juntoquantimeter was that model which called for a reproduction of the electrical conditions as though the patient was being treated. The anode of a certain tube was set the desired distance from the front surface of a water tight box, the latter representing the patient's skin and in front of this surface was placed a lead diaphragm with an opening of the size selected for the treatment field; over this opening in the diaphragm was placed a filter. Water representing the human tissues, was placed in the box until the desired depth was obtained; back of this was the ionization chamber connected with the electrometer. With the apparatus set in this way one could ascertain how much time was required to obtain a certain depth dose. Still another ingenious method of determining the depth dose was by the use of Dessauer's curves. Professor Dessauer of Frankfurt à Main had devised a series of charts, covering practically all possible electrical conditions. The curves on these charts gave the operator accurate information regarding the actual percentage of the skin dose which reached certain depths. Thus one could estimate how many fields were required with a certain voltage, distance, diaphragm and filter to administer a certain dose of *x*-ray. The method, if used by skilled technicians, seemed very accurate; Professor Dessauer had made his estimate of depth doses as a result of investigations covering a period of three years. Three different tests—all giving the same identical results—were employed. With such painstaking work one could readily understand why he himself and the advocates of his method placed such confidence in the accuracy of Dessauer's curve. Even with all these apparently successful methods of measurement, one must not forget that there was a considerable variance in the estimation of what an erythema was—the degree of reddening was a very potent factor. The susceptibility of the skin was also to be considered. There were many individuals, especially blonds, whose skins were conspicuously more sensitive to the ray than others. *The determination of the correct depth dose of the ray for various lesions, both benign and malignant,* was one of the most difficult problems. The establishment of a definite carcinoma dose was almost impossible because of the great variance in carcinomatous structures and their radiosensibilities. This radio-sensibility was not altogether histological, the general condition of the patient being an important factor. The skin of a cachectic patient did not always show erythema when a full erythema dose was given. In fact, subjects showing a distinct cachexia were unfavorable for roentgen treatment. We must also bear in mind that all tissue was not equally sensitive to the *x*-ray. For instance, youthful subjects were more sensitive than persons of more mature age. Malignant growths in which connective tissue predominated required considerable more *x*-rays than those in which the cellular structure was most abundant. Carcinoma of the breast and uterus responded more favorably to deep roentgen treatment than carcinoma of other organs although some favorable results had been obtained in cases of carcinoma of the rectum. It was generally conceded that it was necessary to introduce into a carcinoma at any given depth 110 to 120 per cent. of the skin or erythema dose in order to destroy the growth. This was estimated by multiplying the number of fields by the percentage of the skin dose, which reached a required depth below each field. It was found that the destructive roentgen dose for the ovarian follicle was 30 to 40 per cent. of the skin dose. Permanent or temporary amenorrhea was easily established. Small myomas disappeared with the same treatment. Large myomas required 50 to 60 per cent. of the skin dose. Sarcoma as a rule did not require as large a dose of *x*-ray as carcinoma, although here again the location and the histological elements, as well as the condition of the patients, must be given consideration. As a rule, however, 50 to 60 per cent. of the skin dose was all that was required. In conclusion Dr. Stewart stated that the exact measurement of the depth dose was most important. Apparently the problem had been solved by the use of the juntoquantimeter; it might be true, however, that in the hands of a responsible physicist the instrument was absolutely reliable while in the hands of an inexperienced person it might cause considerable miscalculation.

Dr. CHARLES N. DOWD, continuing the discussion, said that anyone who had listened to the papers must appreciate that the forms of radiation they described were tremendously powerful. It had been interesting to trace the development of the subject. He remembered when the first radium brought to this country was placed at the disposal of the Memorial Hospital during the intervals when it was not on exhibition at the Museum of Natural History, through the generosity of Mr. Geo. F. Kunz of Tiffany Company. Dismay followed the leakage of a portion of this radium from its faulty capsule. Fortunately it was recovered but the Hospital Authorities were unwilling to longer assume the risk of keeping so valuable an agent. The development of the problem in the intervening years had been most interesting, but this development had not been a steady one. Like most therapeutic agents it had progressed by oscillations. There had been periods of therapeutic hopefulness, "inflation," if one might so speak and these had been followed by periods of depression. These oscillations had been dependent in some measure on the results which had been obtained from the use of radiation and in some measure in the optimism or pessimism of the particular men who had been working on the problem. It was of the utmost importance that we should keep our poise and give to radiation all the credit which belonged to it, but that we should also remember its limitations. In studying all problems connected with malignant disease we must continually think of two factors of paramount importance: (1) Diagnosis. (2) Natural History of the Disease. In comparing the diagnosis as made by the surgeon and the diagnosis as made by those who used radiation, we must acknowledge that the surgical diagnosis was more likely to be accurate. If the diseased tissue was removed and inspected both macroscopically and microscopically the percentage of diagnostic error must be very small. Benign growths were not likely to be confused with malignant growths. In noting the work of those who used radiation it had been very evident that at least a portion of that work had been done on insufficient diagnosis. We were much pleased to hear Dr. Kelly state that he regularly removed a specimen in cases of Hodgkin's disease to confirm his diagnosis. The entire question of removal of specimens for diagnosis needed revision. It was possible that the danger of spreading infection had been exaggerated. The reports of Dr. Wood on rat tumors and recent reports made by Dr. Peck on the later history of some breast cancers from which specimens had been removed indicated that there were many instances where proper removal of a palpable portion of a growth for diagnosis might be done with such safeguards as to conserve the patient's welfare. Certain other observations which had come to our notice also indicated that radiation was frequently done without appreciating the Natural History of the Disease, for instance a patient recently came to the hospital, on whose thigh a small malignant growth had been locally cured by radiation, but she had an enormous metastasis in her groin from which she died. It manifestly was wrong to treat the thigh without treating the groin. Similarly one who treated scirrhous carcinomas in women over seventy with radiation might easily get an erroneous hopefulness concerning its efficacy. These patients usually lived for a long time without any treatment, and naturally did well under radiation. It would however be very unfortunate to believe that the same treatment was equally good for young women with rapidly progressing breast cancer. Only to-day, Dr. Dowd said he had been talking with a director of a very important Cancer Institute who insisted that radiation should only be used for those patients who are distinctly inoperable and that it should be used not as a curative agent but as a palliative agent. With regard to tuberculosis of the neck lymphatics, we must similarly appreciate that radiation had a definite place. It was, however far more important to recognize that these patients should be taken in the early

stage, that this disease was usually of many years' duration, beginning in childhood, and that there was a very definite period in which a carefully performed operation with a duration of one-half to three-fourth of an hour would give 80 to 85 per cent. of permanent cure. This he believed was a far better result than would be obtained by any form of radiation. Surgeons were continually operating on patients for whom radiation had failed. On the other hand they frequently referred patients with extensive neck infection for radiation after making as thorough a surgical removal of the disease as was practicable.

Dr. Burton James Lee said it seemed to him that they all appreciated without saying it that radiation by *x*-ray and by radium was here as an established therapeutic agent. The experimental stage in radiation had gone by some years ago. He felt that such a statement was proper because we had behind us at the present time Dr. Kelly's thirteen years of work more or less, certainly a great many years in the use of radioactive substances. As a surgeon in an institution using radiation, certain experiences had come to him. In the first place, rather often the physician might feel that the use of radium in malignant disease was only designed as a more or less forlorn hope, as a thing to be used in the last end of the issue. That was not their feeling at the Memorial Hospital. As the consequence of results obtained there that idea was falling more and more into the discard and better cases were coming to the institution. This more hopeful attitude was shown by the fact that epithelioma of the lip was being treated by radium with radium along the lymphatics. Epithelioma of the tongue was treated by excision of the growth and the implantation of radium. Epithelioma of the tonsils was treated by excision and implantation of radium. They were all agreed as to the advisability of operation in primary operable carcinoma. In older patients selected cases were now treated by radium. They had for several years been treating recurrences and primarily inoperable cases with radium. In cancer of the cervix operation was followed by radium implantation. In cancer of the body of the uterus radium followed by hysterectomy had shown encouraging results. In carcinoma of the bladder and prostate they had been using radium, often by a suprapubic incision. All this work was in its infancy. The talk by Dr. Duane was enough to show that the medical profession must have the help and guidance of the physicist and the physiologist, who must not only be competent men but must be interested in the treatment of tumors. The work must be done by an intelligent group of men (among whom must be included an internist) looking for the truth and they must be permeated, as Dr. Kelly had said, with a great deal of optimism. He felt that the results were very encouraging and that if we could keep our feet on the ground and not go off on by-paths, but consider each case as an individual problem, then with the aid of the physiologist, the physicist, and our medical confrères, we must get more and more benefit from the use of radium.

Dr. C. Everett Field stated that their work at the Radium Institute had extended over a period of eight years, and had permitted them an opportunity of observing all branches of radium therapy. Early in the investigation they took up the internal administration of radium chloride in dosage infinitely small. The early reports by Dr. Robert Abbe of his experiments in stimulating the germination of vegetable life, by means of radium, directed their attention to the physico-chemical action of this element on certain processes of the body chemistry. Radioactivity had been shown to possess a potent influence on metabolism that might be good or bad, according to its administration. Attention had rightfully been directed to the dangers which might follow the use of radium as applied in malignant disease. It was quite true that in radium we were dealing with an agent capable of exerting as much harm as good. There were a few situations where radium alone had been shown to accomplish certain definite good. In cancer of the uterine cervix, in many of the malignancies of the head, in laryngeal and osophageal cases, in lymphosarcoma, and in tuberculous glands of the neck, the reports were so favorable as to permit us to advise the surgeon to keep his hands off. Beyond this limited field, radium was but the direct adjunct of surgery. When it came to the discussion of deep radiation either by *x*-ray or radium, they were familiar with the danger that lurked in overdosage. Frequently they witnessed a shock to metabolism and subsequent toxemia that at times was followed with fatal termination. The new deep *x*-ray therapy now being investigated had as its chief criticism, a very large element of damage to the metabolic processes, with a heavy primary mortality. For preoperative and postoperative care of malignant cases, it was highly important that radium be considered. The pathologist and biochemist had shown us that radiation checked malignant cell proliferation, and changed the chemistry of the fluid of the tissues treated. We were made certain that for a period, limited at least, proper radium application served to check the processes of metastasis. If such a statement were correct we should be in a position to advise preoperative radiation in every prospective operative case, say two or three weeks before surgical intervention. He felt that such a course could not fail to be productive of much better statistics. Radium itself needed no defense but a better understanding. It had been proven that radium had certain properties that could serve well in the destruction of cancer. Improper knowledge as regarded the condition of the patient, the type of growth, as well as bad judgment or ignorance governing the application of radium, spelled failure. Radium therapy had suffered at the hands of the over-enthusiast and the skeptic alike in the years past, and it was to be criticized again. In the hands of highly specialized workers with laboratory facilities, its future was safe, and then only. We had neglected to give proper credit to Dr. Howard Kelly and Dr. Robert Abbe, the pioneers of radium work in America, who for fifteen years had been pleading the cause of radium against great opposition. It must be a matter of great satisfaction to these men to see the generous acceptance that was now accorded to their statements. The real problem now before the radium therapist consisted, Dr. Field believed, in the recognition of the need of studying the prospective radium patient, to encourage the support of metabolic function during and after radiation. Such a régime was as important as was the radium itself.

Dr. Kelly said he merely wished to thank the gentlemen for having covered the ground so carefully. Dr. Dowd had brought out a point he wished to insist upon, namely, that the radium therapist ought to be a surgeon who had at his finger ends all the resources of surgery and was prepared to use them immediately. They made it a routine to put everything under the microscope. In closing, Dr. Kelly emphasized his belief that radium had come to stay.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 27, 1921.

DR. WILLIAM P. HEALY IN THE CHAIR.

General Edema of the Fetus Associated with Osteogenesis Imperfecta.—Dr. Harbeck Halsted reported this case, in which the defects seemed to be in the long bones and those of the skull. The long bones were very short and friable and there was evidence in the *x*-ray pictures that fractures had occurred *in utero*, with subsequent healing, in one place making a marked angulation, and in other places represented by callus. The skull bones were only represented by small plaques of bone. The bones had not been studied microscopically as sufficient time had not yet passed to decalcify them. General edema of the newborn was a rare condition. Ballantyne had collected 70 cases from the literature between 1614 and 1898. Shumann had since collected 38 additional cases. Ballantyne described it as "a morbid condition of the fetus characterized by general anasarca, by the presence of fluid effusions in the peritoneal, pleural and pericardial sacs, and usually by edema of the placenta, and it resulted in the death of the fetus or infant before, during, or soon after birth." He stated that there was friability of the subcutaneous

tissues and also sometimes of the muscular and osseous. These two statements taken together described this fetus very well. The clinical history of cases of this fatal malady offered several points of interest. The mother was nearly always well advanced in child-bearing life and in only 7 out of 65 cases was her age less than thirty years; in only one instance was she primaparous. Maternal dropsy and hydramnios were common, and syphilis very uncommon. Premature and difficult labors were common. This woman was 24 years of age and without hydramnios. She had postpartum eclampsia. The etiology and pathology of these cases was quite obscure. One noteworthy occurrence in this case was the speed and completeness of the disappearance of all symptoms in the mother after the birth of the child. The patient was white, born in the United States of American parents. She was delivered November 13, 1921, at about the seventh month. She was toxic, edematous, and said by her physician to have kidney trouble. There was nothing abnormal in her previous history or the first six months of her pregnancy, except a history of frequent attacks of tonsillitis and an attack of jaundice at the age of 14 years. She had had a tonsillectomy performed. One month before her admission her urine began to show a trace of albumin, she developed edema, and her blood pressure began to rise. The symptoms grew progressively worse and she was admitted to Sloane Hospital, November 12, 1921. At this time the specific gravity of the urine was 1020 and the albumin 85 per cent. by gravity; there was an occasional red blood cell, many pus cells and an occasional hyaline cast. She was put on a salt-free and protein-free diet. The next morning she was given a colon irrigation and castor oil and quinine. Labor soon set in. The presentation was breech, R. S. A. After a few hours the breech and both feet presented at the vulva. Gentle traction was made on the right foot; the foot and part of the leg just above the ankle pulled off. Gentle traction was then made in both groins and when the baby was born it was seen that both groins had been split nearly to the bone. As soon as the baby was born the cord broke about two feet from the baby's body. The child's heart was beating and it took several breaths and then died. The baby was a premature male weighing three pounds nine ounces, and was 32 cm. in length. The tissues were all edematous, very friable, and very little bony structure could be made out by palpation. The feet, legs, arms and hands were short, deformed and flattened. The placenta was large, jelly-like and very friable. The patient had several convulsions after delivery, then she gradually improved, her blood pressure dropped, and her urine gradually returned to normal. The autopsy findings were reported in detail and also the microscopic findings in the placenta.

Dr. L. T. Le Wald said that bony defects were exceedingly interesting. He did not think they were specific; he thought the history of this case bore that out. One must differentiate osteogenesis imperfecta from achondroplasia which was a peculiar type of bony development and which was also not specific: both these conditions were sometimes confused with syphilitic conditions. Dr. Le Wald said he regretted that the microscopical study of the bone had not been made, and hoped that some light on the etiology of the condition might result from it. The radiographs showing the healing of the fractures *in utero* were exceedingly interesting, and was a condition he had not seen before.

Dr. Harvey Clock Williamson cited a case somewhat comparable to this. This patient, a para III, was delivered at the eighth month. She showed general edema before delivery and had six convulsions postpartum. In this instance the neck of the fetus was broken and there was a fracture of the humerus but no radiograph was taken. The postmortem examination of the fetus revealed acute degeneration of the kidneys, liver, and spleen. The Wassermann reaction was negative. In a general way the case was quite comparable to Dr. Halsted's.

Primary Sterility: A Study Based on 400 Cases.—Dr. Abraham Rongy nresented this communication, in which he asserted that the reason relatively few cases of sterility were cured was because our entire conception of the etiology an dtreatment of primary as well as relative sterility was entirely erroneous. The mechanical theory of sterility was untenable. The organs of internal secretion had been held responsible for almost all the ills human flesh was heir to and had been held responsible for sterility too. Every steriie woman had been given all sorts of organic extracts. It was soon found, however, that they were falling far short of the claims made for them. If we blindly accepted the theory that the organs of internal secretion were responsible for sterility, we should again be led astray for another thirty years, and in the meantime our attention would be detracted from the true causes of sterility in the largest number of women. During the last decade the men's share for the responsibility for sterility had, in his experience, undergone a great change. In a paper published in 1911, he had found that the man was at fault in nearly 50 per cent. of the cases, and this coincided with the experience of a number of observers at that time. In the present series it was less than 11 per cent. It seemed from this that the educational campaigns that had been conducted by the medical profession and the various public health agencies were just now beginning to bear fruit. In investigating the male aspect of the question many interesting points were brought out from the academic standpoint, but he felt that they were of no practical value. In the light of our present knowledge a man must be pronounced well if a condom specimen showed fully formed and viable spermatozoa. A number of the patients in this series were inseminated—the semen being lodged high in the uterine cavity—but not one of them became pregnant. The failure of conception in these cases seemed to indicate that something was wrong higher up. If the problem of sterility was to be solved at all it would have to be investigated from a purely biological and chemical standpoint. A great many women who were sterile had practically the same developmental characteristics; they were short, fat, stocky, and gave a history of menstruating very irregularly. These women were studied from the standpoint of anatomical defect of the bony pelvis. Unfortunately the findings were negative. In a selected group of women and their husbands the blood was typed; there was no material difference in the grouping between the sterile couples and those who had one or more children. It was found that those patients who gave a history of having developed sudden and severe pain during the second or third day of their menstruation three or fours years after puberty, were more likely to be permanently sterile. Inquiry was made into the possible relationship of the exanthematous diseases and sterility. There seemed to be a greater prevalence of sterility among women who during their infancy or childhood had troublesome throat infections, also that women who had had scarlet fever, complicated by severe kidney disturbances, were not so likely to be sterile as those women who had simple uncomplicated scarlet fever. While it was a highly speculative suggestion, something might take place during an attack of scarlet fever or diphtheria which prevented the ovary from properly developing and possibly at the same time caused permanent structural changes. The fact had been brought out that sterility was very often temporary in nature and that in a certain number of women some readjustment took place and pregnancy ensued. No marriage ought to be considered sterile until after two years. Dr. Rongy said he could not help feeling that displacement of the cervix played a very small rôle in the etiology of sterility. The only findings of more or less importance were: (1) The small infantile body of the uterus, that was narrow from side to side, and usually associated with a small conicle cervix, and frequently found in women who were fair. (2) The large, hard body of the uterus, with a long, hypertrophied cervix, and a history of rather profuse menstruation, which was usually found in the tall, masculine type of women. To him such findings indicated an unfavorable prognosis. If these patients were left alone, some of them would have a better chance to become pregnant, for the various operations performed on them often resulted in the closure of the Fallopian tubes, causing permanent sterility. The patient in whom one found a small, cord-like body of the uterus must be severely left alone. Plastic operations on the tubes held out very little hope for the cure of sterility.

Those patients whose tubes had been closed as the result of gonorrheal infection often had a better chance if they were not operated upon. It was still a mooted question whether to operate on patients who had fibroid tumors. If he found the tubes open he did not advise operation on these women. If, however, the tubes were closed, nothing would be gained by deferring operation. Of 52 patients who had had dilatation of the cervix and the insertion of a stem pessary for the purpose of correcting and enlarging the cervical canal, eight became pregnant, one while the steam pessary was in place, the others remained sterile. Permanent enlargement of the cervical canal in his experience did not occur after a stem pessary operation. There were many other objections to the stem pessary. Ovarian tumors in women who were sterile should be removed as soon as possible, because the tumor might act as an irritant to the other ovary, and by an early operation one might be able to save a part of the ovary which was less involved, and had not as yet been destroyed. Three patients in this series suffered from vaginismus. The classical Pozzi operation was performed and they became pregnant shortly after. The real problem that confronted them in the treatment of sterility was in that group of patients which practically presented no anomaly of the genital tract, except possibly a moderate degree of flexion or version. Dr. Rubin's method of insufflation for the purpose of ascertaining the patency of the Fallopian tubes had changed the entire status of sterility and its treatment. For practical purposes all patients who suffered from primary as well as relative sterility could be classified into two general groups: (1) The clean group or patients who suffered from sterility due to some constitutional disturbance. (2) The unclean group who were still suffering from an inflammatory condition in or about the pelvis. At the Lebanon Hospital, during the past twelve months, they had made 152 examinations by this method. If oxygen was used not more than 300 c.c. should be introduced. If carbon dioxide was employed a greater quantity could be introduced. In this series of cases 90, or 59.2 per cent., were positive, that was, air appeared in the abdominal cavity; in 62, or 40.8 per cent., no air was present in the abdominal cavity. When air passed into the abdominal cavity through the tubes they might be considered patent from the standpoint of mechanical obstruction to the passage of the spermatozoa. However, the Fallopian tubes might be plugged by some inflammatory exudate or some mucogelatinous substance, and still permit the passage of gas under pressure, yet, without artificial distention of the tubes the plugging might act as a barrier to the passage of spermatozoa. The contraindications to this method of examination were acute infections of the vaginal or pelvic organs; it must not be used in the presence of chronic infection if the patient complained of pain. It should not be employed when the menstrual period was about to appear. Patients who had heart disease should not be subjected to this examination. This method of examination should be used in every case in which the sterility was of doubtful origin. Four patients did not menstruate after the insufflation and upon examination were found to be pregnant. He did not believe the occurrence of pregnancy in these patients was purely accidental, but that probably the force of the gas either expelled some mucous plugs or straightened out any kink that might have been present. The treatment of sterility consisted chiefly in the art of being able to select the patients who were likely to respond to treatment. Those patients in whom one found congenitally defective organs ought to be left alone.

Dr. HARRY ARANOW expressed the opinion that Dr. Rongy, in his paper, had practically covered every important point in this wide and intricate subject, so as it was difficult to take up every point for discussion he would just take up the cases in a group. He was younger in experience if not in years, so he was more hopeful than Dr. Rongy. To his mind sterility might be considered in two main groups, namely, those in which the cause was evident, such as cases of dyspareunia, vaginismus, marked stenosis of the cervix, and those in which the cause was difficult to ascertain, or causes were found, such as obstruction in the tubes, maldevelopment or chronic disease of the ovaries, which interfered with ovulation without giving any palpable physical signs. To him the reason we had failed to cure sterility was because we had failed to put our finger on the underlying cause. Dr. Rongy said cases which had remained sterile for two years after marriage might be considered sterile. He did not think we could consider a patient sterile until three years after marriage. A great many women even without prevention would not conceive for two years after marriage. He thought we should allow three years before deciding that a woman was sterile. Some cases with anteflexion of the cervix were cured by dilatation. He had the same feeling about retroversion if it was not caused by an inflammatory process. The cases in which the sterility was due to inflammatory process were rather hopeless, but those in which no inflammation was present were sometimes helped by reposition and operation. He had the same hopeful feeling about fibroids. A woman of over forty recently consulted him, not because of sterility, but for fibroids which were causing pain by pressure. At operation he found five or six fibroids, some intramural, and a small uterus. That woman became pregnant and was delivered without difficulty, though four or five incisions had been made in her uterus. He felt that those cases of sterility which had evidence of being caused by retroversion, or ovarian cyst, or fibrosis, or stenosis, ought to be given the benefit of operation, for some of them might be helped. Of course, before operation they should be thoroughly investigated by Dr. Rubin's insufflation method, a procedure which was very simple and foolproof. The examination might be made under the fluoroscope in the office, and then one could answer the question as to the patency of the tubes at once. One of the most complicated questions we had to consider was sterility. We could examine the cervix and the uterus fairly well, but when it came to the tubes and ovaries it was more difficult, and the question of endocrine imbalance might have something to do with the sterility. This method of insufflation should be made a routine procedure, just as one examined the husband every time before undertaking to operate on a case. One point Dr. Rongy brought out should be emphasized and that was that the gas might go through places where a spermatozoon could not pass through.

Dr. HERMAN LORBER believed they were probably all of the opinion that prophylaxis had its field of usefulness in the cure of sterility. The general custom of the young graduate providing himself with a set of curettes as his first instruments and using them when and where infection was very likely might be a contributing factor to so many cases of acquired sterility. The eugenic test of the male and the cured chronic conditions of the prostate would also help to eliminate future possible cases of sterility. In cases of undeveloped uteri much had been done with endocrines and Dr. Hirst had cited cases treated with the galvanic current in which the uterus was almost doubled in size following his treatment.

Dr. WILLIAM P. HEALY stated that Dr. Rongy had shown that we now had available a very important method of clearing up the question of the patency of the tubes by means of Dr. Rubin's method by the injection of oxygen, and by the method of Dr. Cary of Brooklyn with salt solution. The question of the patency of the tubes had been a problem to all who had to deal with sterility in the female. As Dr. Aranow had said, if we had something in the individual case that was pathological it was well worth while relieving it in order to place the patient in as nearly normal condition as possible before giving up. In regard to the question of using the stem pessary which Dr. Rongy discouraged, he believed it was a valuable form of treatment in dysmenorrhea and stenosis of the cervical canal, and in sterility, not only because it acted as a dilator but because the cervical canal remained dilated thereafter, and also because it helped in the development of the uterus. It acted as a foreign body: the uterus made an effort to expel it, and in spite of the fact that the pessary might be sutured *in situ* one would find it exceedingly difficult to make the pessary remain in place because the uterus would tend to expel it. That meant the uterus had been undergoing mechanical massage, which caused it to increase in size and it was better for the pessary having been there. Of course,

putting a stem pessary in an inflamed uterus was another thing. The cases must be properly selected. Cases of dysmenorrhea were sometimes permanently cured by the stem pessary. As to myomectomy in cases of sterility, he had not had good results. Very few had been benefited so far as the sterility was concerned. Occasionally one patient would be cured, but they were so few that they might be ignored. It was better, however, to do a myomectomy, no doubt. Dr. Rongy's paper brought out the necessity of knowing the condition of the tubes before instituting an operation for sterility. He stated that 60 per cent. of the cases examined had clean tubes and only 40 per cent. showed pathology needing treatment. That had been his experience; in cases of sterility approximately 60 per cent. would be apparently normal and the husband was also normal. It was only in a small proportion of the cases in which pathology existed that one could succeed in curing the sterility by operation.

The Values of Various Methods of Bone Grafting Judged by 1390 Reported Cases.—From an analysis of this series of cases Clarence A. McWilliams finds that there were 82.3 per cent. of successes with 17.6 per cent. of failures. In the order of successes there were with bone pegs 95.8 per cent. successes; with the osteoperiosteal method (Delagenière), 87.3 per cent. successes; with the end-to-end method (without inlaying), 82.5 per cent. were successful; with the inlay method, 80.9 per cent. were successful; with the intermedullary method (Murphy), 76.6 per cent. were successful; with the combined intramedullary (at one end) and the inlay (at the other), 60 per cent. were successful. The presence or absence of periosteum seems to exert no influence on the success of bone grafts. Proportionately, the percentage of successes without periosteum is the same as with. In the end-to-end method, there were 18 per cent. more successes than failures without periosteum, and in the inlay method, 9 per cent. more successes without periosteum than with, while, on the contrary, with the intramedullary method, there were 13 per cent. more successes with grafts with periosteum than without. No explanation is offered as to the cause of the differences with the various methods. Suppuration occurred in 121 cases, or 8 per cent.; 32 per cent. of these succeeded. The conclusion is reached that the most successful method of bone grafting is by the osteoperiosteal method (Delageniere). The bony defect should be filled in with small bone chips, and on one or two aspects, overlapping the ends of the fragments, covering in the bone chips, should be placed one or two strips of periosteum with adherent, osseous plaques, taken from another bone. This method is as applicable to large as to small bony defects. From four to six months' immobilization is ordinarily required for complete success. There is sufficient evidence to prove that the most effectual treatment of non-union fractures is bone grafting. The causes of failure are improper method of grafting, suppuration, insufficient immobilization, or over too short a period of time, fracture and dislocation of the grafts, atrophy of the ends of the bone to be grafted. The intramedullary method of grafting should be discarded. Bone grafting should not be performed, the author warns, in infected fields. —*Annals of Surgery.*

Saccharose in the Production of Fixation Abscess.—Hasenbein injected 50 per cent. sterile glucose solutions into the buttocks of girls with gonorrhea. The amount injected was 3-5 c.c. and novocaine was added in strength of 1 c.c. of a 2 per cent. solution. In most of the subjects a pronounced focal reaction followed. There was also a sort of reaction in the genitals and joints and an improvement in the condition.—*Schweizerische medizinische Wochenschrift.*

Cultivation of Variolous Vaccine.—Despite the fact that no organism has yet been isolated the virus can in a way be cultivated indefinitely on rabbit brain. After eight months of such cultivation inoculation of infants caused very mild pustular lesions of a constant virulence and without the drawbacks of ordinary preserved lymph. As a practically pure culture it should find a limited use among those able to pay the price.—*Le Progrès Médical.*

Medical History.

MY FIRST PATIENT.

By JOHN T. METCALFE, M.D.,

NEW YORK.

[THE following case report was written on the last fly leaf of his first ledger by the late Dr. John T. Metcalfe, then of 785 Broadway, New York, on June 27, 1845. Its publication in the MEDICAL RECORD is through the courtesy of Captain Henry Metcalfe, the author's son.]

As it is not at all impossible that I shall tire of this book,* before the number of my patients compels me to use this page as a record for visits paid and fees to come, I think I'll make it useful, by recording the particulars of my first office call.

Sitting alone, I was agreeably roused from my solitude and Braithwaite's Retrospect, by a ring, which I, somehow or other, felt to have been executed by the left hand of a patient, while his right superior extremity pleasantly depicted itself to my fancy as being engaged in extracting that "V" which was to do its share toward rewarding me for the six long years spent in arduous study, toiling to acquire my profession.

Allowing a decent interval to elapse, I walked with assumed gravity and composure to open the door, Peter having been detailed to execute some commission, in University Place.

With the salutation of conscious ability and that inexpressible benevolence of countenance which marks the truly philanthropic physician, I asked the suffering son of Adam, who presented himself, to enter my sanctum—to be seated, and expressed, in properly guarded terms, my great gratification at seeing him, in my house, a visitor.

"Doctor Metcalfe, good afternoon, sir, how do you do, sir? I have taken the liberty of calling on you. I hope you are well, sir?"

I should have premised that "my friend" was a man of middle age, of respectable appearance and of a certain bearing which gave me to understand that he had been accustomed to the forms of good breeding. To his hopes, regarding my health, I made a proper reply, assuring him that my state of salubrity was unequalled, implying, that mind and body were quite prepared to attempt and go through with anything.

"Doctor, I wish to state my case to you, as it has caused me a great deal of embarrassment."

"My dear sir," said I, soothingly, "make no ceremony with me, but speak out, frankly."

"Well, doctor, about eighteen years ago, I had the misfortune, in a youthful frolic, to contract a gonorrhea. I was a good deal alarmed at the time, and wishing to get rid, as soon as possible, of my trouble, I applied to Dr. Ralph, you know him, sir, a sort of quack who advertises. Well, sir, he treated me, as he said, to stop the running and stop it he did, but the consequence was terrible. One day I found, to my great regret that I was suffering from stricture. This lasted with me for a long time, until I was astonished and alarmed, one day while urinating, to find a spirt of urine fly up into my face, through a fistula which had formed near the root of the penis. There was, afterwards, infiltra-

*His virgin ledger.

tion of urine, which caused great suffering and ended by the sloughing of part of my scrotum."

"Indeed, sir," interposed I, "you must have suffered a great deal."

"That I did, sir," continued he. "I was forced to abandon my occupation which was that of translator of German and Danish and interpreter. I forgot to mention, doctor, that my name is —— (some hard one which I do not remember). I am from the neighborhood of Copenhagen where my relations are respectable persons and well to do in the world. I have received a liberal education.

"As I was saying, this deprived me of my means of gaining a livelihood for a time, though I had no ultimate fears of not being able to get plenty of remunerating employment. I had means of entering the City Hospital, where Gurdon Buck performed an operation which relieved me of my infirmity, but in order to prevent the closure of the orifice through which the urine came, I was obliged to make use of a catheter of gum elastic. Soon after, I was obliged to empty my bladder, every half hour or hour, during the day, but I did not mind that, as I was at work again, in a situation which gave me five or six hundred dollars a year, and for a frugal bachelor, you know, that is enough."

"Quite," rejoined I, "for one of your pursuits, who, as you appear to be, is temperate."

Here I already imagined myself with the sum that *must* pay for two volumes of Forbes' review and might purchase half the set.

"Now, sir, for two months I have been troubled with incontinence of urine. It dribbles away, continually and is so offensive, in warm weather, that I frequently am obliged to change my clothes three or four times a day. Now, doctor, this you must see, is a most loathsome complaint, especially as I am often invited to stay with a friend who has a family of young ladies, grown up (his daughters) whom I am afraid to approach, on *that* account, I wish to see, doctor, if you could do something for me."

"The resources of our art," said I, "are great, and we must try what can be done for your relief, my dear sir. It is wrong to bid any one despair, let us hope for the best and trust that time and proper treatment may relieve you of what, I feel, must render your life most uncomfortable."

"Doctor, I have been obliged to go home to change my clothes *four times* today, I called to see

If you could give me a cast-off pair of breeches."

Work of the American Red Cross in Europe.—According to a recent report from Paris, an American Christmas was celebrated this year at 500 Red Cross child-health stations in a dozen European countries, but this relief work has reached its final stage, except in Russia, and the middle of the coming year has been fixed for the withdrawal of the last medical and relief units of the American organization. While there are still many children suffering from malnutrition and under-nutrition in central Europe, it may be said that there is practically no starvation in the same sense as has been reported in Russia. General health conditions throughout central Europe also provide food for optimism. With the exception of the ordinary infectious diseases, such as scarlet fever and diphtheria, which are endemic throughout Europe, there is comparatively little infectious disease. Cholera, which has assumed alarming proportions in Russia, has not crossed the border, except in a few isolated cases. Typhus occurred widely in Poland, Slovakia, and the Balkans during the post-war period. It will be endemic in these countries for some years to come, but at the present time it is mild in form and is rapidly being brought under control. Tuberculosis increased enormously during the war period. In children it is seen chiefly in the form of bone and gland tuberculosis, which is apparently much more common in Europe than in America. Since the armistice there has been a gradual but steady fall and, though the percentage is still above normal, the steady improvement continues evident. There are no outstanding epidemics of smallpox, typhoid, or recurrent fever this winter. In the Balkans, malaria and intestinal parasites are still abnormally prevalent. The most serious disease, particularly among children, is anemia, due to long-continued malnutrition, but the number of children suffering from severe grades of this disease is decreasing. Rickets, due to deficient diet during infancy, has claimed many victims in all the central European countries, and for years to come there will be very pressing need for orthopedic treatment to correct resultant deformities. Hospitals, medical schools, and dispensaries are all having a very difficult time to exist.

Vision Defects of American Children.—According to the Report of the Hoover Committee on the Elimination of Waste in Industry, approximately a fourth of all the school children of America suffer from poor eyesight, and the proportion of defective vision increases in the higher grades. The principal eye defects disclosed by the investigation are far-sightedness, nearsightedness, and astigmatism. Of 175,153 children examined in New York public schools, 17,888, or about 9 per cent., suffered from defective vision. Examination of 92,552 school children in Boston public schools showed 11,899, or nearly 13 per cent., having poor eyesight. In Pennsylvania 17.9 per cent. defective vision was found among 469,199 rural school children examined. Just 26.6 per cent. of 1,625 pupils examined in Orange County, Virginia, were found with defective vision, and 5.1 per cent. of the cases were serious. Only 19 states, including New York, require the testing of school children's eyesight. Five cities, New York, Minneapolis, Cleveland, Milwaukee, and Rochester, have eye clinics in the public school system. The New York clinic corrected eye defects of 8,789 children in one year. In only three states, New York, New Jersey, and Colorado, is it possible to proceed against parents to compel them to take care of their children's eyesight. These recommendations are made for the improvement of a disturbing national trouble: Enactment of laws compelling parents or guardians to comply with notices to provide refractory aid for children with poor eyesight. Extension of eye clinics and conservation of vision classes to all cities and into the rural schools. Codification and unification of all State laws regarding defective vision. Enactment of sane measures, compelling eye tests in public schools.

THE NON-OPERATIVE TREATMENT OF URETERAL CALCULUS.

BY LEO BUERGER, M.D.,

NEW YORK.

SINCE the development of special methods of attacking ureteral stones through the cystoscope, the attention of urologists has been focused on the treatment of stones impacted in the lower pelvic ureter. Little mention has been made of a more important phase of therapy which concerns itself with the treatment of calculi situated anywhere in the ureteral path, and from the very onset of the symptoms. Some of our most eminent authorities in recent contributions seem to accept the view that Nature should be permitted to expel a ureteral calculus without instrumental aid. It has been said that in the absence of intense and recurring pain lasting for some time, or in the absence of complications in the kidney, such as acute cortical or perinephritic lesions, or in the absence of urinary retention sufficient to damage the kidney, one can well afford to await spontaneous expulsion of the calculus, provided it is not too large to pass; and, that as a rule it is best to allow a stone less than two centimeters in diameter to pass spontaneously.

Little can be found in the literature bearing upon the advisability of the application of the cystoscope as a therapeutic measure from the very beginning of the clinical history.

If I may anticipate by presenting the thesis of my present paper at this juncture, I would state that cystoscopic intervention is advisable in almost all cases of ureteral stone within a short period after the stone has found lodgment in the ureter in its descent from the kidney.

This view is somewhat at variance with that of clinicians and even some urologists, who out of conservatism have been wont to counsel their patients to wait weeks or months for the stone to pass. Whilst on the one hand there are those who intervene too early in a case of descending ureteral stone, as well as in a case of renal calculi, there are others, who withhold all methods of treatment, except merely symptomatic medical care. If it can be shown by clinical, surgical, and pathologic observation that it is a fallacy to wait altogether for spontaneous expulsion of calculi in the ureter, my hypothesis that cystoscopic treatment should be given early in the clinical course will find substantiation. Such a view has been arrived at, firstly, by reason of the most satisfactory results obtained by the application of the author's special cystoscopic methods for facilitating the descent of ureterel calculi, and secondly, in a review of the outcome of those cases in which such treatment had not been applied.

To accept the dictum that calculi one centimeter or more in diameter, even to a diameter of two centimeters, are often expelled spontaneously by Nature, is a generalization that is fraught with considerable danger to the individual case, although true in many instances. For, a sense of false security is thus very easily inculcated. So many are the complications in the ureter and kidney, and so great is the danger of impaction and local growth of the calculus, that we feel convinced that many of the cases in which ureterotomy or some renal operation has become necessary would have escaped either one or both of these procedures by the timely application of the methods that I shall describe later. Even though it be true that a stone of considerable size may occasionally pass spontaneously without aid, our aim should be directed toward the prevention of the complications (which I shall discuss further on), and toward expediting the downward travel of the calculus in its course through the ureteral channel.

It may be accepted as proven by cystoscopic researches that certain transitory or even permanent lesions are wont to accompany the majority of attacks of so-called ureteral colic. These are the purely mechanical results of obturation of the conducting system with retention of excretion products in the pelvis of the kidney and ureter and consequent infection.

Hydroureter and Hydronephrosis.—The rôle of retention of urine in the production of colic has not been correctly appraised, since it has been generally believed that the mechanical effect of the descent of the ureter stone, either from the kidney into the ureter, or down the ureter, was sufficient cause, either by virtue of the spasm created, or by the mechanical destructive effects on the inner surface of the ureter, to account for the symptom of pain. If one, however, makes a practice of performing a cystoscopy on a large number of cases of ureteral colic or renal colic during the attacks, one will be surprised to learn that not only acute pain, but persisting severe pain in the lumbar ureteral region is in most instances due to the distention of the pelvis of the kidney and ureter with retained urine.

The immediate lesions as well as the complications can be best combated by the establishment of drainage through the ureter alongside of the calculus. It is by the cystoscopic methods to be described that such reestablishment of the continuity of the conducting channel can be brought about. In other words by certain conservative cystoscopic pro-

cedures, we aim not only to further the passage of the calculus, but to conserve a sufficiency of drainage, thereby diminishing or even obviating the dangers of renal infection.

The necessity for more active interference rather than the expectancy, advised by some, is based on the following facts:

Firstly, ureteral calculi more than one-quarter of an inch in diameter are frequently arrested in certain well known narrow portions of the ureter where they become permanently incarcerated, the blockage produced leading to dilatation of the ureter, dilatation of the pelvis of the kidney, secondary infection and destruction of the renal organ.

Secondly, even small stones over two-sixteenths of an inch in diameter and occasionally three-sixteenths may be similarly arrested. We are not able to prognosticate in which instances such permanent halting with blockage will take place.

Thirdly, by the passage of one or more ureteral catheters of varying sizes, or by the simultaneous passage of bougies and catheters, or bougies alone, ureter drainage can be established and a definite effect produced upon the descent of the stone.

Fourthly, even large stones (one centimeter or more in diameter) can be attacked by the above and other methods.

Fifthly, the timely introduction of ureteral catheters can be demonstrated to be most effective in the prevention of complications of the kidney.

Sixthly, the emptying of the distended renal pelvis by reason of ureteral blockage by stone is a most reliable means, not only in relieving the suffering of the patient, but also in conserving the integrity of the kidney, which might be otherwise irremediably damaged.

In addition to the above reasons for cystoscopic intervention, there are other symptoms that often require relief. And this cannot be obtained by the use of drugs, either morphine, benzyl benzoate, or other means. The employment of the ureter catheter, however, is a most remarkable and effectual measure which we recommend early in the clinical course of the malady.

The acute symptoms that may make a demand upon our resources are unusual degrees of retention of urine in the kidney, repeated colic with or without fever, symptoms of intestinal obstruction and anuria. It is self-evident that when colics are repeated and become insufferable (usually due to the large amount of retention in the affected kidney), and if there be fever, either aseptic or due to infection, the renal pelvis must be emptied as soon as possible, and cystoscopic methods must be applied.

But it is also in the subacute and chronic forms of the malady that we advise the early introduction of instruments into the ureter. It is perhaps only in those mild attacks with or without hematuria, which are due to concretions or very small stones, that we advise waiting. Here the patient may be allowed to undergo *x*-ray examination after the acute symptoms will have subsided and if this is negative, be permitted to wait for a recurrence of the symptoms. But even here, if the attacks be repeated, the patient should submit to cystoscopic examination and treatment. In the very mild cases, if the hematuria is severe, and if the pain recur within a short period or be continuous over more than twenty-four or twenty-eight hours, cystoscopy is also in order. Even in mild cases, when there is fever or other suggestion of infection, one should not wait longer than twenty-four or forty-eight hours before introducing a catheter into the ureter.

In all cases where the attacks are unusually severe, persistent, with the presence of rigidity or a renal mass, with or without complications, such as fever, intestinal obstruction or suppression of urine, it will not be wise to procrastinate.

Varying Degrees of Hydronephrosis and Hydroureter: As before mentioned, the usual sequence of ureteral obstruction due to stone is dilatation of the conducting system above the obstacle implicating the ureter and renal pelvis. In fact, most of the symptomatology is due to this dilatation, particularly when pain is intense, and the urinary secretion continues. In rare instances, after a certain degree of stretching of the renal pelvis and ureter has occurred, unilateral inhibition of secretion takes place. Relief is often the result and thus not due to abolishment of the obturation. Or, as the kidney ceases to secrete, the retained fluid gradually leaks alongside of the stone or is absorbed, and a small kidney is the result. This, however, is not the usual outcome, and we are usually confronted with the mechanical effects of hydrostatic pressure, which afford a problem both for the relief of symptoms and relief of pathology.

The ordinary course of events, when a stone becomes impacted in the ureter, is an attack of pain with ballooning of the ureter and pelvis until the pressure becomes so great that urine may find its way between the calculus and the ureteral wall, and spontaneous relief is obtained; or, by virtue of the pressure and repeated colic, the stone passes to another or lower portion of the ureter, and in its descent, permits of evacuation of the retained renal contents. In both ways amelioration or disappearance of the pain is brought about.

All will admit that therapeutic measures will find application in the acute attacks of retention. There is, however, another type of subacute, or more or less chronic retention of urine above the calculus, whose clinical course does not seem to have been appreciated by the clinician because of the paucity or absence of symptoms in many of the cases.

In short, accumulation of secretory products may occur to varying extents, either (1) leaving remediable alterations in the kidney and ureter, or (2) eventuating in irremediable effects, depending upon the duration of the hydrostatic pressure.

1. *Remediable Forms of Distention.*—Dilatation of considerable duration (weeks or even months) is apt to respond to drainage with the ureter catheter. The absence of symptoms in many of the cases may mislead us into a casual disinterested attitude toward the application of remedies, and often it is only when there are exacerbations of pain or attacks of infection that the true nature of the changes that are going on in the kidney and ureter is appraised, and therefore an estimation of the conditions above the calculus should be arrived at by the proper cystoscopic measures. When the long duration of the distention of the kidney and ureter has led to marked pathological lesions, with atrophy of the renal cortex, the opportunity for a restoration to normal will have been lost.

An excellent example of more or less chronic dilatation of the pelvis and ureter in a case of stone impacted in the lower ureter, is afforded by the clinical history of this patient, in whom the existence of a dilated pelvis would have been overlooked, had not the cystoscope been frequently applied.

Moderate Hydronephrosis with Calculus in Lower Ureter Reduced, and Treated by a Ureter Catheter.—H. K., male, had an attack of left renal colic two years previously. He had been well until one month ago when he had an attack of renal colic with blood in the urine and pain in the left lumbar region radiating into the bladder.

Cystoscopy, November 16, 1916. The right urinary tract was negative. In the *left ureter*, 2 cm. above the bladder there was an obstruction which was finally surmounted, followed by a sudden gush of urine, more than 40 c.c. being collected in a continuous stream. After thorough evacuation of the pelvis of the kidney, pyelography was done, and a typical hydronephrosis demonstrated with a moderate degree of dilatation of the pelvis and calyces. A shadow was found about 3 cm. from the bladder, corresponding to the situation of the obstruction.

In spite of the advice given the patient to have the renal pelvis emptied at least once a week or oftener if necessary, he did not present himself for examination until the 18th of December, 1916, about one month later. Cystoscopy revealed the fact that the left renal pelvis contained about 25 c.c of retained urine, which was completely evacuated after the catheter had been allowed to remain in situ for one hour. A second catheter was passed up alongside of the first, which caused considerable dilatation of the ureter and permitted the stone to descend.

Examination March 12, 1917, exploratory cystoscopy, to determine whether the obstruction still existed. The catheter passed without interference, and no retained urine in the kidney was found. Subsequent *x*-ray examination failed to reveal the presence of the stone.

This case, as well as others of this type, permits us to draw the following lessons:

1. Chronic states of hydronephrosis may result from leaving the expulsion of the stone to Nature alone.

2. Interference with the cystoscope and employment of catheters to drain the kidney and to stimulate the passage of the stone by dilatation of the ureter, are valuable and reliable means not only in combatting the distension and restoring the pelvis and the kidney to normal, but also in furthering the passage of the stone.

3. The case described demonstrates conclusively that an interval of one month is too long to wait for cystoscopic treatment.

4. If the course of this case be compared with others in which treatment had been more frequently applied, it will be noted that the restoration of the renal pelvis to normal capacity was usually accomplished in much shorter time.

5. The absence of symptoms must not make us believe that the kidney is emptying itself.

6. It may only be during attacks of acute swelling of the ureter about the stone with increasing distension, or with the advent of mild degrees of infection, that attacks of colic are noted, the patient feeling well in the interim.

Two types of clinical course are encountered; those cases in which there is more or less constant pain, where intervention of some sort is usually demanded for relief, and secondly, those insidious types whose manifestations may be absent. Absence of pain, therefore, must not be interpreted as indicative of the absence of hydronephrosis.

Therapeutic Conclusions.—1. Treatment with the ureter catheter should be given so as to prevent chronic hydronephrosis, both by emptying and dilating the ureteral channel, even if this does not move the ureter calculus.

2. In every instance of positive calculus obstruction demonstrable either with the *x*-ray or with the cystoscope, cystoscopic treatment is in order, unless the stone is immediately passed within 24 to 72 hours.

3. Attacks of pain are usually an indication of retention of urine.

4. Continuous pain usually indicates complete retention.

5. The absence of pain after one or more attacks of ureter colic does not imply the absence of renal distension, for chronic distension may exist with rare attacks of exacerbations, the latter manifestations being the only ones that arouse the interest of the patient.

6. Treatment should be given in the free interval, particularly if data are at hand that suggest that retention is present.

Ureteral calculi requiring ureterotomy and renal drainage. Many are the instances in my own experience in which I have been convinced that the timely application of the cystoscope immediately after or during the first attack of renal or ureteral colic, would have prevented infection of the kidney and avoided the necessity of operative procedure. Let us analyze a single example.

Small ureteral calculus impacted in the lumbar ureter, with renal infection, infected hydronephrosis; ureterotomy, nephrotomy, recovery.

Three attacks of renal and ureteral colic in a young woman, (L. L.), the first three months previously in the left lumbar region, radiating to the pubis and lasting two days; the second, six weeks ago with fever, lasting three days; and the third, four days before examination with temperature as high as 102°.

September 12, 1921, cystoscopy demonstrated obstruction at 20 cm. from the left ureteral orifice in the bladder, a No. 6 French catheter being too large to pass. A smaller catheter drained off a test tube full of purulent urine, and was allowed to stay in situ for fifteen minutes so as to drain the kidney, (*Bacillus coli* in the urine).

X-ray examination showed considerable enlargement of the left kidney, and between the third and fourth transverse processes a small shadow less than ¼ inch in diameter, doubtless a stone in the ureter.

In view of these findings, an obstructed ureter, an infected kidney above, a history of three months' duration and the temperature, operation was advised, although another attempt to drain the kidney and mobilize the stone was suggested. With temperatures ranging from 100° to 101.4° while at the hospital from the 12th of September to the 14th, another cystoscopy was done on the 14th together with *x*-ray examination, the calculus being found well imbedded in its previous situation.

Operation September 14, 1921, revealed a large kidney with edema of the perinephritic fat particularly about the lower pole of the kidney, the kidney bluish, cyanotic and adherent. The ureter was at once located and lifted up with the finger, the calculus brought into view, being tightly incarcerated in a small ureter. The ureter was distended at the site of the calculus, its wall being tensely stretched, pale and almost whitish. A clamp covered with rubber tubing was applied above the stone so as to prevent the escape of purulent urine. A small incision was made, and the calculus extracted. One suture was applied. While this was being done, the clamp slipped inadvertently. A gush of pus through the opening in the ureter followed, demonstrating that the pelvis of the kidney was

filled with thick, purulent material. Then a small button hole nephrotomy was done to drain the kidney, the capsule of the latter being stripped; uneventful recovery.

Epicrisis and Conclusions.—This case teaches us that a small calculus well within the size that can be made to pass by cystoscopic methods, can remain in the lumbar ureter for weeks or months without passing, and be complicated within three months from the time of its impaction, with infection of the kidney, necessitating an extensive operation.

2. The fact that the catheter was able to pass a short distance beyond the stone, even after three months, would indicate that more could have been accomplished at an earlier moment.

3. The prevention of overdistension of the renal pelvis by the timely use of the catheter would doubtlessly have contributed at least toward the prevention of infection of the kidney, even though the two catheter method of the author had not been previously successful in causing the complete expulsion of the stone.

4. Small stones, particularly in the upper lumbar ureter, are just as apt to become incarcerated and be complicated by infection of the kidney as large ones, and it is these, therefore, that should be attacked early, so as to facilitate their descent.

5. Infection of the kidney in my experience, as a complication of stone, both as to severity and frequency of occurrence, varies inversely as the distance between the stone and the kidney increases; so that, the greater the distance between the stone and the kidney, the less the chances of severe destructive and infectious influences on that organ. Therefore, every attempt should be made to further the passage of the stone to a part of the ureter in which complications in the kidney are apt to be less extensive and less severe.

Other Complications.—These may be divided as follows: (1) Marked hydronephrosis with secondary infection. (2) Infections of the non-hydronephrotic kidney. (3) Rupture of the hydronephrosis or pyonephrosis. (4) Perinephritic abscess. (5) Dilatation of the ureter. (6) Sclerosis and stricture of the ureter. (7) Secondary stone formation in a dilated ureter or in a ureter above a stricture. (8) Periureteritis and periureteral abscess with or without ureteral perforation.

Time will not permit me to give a comprehensive account of the variegated pathology in both kidney and ureter that may result from the retention of impacted stone in the ureter. Suffice it to say here that the finding of extensive hydronephrosis with secondary calculus formation and subsequent infection, necessitating nephrectomy some time in the clinical course is a most common complication. Nor must we lose sight of the infections that may occur in kidneys that are small or very slightly dilated, for even these are prone to attacks of pyelitis, pyelonephritis and multiple abscesses as also suppurative infarctions, when the obstacle in the ureter is not removed. We have encountered a large number of hydronephroses and even pyonephroses with rupture, the patient presenting himself with a large perirenal exudate of urine and pus.

Occasionally a perinephritic abscess will be diagnosticated clinically, where investigation will demonstrate infection through a dilated kidney, the ureter stone having been wholly overlooked. Moderate and extensive dilatations of the ureter are so common as to require but passing mention. However, where marked and indelible alterations have impeded the conducting system, these must needs lead to grave changes in the whole corresponding tract. The ureter behaves differently, according to the degree of obstruction and type of infection.

Thus, there are cases where the ureter is found enormously attenuated and dilated, and in other cases the dilatation is but moderate and the sclerosis and fibrosis of the ureter wall are marked. Such sclerosis may take place not only about the stone, but above it; when in the neighborhood of the stone it not infrequently leads to subsequent stricture formation, and the whole urinary tract may be compromised by a relatively minute lesion.

By virtue of the ureteral changes, dilatation, sclerosis, and stricture, retention of urine with puddling takes place, leading to secondary stone formation in the narrowed portion of the channel.

Periureteritis is exceedingly common in the pelvic portion of the ureter, leading to the formation of large sclerotic masses of fat in which the ureter is tightly imbedded, forming a mass which in itself plays a deleterious influence upon the ureter as a conducting mechanism. In the lumbar portion of the ureter we not infrequently encounter the formation of periureteral abscesses, particularly when perforation of the ureter takes place.

Methods of Preventing Complications of Ureter Stones.—The title of this paper has called for a discussion of methods of preventing the complications of ureter stones. Such prophylaxis is tantamount to the application of the most improved measures for expediting the passage of ureter stones, and for relieving the kidney and ureter of the effects of distension and infection. The methods that have given me the best results during the last ten years may be summarized as follows: (1) The employment of catheters and bougies in the ureter; (2) the use of olivary dilators; and (3) instrumental intravesical procedures to remove calculi from the intramural portion of the ureter by incision through the cystoscope or otherwise.

Much has been said regarding the removal of impacted stones through the cystoscope, and vague and general statements are encountered in the literature regarding the mode of manipulating instruments in the ureter for the expulsion of ureteral stones. Success, however, depends upon careful attention to minutiæ as well as to general principles, and I may, therefore, be permitted to go into detail as to the technic and procedure that have given me the best results. Let me say at the outset, that one should look askance upon the claims of those who would possess such unusual skill and such highly specialized cystoscopic instruments as to enable them both to seize and extract a ureteral calculus when it lies above the bladder. Not only do I believe such statements to be gross exaggeration, but I wish to go down on record as expressing the view that any radical means sufficiently intensive to extract by force an impacted calculus within the ureter above the bladder is not only incompatible with the mechanical possibilities in the bladder and ureter, but if possible, would be dangerous to the integrity of this channel.

Those who have had an opportunity to operate upon many cases of ureter stones, will appreciate what force is necessary to bring about even a milking of the stone from one part of the ureter to another, when the channel is within one's grasp. To be sure, those calculi amenable to conservative treatment may not be imbedded so tightly. But even these require the more delicate procedures, those whose action is slow in bringing about dilatation of the ureter, and such as are successful by reason of the very tardiness of their action.

It will not be possible, here, to go into every phase of the application of my methods, because of lack of time. Enough, however, shall be said to elucidate the chief points that are essential in the treatment of the usual type of cases encountered. Two large classes may be recognized: (*a*) Cases with a calculus in the lower pelvic ureter (true pelvis), (*b*) with the stone in the lumbar ureter or in the false pelvis.

The Treatment of the Ureteral Calculus in the Lower Pelvic Ureter.—1. By means of catheters or bougies: The armamentarium requisite for aiding the expulsion of ureteral stone varying in size up to 1 cm. and even ½ inch in diameter is in most instances a simple one, and comprises a cystoscope, ureter catheters of sizes from 4 to 7 Fr. caliber, ureteral bougies in sizes of 3 and 4 Fr. and a garceau catheter tapering from 11 French to a terminal opening of about 5 Fr. It is only for certain special cases that are recalcitrant, and do not respond to the author's catheter method, that the operating cystoscope, special olivary metal tipped bougies, punch forceps and scissor forceps are required.

So, armed with an ordinary catheterizing cystoscope in which one No. 6 catheter and a No. 5 catheter of the olivary style have been threaded, the affected ureteral orifice is sought. With the stone in the intramural portion, or near the orifice, distinctive changes will be observed, such as swelling of the ureteral mound, and even edema of the ureteral orifice. But with the calculus at its most frequent location, that is, 3, 4 or 5 cm. from the bladder, no visible alterations of the intramural portion of the ureter and ureteral lip are usually in evidence. In many cases, however, careful attention to the ureteral mound when the stone is as low as this will reveal a slight protrusion of the corresponding portions of the bladder wall. A large ureter catheter (No. 6 Fr.) is introduced and the findings and procedure will depend upon whether an obstruction is met or not.

A. Calculus With Obstruction: An olivary-tipped catheter must be used, since the whistle tips or other types of catheters may encounter artificial obstructions that are not due to the presence of a foreign body. With the stone in this situation, the catheter will meet with an obstacle which is either surmounted or not (passable or impassable).

Procedure in the case of Passable Obstruction: When the catheter meets the obstruction, it is rotated on its long axis, withdrawn and introduced again if necessary, and will then finally surmount the obstacle and drain out urine which has been retained in the ureter and pelvis above. After evacuating the contents of the ureter and pelvis, the catheter alone may be allowed to remain in place from ½ hour to 1 hour, the cystoscope being removed, or, an attempt is made to pass the second catheter beyond the obstruction. This may or may not be feasible, depending upon whether the orifice is large enough to admit the catheter, whether the patient is sufficiently tractable, and on whether the obstacle will permit the second catheter to go by. If one catheter alone will pass, this should be allowed to remain inside for at least ½ hour, preferably 1 hour or more, and then removed. If pus be found in the kidney specimens, irrigation with mild silver nitrate solutions, such as one to one thousand, or one to five hundred, is in order.

The proper time for a second treatment of this sort varies according to a number of factors: first, a recurrence of acute colic with retention of urine; and second, the advent of a second attack with continuous unremitting pain, with or without infection. Infection is never seen as the result of cystoscopic manipulations.

If no such complicating conditions arise, a second treatment may be undertaken one week after the first, or earlier, an attempt being made to accomplish more and more at each sitting.

The Two-Catheter Method: This is the method *par excellence* when applied sufficiently often and in the proper way, for expediting the passage of a ureteral stone. Either at the first séance or at the second, it will be possible by the proper manœuvers to pass two catheters into the ureter beyond the stone. In some instances it may require a great deal of patience, and we will be unable to accomplish our purpose until the third or fourth séance. Eventually, however, with the application of the correct technic, two No. 6 Fr. catheters, or one No. 6 and one No. 5 will be made to pass, and it is from this time on that quick progress will be made in causing the descent of the calculus, if some has not already been made in the previous procedures.

It will often be observed that the second catheter, which may be a smaller one, will at times pass only as far as the obstruction and no higher. The injection of olive oil or glycerin may aid its passage, as well as the lubrication of the catheter tip with sterile vaselin. Or, if we wish, a small amount of adrenalin oil may be injected, admixed with 2 or 4 per cent. novocain (five to ten drops)—methods which, if used alone, are far inferior in their efficacy to the mechanical procedures. Until the second catheter passes, we should repeat the leaving of one catheter *in situ* for an hour or more, and cause dilatation of the intramural portion of the orifice by the graded use of two catheters of varying size or with a bougie. When finally we have succeeded in passing the two catheters beyond the obstacle, these should be introduced sufficiently high, twenty-five centimeters or more, so that in withdrawing the cystoscope, they may not be dislodged into the bladder. With the cystoscope removed and the two catheters *in situ* beyond the stone, the patient is carefully transferred to a stretcher carriage and allowed to remain there with the catheters draining from one-half hour to an hour or more.

The removal of the two catheters is also an important step. Both catheters should be pulled out simultaneously. As they are being withdrawn, considerable resistance may be encountered, so that at

times some force may be necessary to extricate them. Indeed, by some sort of chemical process, the nature of which is hard to explain, agglutination of the catheter and the stone can and does take place, as a number of remarkable circumstances have taught me. It is by friction, however, that I believe the downward course is usually accomplished.

As the catheters are being still further withdrawn, we may in rare instances encounter another obstruction. The calculus agglutinated to the catheters in reaching the ureteral or urethral orifice may give rise to this sensation. In several cases the stone was immediately dislodged from its site of impaction in the ureter. In one case (L. B.) the calculus was drawn out through the urethra attached to the catheters, these having been allowed to remain *in situ* over night. In another instance the calculus was broken up, which is a rather frequent result, and several fragments remained firmly adherent to one of the catheters, the rest of the stone having been withdrawn into the bladder. In other instances, the stone was displaced into the bladder, where it was removed with the forceps of the operating cystoscope.

Through the author's operating cystoscope, or through the direct cystoscope provided with the author's operating telescope, more than two catheters can be inserted into the ureter if necessary, Number 6 Fr., and a smaller catheter, or several filiform bougies. In the employment of the latter, care must be taken to inspect their points carefully, so that they may not be broken off in the effort to cause them to pass beyond the obstruction. Where the two catheters will not pass, the filiforms will gradually make way for the first one to surmount the obstacle, after which subsequent manœuvers are easy.

The following most unusual and interesting example of acute symptoms, associated with stone in the ureter, beautifully illustrates the value of the retention of two catheters in the ureter, and how in one treatment the stone may be extricated.

Impacted obstructing ureteral calculus, dilated ureter and renal pelvis, with manifestations now of intestinal obstruction, of peritonitis, with fever, abdominal distention, rebound tenderness, completely relieved and cured through cystoscopic methods by causing expulsion of the stone.—L. B., male, presented the following clinical picture: A distended abdomen, constipation, severe pain in the left iliac fossa, rigidity of the left iliac region, distinct rebound tenderness and per rectum a small indefinite mass, high up in the cul-de-sac on the left side, and moderate fever.

Cystoscopy, October 4, 1919, demonstrated that there was urinary retention in the left ureter and kidney, for about one ounce of turbid urine, containing some red blood cells, without pus, could be collected in a continuous stream when a catheter was inserted some 10 cm. into the ureter, suggesting a calculus low down in the ureter, with dilatation of the ureter and acute hydronephrosis.

In spite of the relief that was afforded in this case by the emptying of the kidney, distinct aggravation of the symptoms occurred on the following day, when the temperature rose to 102° in the afternoon. It was surmised that by virtue of the swelling of the ureter, obstruction had again taken place, so that catheterization of the ureter was again in order. On the following day, October 5, the tongue was coated, the left side of the abdomen was hard, with board-like rigidity, the temperature 103°, and the patient was unable to take food. In short, symptoms suggestive of a combination of intestinal obstruction and possibly peritonitis.

On the 6th of October, therefore, catheterization of the left ureter was done again, and the same phenomena of retention of urine could be demonstrated. So great was this retention that pressure over the kidney and bladder regions, as well as over the left iliac fossa, increased the flow through the ureteral catheter. Two ureteral catheters were then inserted into the left ureter up to the kidney and the cystoscope removed, *the catheters being allowed to remain in from the time of insertion*, 3 P. M. *on October 6 until the next morning*, (9.30 A. M.).

On the 7th of October, the abdomen was distinctly less rigid, the patient's condition considerably improved, the temperature having dropped to 100°. The catheters were then slowly withdrawn simultaneously, and as they were being tugged, it seemed that an obstruction to their exit could be distinctly made out. *As they were pulled out, this resistance was seen to be due to the extraction of a ureteral calculus that was tightly adherent to the two catheters, as it was drawn through the ureter, bladder and urethra without being dislodged—a most remarkable and unusual occurrence.*

From then on the patient made an uneventful recovery.

Such a startling result can only rarely be obtained, but the extrication of the calculus, either immediately upon withdrawing the catheters or shortly thereafter has occurred so frequently in our experience as to permit us to consider this the most valuable of all the procedures.

Ureteral Stone with Infection. Where a ureteral stone in the lower pelvic ureter is associated with infection, usually of the *Bacillus coli* type—the question of operative intervention may have to be considered. Usually, however, the methods described, or with slight variation, will suffice to cause the symptoms as well as the infection to subside. Whereas most patients may be treated in ambulatory fashion, at the office, and allowed to remain one-half hour, one hour or more with the catheters *in situ*, it is best to keep the patient with renal infection in bed at the hospital, where the catheter is allowed to stay in a longer period of time—two to ten hours, as a rule. Silver nitrate irrigations of the renal pelvis are recommended both after evacuation of the pelvis as well as before removing the catheters.

B. The Nonpassable Obstructions: What may appear to be an insurmountable obstruction in the ureter will by the application of correct methods, and with patience, develop into a passable obstruction. The technique is as follows. The ureter below is injected with oil or glycerin, with or without adrenalin and novocain. One catheter is introduced and followed by a bougie of small caliber, 3 or 4 Fr., or one or more bougies, or whalebone filiforms are passed up the ureter with the view to passing the barrier, just as is our custom with filiform strictures of the urethra. When this fails, we still have recourse to dislodgment by means of the olivary dilators, which I shall describe later on. It is but in rare cases that our patience and persistence are not rewarded by the passage of one catheter and finally a second one beyond the stone.

Intervals Between the Séances. As before mentioned, it is our rule to give treatments at weekly intervals, where the following complicating factors are absent: rapidly recurring attacks of pain, persisting hydronephrosis and hydroureter, infection, suppression of urine or reflex ileus. Any of these eventualities may require precocious intervention with the cystoscope. Otherwise it is well to wait, five to seven days (as a rule a week), before repeating the treatment.

The Results of the Two-Catheter Method of Treatment: Four types of results are obtainable. Firstly, renal drainage with dilatation of the ureter but without immediate descent of the stone; second, immediate movement of the calculus downward; third, immediate expulsion of the calculus after treatment either with the calculus attached to the catheters; or, by the spontaneous evacuation of the calculus with micturition, or followed by removal from the bladder through the operating cystoscope; and fourth, expulsion, shortly, few hours to a day, or more after the last treatment.

Technique for Dilatation of the Intramural Portion of the Ureter: Occasionally, after several treatments, if the stone has made considerable descent, and if it has approached the wall of the bladder, near the beginning of the intramural portion of the ureter, it is advisable to have recourse to special manœuvers for the purpose of dilating this portion of the ureteral channel. To accomplish this, we make an attempt to cross the catheters in the ureter and simultaneously engage them against the ureter stone. The special manipulations employed are the following: After the introduction of the second catheter, the first one is withdrawn somewhat and reintroduced. Then a similar manœuver is carried out with the second catheter. These procedures are repeated until we find that by simultaneously pulling upon both catheters with the ureter orifice in view, the catheters instead of pulling out in the line of the ureter is made to diverge. In doing so the ureter orifice is forcibly dilated. This effect is produced not only at the orifice, but throughout the ureteral wall, and, occasionally, such force can be exerted upon withdrawal as to actually produce a downward movement of the stone. In a few cases the stone was made to pass through the intramural portion of the ureter by this method, *and seen to emerge under the guidance of the eye.* As a rule, however, the effect is not so striking and accomplishes merely the dilatation of the lower ureter, with or without immediate appreciable movement of the calculus.

The Treatment of Calculi in the Lumbar Ureter.—The problem here is somewhat more difficult, for, not only is the impaction apt to be less easily surmounted but, also, because a small calculus may be occasionally caused to move back into the pelvis of the kidney. However, the general methods employed are the same, except that greater care must be exerted to refrain from withdrawing the catheters as the cystoscope is removed.

Use of the Author's Olivary Dilators: This method was suggested by me some nine years ago. It employs a bougie electrode whose proximal end is furnished with a screw thread and whose distal end is provided with a coupling for connection with the high-frequency machine. The screw end allows of the attachment of small olivary tips, of varying sizes from 5 to 15 Fr. The bougie is introduced through the operating cystoscope into the ureter, whose lumen is gradually dilated by the successive employment of olives of increasing size. Originally the d'Arsonval current was suggested as an adjuvant, although more lately it has been found that as good results can be obtained without the use of electricity.

This method is applicable under two conditions; firstly, when the two-catheter method fails to coax the stone beyond a certain point, and the lower ureteral channel is too narrow; and secondly, in the case of larger stones, particularly when these have been imbedded for a considerable period of time.

The olivary dilators are exceedingly efficacious, not only in dislodging a calculus that has been well incarcerated, but the dilating effect produced is valuable. We anoint the olive well with vaseline so as to make introduction easier, and attempt not only to reach the stone, but gradually to insinuate the olive beyond the stone, which it will frequently pass. When carefully used and rotated on their long axis, as soon as an obstruction is reached, and if the calculus with a little patience on the part of the operator. In my experience I have never encountered any deleterious results from the application of olives. Many are the instances of calculi (1 cm. or more in diameter) that had been arrested in a lower ureter for months that have been made to pass by this method.

Large Ureteral Stone Impacted Four Inches from the Bladder Made to Pass by the Use of Olivary Dilators.—A. G., male, 57 years of age, had had attacks of left renal and ureteral colic for about five years, with frequent hematuria. He consulted me October 10, 1916, with a history of having had pain in the left flank and ureteral region for several months. On that day *x*-ray examination demonstrated a calculus over the left sacroiliac synchondrosis, three inches lower than demonstrated in 1914, a period of two years.

In all probability this passage was accomplished during one attack, so that it is fair to assume from the history that the calculus had become impacted at the base of the sacrum for some time.

October 27, 1916, *x*-ray examination showed a calculus almost two centimetres by less than one centimetre over the sacroiliac synchondrosis, about four inches above the bladder, in the course of the left ureter. Cystoscopy demonstrated an obstruction in the left ureter between nine and ten centimeters from the orifice, and no urine was obtainable from the corresponding kidney. A shadowgraph catheter inserted identified the shadow as being in the ureter. One week later at cystoscopy one catheter was made to pass beyond the calculus.

November 16, 1916, dilatation with olivary bougies to 11 Fr., and a No. 9 Fr. olive passed beyond the stone to a distance of about 20 cm. thus dilating the ureter considerably. *X*-ray examination showed the olive beyond the situation of the stone.

December 5, 1916, dilatation with the olives again, the stone having descended somewhat.

December 14, 1916, stone still further down, approaching the true pelvis. The ureter orifice was dilated sufficiently for the stone to pass. This stone was passed spontaneously shortly thereafter.

Special Intravesical Operative Procedures.—When a calculus of considerable size (approaching one-half inch or more) has been arrested in the intramural portion of the ureter for some time, particularly when it has caused protrusion and marked edema of the ureteral lip, it presents a problem for solution with the operating cystoscope. With the author's punch forceps and scissors the upper lip of the ureter can be incised and the stone then dislodged. It may then be grasped with the forceps and directly removed or manipulated out with catheters and bougies.

An interesting example of a stone one-half inch in diameter which had been impacted for some time in the intramural portion of the ureter and was made to pass after incising the upper ureteral lip is worthy of citation:

Ureteral Meatotomy for Impacted Ureteral Calculus.—S. B., female, age 52, consulted me on the 8th of November, 1920, with a history of attacks of right renal colic for about eight years, accompanied now and then with chills and fever. Cystoscopy showed a moderate degree of cystitis, the right ureteral mound tumefied, the orifice small and its appearance suggestive of a stone just behind the orifice. It was possible to introduce a ureteral catheter with considerable difficulty beyond the stone, but unable to dislodge it. An *x*-ray examination confirmed the diagnosis of calculus by the finding of an ellipsoid shadow about three-eighths of an inch by one-half inch at a point corresponding to the situation of the stone as diagnosticated at cystoscopy, that is, just above the orifice.

On November 12, 1920, the stone was still in the same situation, and the question of operative intervention was considered in view of the fact that the orifice was so small that the passage of such a large stone through it was considered out of the question. However, it was decided to cut the orifice and fulgurate the margin of the incision with a view to stopping the hemorrhage. This was carried out on the 12th of November, when catheterization was found impossible. Immediately after the cutting of the orifice, the stone was partly visible, although still fairly imbedded in a pocket of mucous membrane, and due to the irritability of the patient it was decided to wait until the following day before making further attempts to dislodge it from its bed. This was not necessary, since the patient passed the stone spontaneously soon thereafter.

1000 Park Avenue.

THE MORTALITY FROM BILIARY AND URINARY CALCULI IN THE UNITED STATES REGISTRATION AREA.

By FREDERICK L. HOFFMAN, LL.D.,

NEWARK, N. J.

THIRD VICE-PRESIDENT AND STATISTICIAN, THE PRUDENTIAL INSURANCE COMPANY OF AMERICA.

The following statistical observations are merely in explanation of three standard charts exhibited in the Scientific Section at the Annual Meeting of the American Medical Association, Boston, June, 1921. The charts were prepared in cooperation with an original investigation into the subject by Dr. L. D. Keyser, of the Mayo Clinic, Rochester, Minn. They have been amplified by international data for such countries as conveniently provided the necessary information within the limitations of time available for the purpose.

Chart A exhibits the geographical distribution of biliary and urinary calculi in the United States Registration States and the six principal geographical divisions of the country. The mortality is also given separately for ages 30 and over; the mortality for ages under 30 being relatively of no importance. It is shown by this table that the mortality from biliary calculi has been highest in the State of Minnesota, and from urinary calculi in the State of Utah. The Minnesota figures are unquestionably affected by the Mayo Clinic, but there are reasons for believing that when proper allowance is made for this factor the relative position of Minnesota will not undergo a material change. It is significant that in both groups Oregon and Utah should hold a position of preeminence next to Minnesota.

Leaving out of consideration the individual States, however, the analysis shows that biliary calculi as a cause of death occurs most frequently in the Central States, followed by the Rocky Mountain States, while a middle position is held by the New England States and the Middle Atlantic States, the fatalities being least common in the Pacific Coast States and the Southern States. The incidence from urinary calculi is highest in the Middle Atlantic States and the Central States, a middle position being held by the New England States and the Rocky Mountain States, while the lowest figures are for the Pacific Coast States and the Southern States. The favorable position of the Pacific Coast States is much more significant when the preeminence of Oregon is taken into consideration, this State holding second position for biliary calculi and third position for urinary calculi.

It is not intended that these figures should be looked upon otherwise than as a tentative contribution towards the geographical study of biliary and urinary calculi in this country, but the regularity of the data is certainly suggestive of local conditions more or less favorable or opposed to a high or low incidence of the two affections.

Considered by sex, race, and age, some extraordinary differences are brought out by Chart B, which presents the consolidated data for the United States Registration Area for the five years ending with 1918. This table re-emphasizes the well-known fact that both biliary and urinary calculi are more common among the white population than among the colored. I am not aware that a corresponding analysis has heretofore been made which would justify definite conclusions useful for prognostic purposes.

Chart C presents the statistics for foreign countries and cities, indicative, also, of a range of local frequency which may properly be referred to as extraordinary. Limiting the present discussion to the larger foreign cities, it appears that Berlin has the highest rate of frequency for biliary calculi, while the lowest rate is reported for St. Johns, Newfoundland. There are no reasons for questioning the returns, especially for such cities as Belfast, Barcelona, Singapore and St. Johns, all of which indicate a tremendous difference when compared with the returns for Berlin, Copenhagen, Alberta and Manila. Of similar interest is the extremely high rate of urinary calculi for Victoria, B. C., given as 26.2, while for the same city the mortality from biliary calculi is only 5.2. Copenhagen and Manila hold a preeminent position as regards an excessive frequency of both biliary and urinary calculi, which is also true of Montreal and Edinburgh.

The contrast between the two series is very striking, particularly as regards the excessive frequency of biliary calculi in Tasmania and the comparative rarity of urinary calculi in the same country. England and Wales holds a preeminent position in both instances, while relatively high positions are held by New Zealand and Scotland.

How far these differences can be explained on account of local conditions—possible chemical properties of the water supply, or other environmental factors—can not, of course, be stated at the present time. It may be said, however, that there are no reasons for believing that there is serious inherent inaccuracy in the figures which would make a local or an international comparison inadvisable at the present time. The data are certainly suggestive of a much more extended consideration of the geographical aspects of these two

diseases than has thus far been given to the questions involved, and are also, as a matter of race pathology, indicative of possible far-reaching results if subjected to further and qualified inquiry.

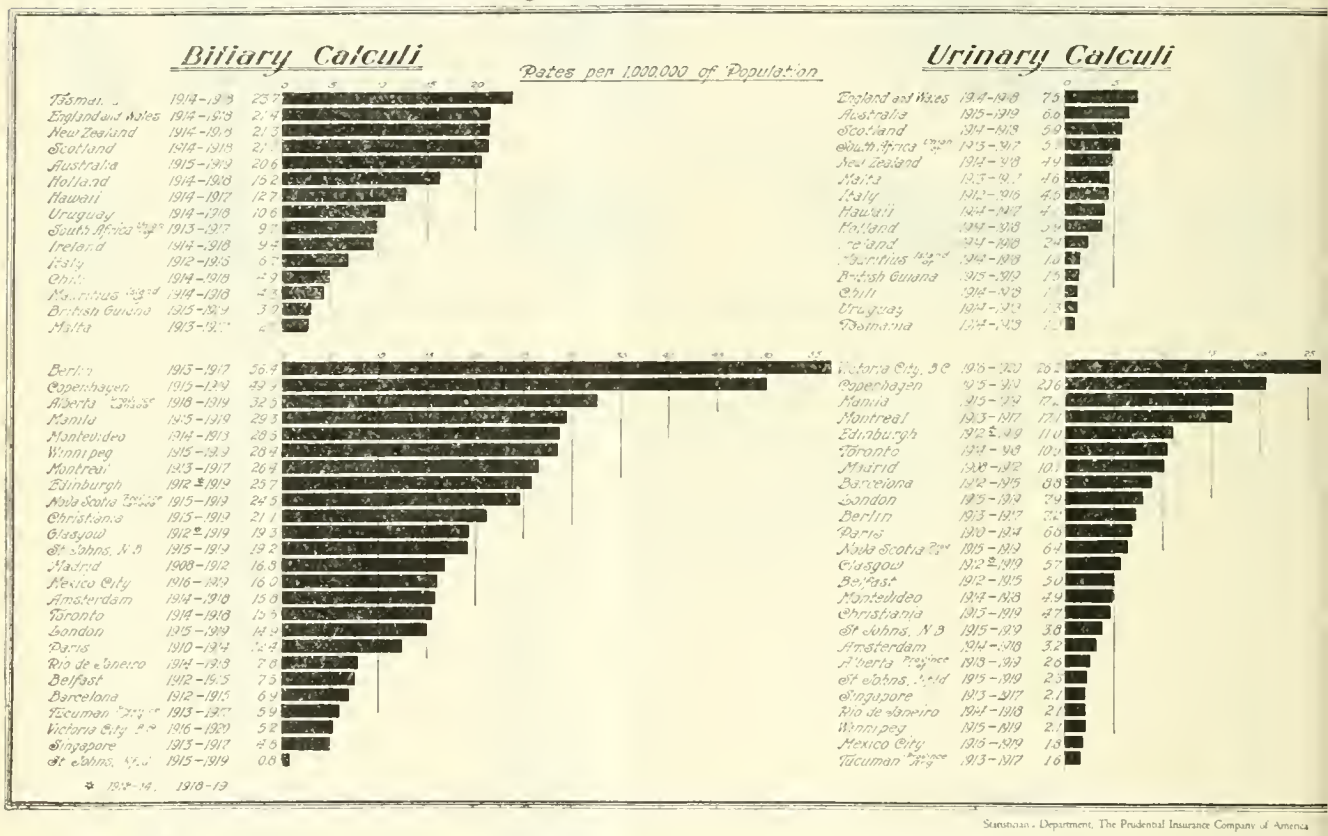
The question naturally arises as to how far these statistics are affected by methods of death classification. In its final analysis, practically every case of biliary or urinary calculi, in the absence of an operation, involves the possibility of an erroneous diagnosis as merely a biliary or urinary disease. I have carefully considered this question on the basis of the joint causes investigated by the Census Office for the year 1917. For urinary calculi that year there were reported 496 deaths in which calculi of the urinary tract was given as a primary cause, while in 379 deaths it was given as a contributory cause, and in 128 deaths it was listed as a mortality from urinary calculi of 17.1 for Montreal and 3.2 for Amsterdam.

With reference to biliary calculi, there were 2,475 deaths returned in the United States Registration Area in 1917 with this disease as a primary cause; 1,641 deaths with this disease as a contributory cause, and 813 deaths with this disease as a secondary cause. The analysis of these contributory and secondary causes reveals a large amount of important information, which, however, can not conveniently be dealt with at the present time. The information can readily be obtained by reference to the Mortality Report of the United States Census Office for 1918.

The present investigation, which is merely tentative to a further inquiry, is submitted as a contribution towards a question which has received

Mortality from Biliary and Urinary Calculi

Foreign Countries and Cities



Statistician's Department, The Prudential Insurance Company of America

a secondary cause. It is, therefore, inadvisable to rely entirely upon death certificates as conclusive evidence of the local incidence of the disease, since the method of classification by a single statistical standard is likely to vary more or less widely in different countries of the world, but such a conclusion would certainly not apply to Berlin, which returned the highest known rate for biliary calculi, or 56.4 per 1,000,000 of population, while for London there was a return of only 14.9 per 1,000,000 of population. Likewise, for Copenhagen the mortality from urinary calculi was returned as 20.6 per 1,000,000 of population, while for Berlin the corresponding rate was about 7.2 and for London 7.9 per 1,000,000 of population. No differences in death certification can account for a difference in far from adequate consideration. As shown by the joint causes, the disease is more common than would appear from the mortality records, while the fact must not be overlooked that there is an immense amount of life-saving as a result of qualified operations.

The subject of calculus is an extremely complex medical and surgical problem which would require wide experience for its discussion as regards aspects as yet but imperfectly understood. The differential diagnosis of the condition clearly illustrates its complexity, and the practically countless possibilities of error in the interpretation of the facts and related phenomena. The duration of the condition has never been properly determined on the basis of a sufficiently large number of cases,

while much remains to be learned as regards the after-results of operations. Most of the published statistics of operative results fail to square with the law of large numbers for, obviously, in so important a group of conditions Israel's cases, for illustration, numbering only 124—with 28 deaths—can not be more reliable than Garceau's cases, numbering 143—with 33 deaths. Brasch recorded a primary death-rate of 11 per cent. in the experience of the Mayo Clinic, but the number of cases operated upon was not stated.

It would serve a most useful purpose if a collective investigation was made into the whole question and, if any way possible, the rejection experience of representative life insurance companies utilized to determine the after-lifetime of persons declined on account of operations for biliary and urinary calculi. In Short's Index of Prognosis it is said that "The remote results of operation upon kidney growths are to a large extent dependent upon an early date of operation and the thoroughness with which the operation is performed. Certain conditions of the growth facilitate early recognition, or militate against a timely diagnosis." This conclusion applies to all operations, but particularly to operations for biliary and urinary calculi, in which it is safe to assume that the delay intervening between onset and operation is probably on the average longer than in many other affections requiring operative interference, such as appendicitis or cancer of the breast.

The present investigation re-emphasizes the urgency of a larger basis of experience for trustworthy conclusions, for operation will become more general as the public feels assured of really helpful results.

The foregoing observations are, in part, affected by the statement made by French and Williamson in the Fourth Edition of the *Practice of Medicine*, 1910, that "More than half the cases of cholelithiasis occur in persons above forty years of age; rarely in those under twenty-five, but congenital cases have been recorded. Fully 75 per cent. of cases occur in women; 90 per cent. of whom have borne children."

The present investigation justifies different conclusions, by providing a definite statistical basis as regards the number of cases utilized. It is owing to the weakness of much of the medical evidence on disease frequency that the statistical method is quite generally abused rather than utilized to the best advantage. There is no justification for quoting percentages yielding a definite measure of probability of occurrence without a statement of the number of facts upon which the conclusion is based. In the Registration Area during 1918 there were 2,458 deaths from biliary calculi, of which 72 per cent. were deaths of women. There were 472 deaths from urinary calculi, of which 30 per cent. were deaths of women. The proportion of deaths at ages under 30 in the first group was 4.7 per cent., and 7.5 per cent. in the second group.

Saville in a discussion of the etiology of gallstones remarks that "They are much commoner after than before 50; much more common in women than in men; more common in stout persons of sedentary habits who consume a diet rich in fat and sugar, while there is frequently a history (family or personal) of gout, asthma, or migraine." They are said to be less common in hot countries.

Broadly speaking, these conclusions are in accordance with the facts and they would gain immeasurably in value if more precise data were given for the principal etiological factors of practical value in both diagnosis and prognosis.

Of importance in this connection are some observations by Jeffries and Maxwell, in their discussion of diseases in China, on vesical calculus, which is apparently met with throughout China, it being said that "nearly every center reveals from one to ten cases a year for the average hospital." There are, however, some towns where, regardless of the fact that they are well provided with medical and surgical facilities, no cases are reported. This, it is said, considering the ease of diagnosis and the painful nature of the affection, should be considered strong presumptive evidence of its rarity in those centers. China "boasts of at least two of the greatest stone-producing districts in the world, Kwangtung Province, especially in the general neighborhood of Canton, first reported upon by J. G. Kerr, and Northern Anhuei, City of Hwaiyuen, a neighborhood reported upon by Samuel Cochran. The latter district seems to extend northward towards Ichowfu, Shantung." The concentration of vesical calculi in these two sections is certainly suggestive of further inquiry.

I can not for the present further enlarge upon this interesting question, having had merely in view the bringing of the facts, as illustrated by the charts, to public attention as a subject for further and more extended consideration. The statistical details of the chart for the registration area are given in full in the appended table.

Mortality from Biliary and Urinary Calculi in United States Registration Area, 1900-1919. Rate per 1,000,000 of Population.

Year	Population	Biliary Calculi Deaths	Biliary Calculi Rate	Urinary Calculi Deaths	Urinary Calculi Rate
1900.....	30,765,618	459	14.9	116	3.8
1901.....	31,370,952	500	15.9	126	4.0
1902.....	32,029,815	668	20.9	150	4.7
1903.....	32,701,083	795	24.3	151	4.6
1904.....	33,345,163	832	25.0	154	4.6
1905.....	34,052,201	883	25.9	193	5.7
1906.....	41,983,419	1,134	27.0	227	5.4
1907.....	43,016,990	1,110	25.8	229	5.3
1908.....	46,789,913	1,275	27.2	250	5.3
1909.....	50,870,518	1,486	29.2	292	5.7
1910.....	53,843,896	1,501	27.9	329	6.1
1911.....	59,275,977	1,749	29.5	361	6.1

1919.....	85,147,822	2,887	33.9	520	6.1

ENZYMES AND LIFE: WITH SPECIAL REFERENCE TO THEIR ROLE IN THE CELL.

By DONALD A. LAIRD,

IOWA CITY, IOWA,

INSTRUCTOR, UNIVERSITY OF IOWA; RECENTLY RESEARCH ASSISTANT, IOWA CHILD WELFARE RESEARCH STATION; FORMERLY EXAMINER, PSYCHIATRIC UNIT, GREAT LAKES NAVAL STATION.

Living organisms and their constituent living cells are characteristically chemical machines. They store their energy in a chemical form and utilize chemical processes in changing food materials into a part of their intimate living structure. The living cells are of a colloidal structure, and while their

functioning is dependent upon their electrolytic as well as their colloidal structure and both the inorganic and the organic components are essential, nevertheless the dynamic, driving power which apparently introduces the "spark of life" is found in their enzymic contents. The metaphysical entelectical explanations of life are scarcely needed since the discovery of the enzymes and their functions. In fact, these long outgrown conceptions are no longer compatible with the observed facts regarding the cells and the organism of which they are a part.

Biochemical progress was rather slow at first. Lavoisier and LaPlace in 1780 demonstrated that the heat of animals, which had long been an object of wonder and unexplainable mystery, was simply a product of the slow combustion of oxygen within the organism. And they went so far as to reproduce this process artificially in the laboratory.

About fifty years later Woehler produced urea in an artificial manner outside of the body by the metameric transformation of ammonium isocyanate: $CO.N.NH_4 = CO(NH_2)_2$. Woehler thus succeeded in producing by purely laboratory methods a

product which in man is an end product of cellular metabolism. These discoveries, which mark the beginning of biochemical studies and results, fell far short of establishing the identity of the processes within the test tube and those within the living organism. While the end products of the biochemical machines—the animal cells—could be produced in the laboratory it was only by using methods and reagents, which, if used in the living cell, would destroy all evidences of life. Powerful acids and akalies and extremes of heat were still necessary to produce these artificial products. In the living organism these products are formed in a medium which is practically neutral and with only the formation of moderate degrees of heat.

It was not until 1836, eight years after the observations of Woehler on urea, that Berzelius pointed out the remarkable similarity which exists between the life processes in the cells and the chemical effects of certain "activators by presence." This chemical force operative in certain reactions, and which is exerted by some substances which come out of the reaction unaltered, early received the designation of *catalytic force*. Thus it was shown for the first time that there is in fact no mysterious difference between the processes occurring in the animal cell and the somewhat related and analogous processes of the laboratory. While Berzelius' concept of the nature of the action of the "activators by presence" has been proven to be incorrect in numerous details his concept of the catalytic force still remains in substance and he must receive full credit for first indicating what may be termed the dynamic force which releases the "spark of life" in all cells, both plant and animal.

The organic catalyzers as they exist in the animal cell are designated the *enzymes*. It is through their presence and powers that chemical reactions are made possible within the living organism under temperature conditions which do not endanger the colloidal structure of the cell, and without the use of destructive acids or alkalies. These enzymes reduce complex and varying chemical substances into their common elements and then other enzymes take up these products and build up, from these cleavage products, the complex within the body. The end result is that, by and large, the tendency is to produce an approximate equilibrium with chemical processes still taking place. In general the organic enzymes are very similar to the inorganic catalysts in their activities, but there are several disparate characteristics which serve to separate into two groups what was once termed simply "activators by presence."

The cell catalyzers—the enzymes—like the cells themselves, are colloidal in nature. The body cells of the living organism are in a fluid state, but the essential cell materials are in no sense in a real solution. They are, rather, colloidal. That is, they are heterogenous rather than homogenous as is the case in a real solution. The colloidal state is characterized by solid, but minute, particles being suspended in a liquid phase. This condition is thus aptly termed heterogenous for there are indeed two phases, one solid, the other fluid or liquid. Cellular protoplasm under ordinary conditions of observation appears clear and free from a solid phase. When viewed under the ultra-microscope as perfected by Zsigmondy,[12] however, the minute colloidal particles become visible. This is splendidly shown in the accompanying illustration from Gaidukov of the cell of a spirogyra. This colloidal state is the condition in which the cell enzymes are found. The experiments of Bertrand might tend to indicate, however, that the colloidal structure in the case of the enzymes functions principally as a foundation or a protection for the inorganic constituents of the enzyme in which their peculiar catalytic powers are located. That this is not the case, strictly speaking, is indicated by Rideal and Taylor,[9] who point out further that this theory would fail to account for the specific activities of the enzymes. The more recent work of Beatty[5] attributes the dissociative powers of enzymes to their metallic colloidal content. But be this as it may, the fact remains that the grosser structure and the bulk of the catalytic material of the cell is fundamentally colloidal and organic.

Enzymes are further distinguished from the other catalysts by the specificity of enzyme action. The inorganic catalyst platinum will serve as an accelerator in several reactions. The organic catalysts, nowever, are highly specific in their action. The

enzyme lactase may be taken as an example; this activates either synthetically or by cleavage only those reactions in which lactose or its cleavage products are formed. In other reactions it has not a particle of catalytic influence. An orderly system of life processes is assured by this specificity of enzyme action. A given enzyme will carry the reaction only to a certain point when the substrate is passed on to another enzyme for further synthesis or reduction. This is illustrated in the case of the "digestive" enzymes:

(1) Protein food + pepsin = proteose.
(2) Proteose + trypsin = peptone.
(3) Proteose + peptone + erepsin = amino acids.

As is intimated above, the enzymes carry the reactions for which they are specific either forward or backward, depending largely upon the availability of water. Neutral fats in the dietary are broken down by the *lipase* of the pancreatic juices. Water is usually present and the following reaction is catalyzed:

$C_3H_5(O\,OC\,C_{17}H_{35})_3 + \text{lipase} + 3H_2O = 3C_{17}H_{35}COOH + C_3H_5(OH)_3 + \text{lipase}$.

When, however, the cleavage products glycerol and stearic acid are in the presence of lipase with a minimum of water the enzyme produces a synthetic reaction, and the neutral fat Tristerin is formed.

Very little is known regarding the chemical constitution of the enzymes. It was thought for a considerable time that the "living ferments," as found in yeast cells and certain bacterial forms, possessed their catalytic or fermenting properties largely through the fact that they were living organisms. The experiments of Buchner in grinding yeast cells and obtaining an extract which possessed characteristic enzymic qualities is proof that even in these "living ferments" the basis for their fermenting activities is in certain enzymes in the simple organisms. To date it has been impossible, however, to isolate an enzyme by chemical process. Due to their tenacious absorptive qualities they are difficult to separate in an unadulterated condition. In many instances their presence and character has to be inferred from indirect observation.

The exact nature of the action of the enzymes is still an open question. We need not be detained by the antiquated vitalistic theories of fermentation or the vibrational theory of Leibig, which was put forth in an attempt to break away from the bondage of vitalism. At present the scientific sentiment seems to favor a physical rather than a chemical theory of the nature of enzyme action. Apparently the enzymic acceleration given to certain reactions is made possible by a process of adsorption. *Adsorption* is a surface phenomenon; the compounds are formed at or on surfaces. They are not of the same constancy of composition as chemical compounds and neither are they so resistive to decomposition as are chemical compounds. A rather common example of an adsorption compound is observed in the collection of litmus out of a solution onto the surface of charcoal. Recalling that in the colloidal state, as found in living cells, there is essentially a mixture of solid particles in a liquid, it becomes apparent that here we have an ideal medium for adsorption to take place. The enzymes do not cause chemical reactions that would not take place in their absence[5] but by their extreme minuteness they offer a relatively large *surface area*. It is upon this vantage point, in coordination with certain other physical properties, that the substrate becomes *concentrated* by adsorption, thus permitting a more rapid reaction than would otherwise be possible.

The *electrical nature* of the enzymes is another physical factor contributing to their catalytic properties. This is of special significance in the case of the so-called antienzymes and in immunity reactions where an enzyme or other colloid is precipitated by oppositely charged colloids. The investigations of Michaelis have demonstrated that the electrical charge of the enzyme varies from enzyme to enzyme, very few being even amphoteric. Enzyme action is also influenced by the electropotential of the substrate; this fact lends more support to the contention that they act primarily by physical means.

Berzelius, the pioneer in this field of biochemistry, was of the opinion that the enzymes go through the various reactions unaltered. There seem to be a few organic enzymes, however, which apparently experience some change during their catalytic activities, although they do reach the end of the reaction restored to their original form. If the enzymes do not experience some participation and change of this sort it is rather difficult, if not impossible, to account for their gradual deterioration.

Several of these characteristics of enzyme action are of considerable biological, medical, and psychological importance. Perhaps of first importance is the reversibility of enzyme action; one enzyme serving either to synthetize or reduce compounds for which the enzyme is specific. Since the enzymes are always active, whichever reaction is facilitated depends largely upon contributing factors in the cell itself, especially the availability of water. Autolysis through which the rudimentary embryonic structures are removed and which is responsible for postmortem and pathological changes of certain sorts is due primarily to this reversibility of enzyme action in causing cleavage reactions on its synthetized products.

Autolysis or "self digestion" is present in the living as well as in the dead cell. So long as food and water are supplied constructive action occurs. Absence of food or water causes a reversal of the enzyme action. In reality then, it becomes apparent that "life keeps just a little ahead of death" in every cell.

It may be stated that in general each enzyme is specific for only a single reaction course. There are, however, a few extracellular enzymes which are still specific, but for a *variety* of foreign proteins. These are on guard against the entry of foreign proteins into the living cells.

Enzyme activity is also apparently autocatalytic. That is, products of the reactions which the enzymes facilitate serve to accelerate the reaction still further so that the process becomes, to a certain extent, autocatalytic. As a general rule, however, with a further increase in the autocatalyzed reaction products and with a change in the chemical equilibrium there is a retardation of the velocity of the reaction. In true autocatalysis the actual quantity of the catalyst is increased, as, for example, in the hydrolysis of methyl acetate in water. Free acetic

acid is formed and this serves as a catalyst and by thus increasing the velocity of the reaction it automatically increases its own bulk, since it is a product of the reaction. Increasing the amount of the acetic acid in turn increases the velocity of the reaction. Enzyme reactions, strictly speaking in this sense, are not autocatalytic since the actual quantity of the enzyme is not increased during the reaction. Practically, however, the end results are the same as in an autocatalyzed reaction.

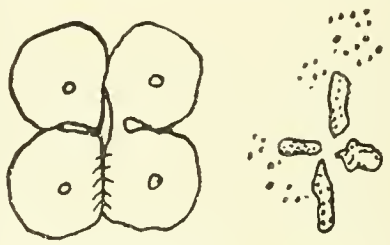
The enzymes are formed within the cell, apparently from the nucleoproteins. But, fortunately, they are usually formed in an inactive state. If it were not for this the cell itself would not be safe from its own products. The terms pro-enzymes and zymogens have been applied to these inactive enzyme forms within the cell. These forms become active immediately upon being secreted. Pepsin, for example, is formed in the secreting cells first as pepsin*ogen;* during the process of secretion it is changed slightly and liberated as pepsin. Nature has provided still further protection for her cells, however. The pepsin does not become active as an enzyme until it is in a mildly acid medium. In digestion this is provided by the hydrochloric acid of the gastric juices.

The entire metabolic activities of the living organism rest largely upon the action of the enzymes. It is through enzyme activity that the food stuffs are separated into nutritive elements in the alimentary tract. The synthesis of these elements in the tissues and cells of the animal are also dependent upon the presence and functioning of certain very specific cellular enzymes.

The rôle of the enzymes in the life processes outside the alimentary tract is usually much underemphasized if not usually overlooked. The essential metabolic and respiratory reactions occur in the cells and not in the so-called digestive and respiratory organs. And, furthermore, if it were not for the presence of certain cell enzymes, in addition to the digestive enzymes, the nutritive elements absorbed from the digestive tract and the fresh supply of oxygen received through the respiratory apparatus would not be completely metabolized. Cellular starvation, with the accompanying death of the organism, would be the outcome. The fundamental problems in general physiology and its subdivision, general psychology, are being and to be solved in terms of the processes in the cells rather than in the organs. We may take the essential processes in respiration as our first detailed example. Common observation emphasizes the importance of free oxygen to the organism. Death is very quick in the case of drowning where the oxygen is suddenly removed. Lack of oxygen also produces irreversible cell changes as is evidenced by the difficulty of resuscitation upon drowning and the more detailed observations of Loeb upon the egg of the teleost Ctenolabrus.[6] It was found by Loeb that in eggs from which the carbon dioxide was removed by a current of hydrogen and which were then deprived of a further supply of oxygen the segmentation stopped within an hour. Furthermore, if the eggs were not soon supplied with fresh oxygen they completely disintegrated.

While Lavoisier and LaPlace succeeded in showing oxidation to be taking place within the body they were unable to explain how this was possible with the low body temperature of the animal and in the relatively neutral medium presented by the body substance. It was Traube who first adequately applied the ferment concept to this process and also pointed out that the primary oxidizing processes occur in the individual cells, the blood and lungs serving principally to remove the carbon dioxide and exchange fresh oxygen for the cell gift of dioxide. This conception of the essential respiratory processes taking place in the cells received confirmation in Spitzer's[11] extraction of oxidases from the cell nucleus.

Lillie[5] experimented further along this same line. He used as staining substances in the cells materials which change in color when they are oxidized. In this way he could determine what part of the cell itself was chiefly concerned with oxidation. Lillie found that the greatest change in the color of his staining substance was in the nucleus and on the surface of the nucleus. Apparently this evidence demonstrates that the essential respiratory changes occur in the cells, and especially in the nucleus. This is what one would be led to expect from the distribution of the cellular enzymes. In the cells the enzymes are given off from the nucleus, apparently from the chromatin materials. This is the



Showing the effects of deprivation of oxygen on the egg of *Ctenolabrus:* To the left, normal egg; to the right, the same egg after being deprived of oxygen for one hour. Adapted from Loeb.

"mother substance" for enzyme formation. It is only in order, then, for the nucleus to be the greatest oxidizing center since the oxidases are formed there and probably most concentrated at that part of the cell.

Oxygen is sometimes considered as supplying energy to the cells but its specific rôle seems to be to enter into the oxidizing reactions by which other energy sources are tapped. In the reduction of dextrose, for example, the presence of oxygen and of the proper enzyme will make it possible for the sugar energy to be liberated. The chief source of the energy in the cell is found in the oxidation effected in the food or food products and not in the oxygen itself. And, further, it is largely, if not entirely, by the aid of the proper oxidizing enzymes in the cells themselves that this oxidation is made possible.

Other accounts of the action of the enzymes in some fundamental life processes may be given. For example, in urea formation the poisonous NH_3 radical, which is a product of the deamination of the proteins, is rendered harmless by the synthetic enzyme urease which enables the body to be freed of the surplus nitrogen. The following formula shows this chemical process for fishes and amphibians:

$$CO_2 + 2\ NH_3 + \text{urease} = OC\begin{matrix}NH_2\\ \diagdown\ \diagup\\ H_2O\\ \diagup\ \diagdown\\ NH_2\end{matrix}$$

The essential processes in the conversion of food materials into a part of the living body substance are also dependent upon the action of certain enzymes. The protein food which is eaten by the organism, for example, is largely converted into the proteoses and peptones by the pepsin active in the gastric juices. As this reduced material passes through the duodendum into the intestine proper the trypsin of the pancreatic juices produces still greater hydrolytic cleavages in the ingested protein. For many years this was as far as the digestion of protein was assumed to progress—the formation of peptones and proteoses. Just how to account for the absorption of these substances, however, was extremely difficult. There is conflicting, and much negative evidence, about the possibility of them being present in or absorbed by the blood.

Cohnheim[3] was engaged in investigating the absorption of peptones and proteoses from the intestine when he observed certain facts which led to the discovery of an intestinal enzyme which he named *erepsin*. This is a peptolytic enzyme which breaks protein into its physiologically ultimate elements, the amino acids. Now compare nature's processes in this connection with those of the laboratory. In the laboratory the hydrolysis of proteins to the amino acids is accomplished only by boiling with concentrated hydrochloric acid. In the body the same hydrolysis is accomplished at a relatively low temperature and in a medium at most only slightly alkaline! But the living organism is supplied with certain enzymes which the laboratory does not possess! That makes the difference.[10]

It will be recalled that there is no positive evidence of the absorption of the peptones and proteoses by the blood from the intestine. Abderhalden[1] actually succeeded in separating the amino acids from the blood of normal subjects living under normal conditions of diet. There can be no doubt about the absorption of the amino acids from the intestine by the blood stream. The presence of small quantities of amino acids in the intestines has been known for some time. But an erroneous interpretation has usually been made of this fact. They were usually regarded as unimportant by-products. But the amino acids are in reality the food-stuffs for the cells. The various tissues build themselves up largely out of the amino acids received from the blood. This is made possible by the presence of synthetic enzymes found in the cells. Although the enzymes are highly specific a variety of compounds from so simple a chemical compound as the amino acids is possible when the large number of enzymes found in the cells of the body. For example, Hoffmeister[4] catalogues ten enzymes present in each cell of the liver. Thus several chemical activities are permitted within a single cell.

Protein metabolism is not limited to one tissue or groups of tissues; protein synthesis takes place in all organs and cells. Any surplus of protein may be eliminated from the body by deamination or the formation of urea by the formula given above. Just as protein synthesis is proceeding in all the cells of the body so all the cells are more or less active in riding the organism of surplus nitrogen by deamination; urea formation is not limited to the liver alone. Other surplus amino acids may be converted into some of the carbohydrates. This has been well established by the experiments of Lusk[7] with dogs rendered diabetic with phlorhizin. Under these conditions in the living body a change from protein to carbohydrate has been observed according to the formula:

$$\underset{\text{Amino acid, alanine}}{2\ CH(NH_2)(CH_3)(COOH)} + H_2O = \underset{\text{Lactic acid}}{2\ CH(OH)(CH_3)(COOH)} = \underset{\text{Carbohydrate, dextrose}}{C_6H_{12}O_6}$$

Proteins taken in as a part of the dietary are reduced to the amino acids in the gastric and intestinal digestion. They are conveyed to the cell as amino acids, not as proteins, peptones, or proteoses. And they enter the cell in the form of amino acids. There they are synthetized, each cell or group of cells recombining the amino acids according to its functional individuality. Each cell or cell group does not take up all the amino acids offered it but only those for which it possesses a specific enzyme. The cell proteins are not seriously affected, therefore, by the proteins of the food. The only requirement is that complex acids be present in the dietary, since it is apparently impossible for the cell enzymes to manufacture certain of the complex amino acids from the simpler. The complex, however, can readily be split into shorter chain acids. Cellular metabolism, complete metabolism, as the one example from the proteins indicates, is dependent upon the presence of cellular enzymes almost to a greater extent than it is dependent upon the dietary.

Enzymes are also prominent in the mechanism of heredity. As has already been pointed out it is by means of enzyme activity that the rudimentary embryonic structures are removed. In embryonic development, also, it is through the progressive development of enzymes that the constant and uniform food supply is formed into differing complex chemical substances and differentiated biological structures. Since the enzymes are carried by the neucloproteins, especially in the chromatic material, it can perhaps be better understood why the chromatin seems to be the prime carrier of the hereditary characters. A chemical basis for mutations is offered in the early stages of embryonic development when a change in nutritional and some other environmental factors may induce sympathetic changes in the progressive development of the enzymes.

It would, of course, be foolhardy to make any pretense of an exhaustive presentation of the detailed functions of enzymes in the living organism in a brief paper. But it has been attempted to indicate, in their proper relation, the rôle of enzymes in some of the vital processes, and the relation of enzymes to some of the things which, to the metaphysician, constitute the unexplainable mystery of living phenomena. There are still gaps and lacunæ in our knowledge of the relations of enzymes to life. During the past century, however, insurmountable obstacles in research have been passed and impregnable barriers removed. Mayhap those of the

younger generation will live to see the day when the remaining paths have been cleared away and shall then see what is now seen "through a glass dimly."

INFERENCES ON ACHYLIA GASTRICA.

By M. GOLOB, M.D.,

NEW YORK.

ASSISTANT IN GASTROINTESTINAL DISEASES, VANDERBILT CLINIC, COLUMBIA UNIVERSITY, AND DEPARTMENT OF GASTRO-INTESTINAL DISEASES, THE BRONX HOSPITAL.

THE object of this paper is to review the facts conducive to the belief that there is no pathognomonic curve in gastric chemism—that the height of an acid curve in ulcus ventriculi and its total absence in gastric carcinoma are interchangeable, and to emphasize the thought that although an abundance of study has been given to the secretory variations of the stomach, we must as yet look upon a gastric curve, whether high or low or conspicuous by its absence, as of remote importance unless it be one of a gastric syndrome.

One is reminded of a like train of thought when hearing indictments of a grave prognosis upon the occurrence of hematemesis—for the latter is neither pathognomonic nor cardinal, in as much as hemorrhage may occur from the gastric mucosa not only in cases of denuded mucous membrane, but also in severe anemia, in the purpuric group of blood diseases, chronic gastritis, rupture of the varicose esophageal veins, and gastric congestion, thus showing that a symptom so severe in its prognostic sense to the general practitioner may be due to some benign etiologic factor.

Likewise the presence of achylia when revealed in an analysis of the gastric chemism has led many a mind to label the case a potential or kinetic cancer, or at any rate, a digestive cripple—when in reality, after a good search and elimination, a diagnosis of achylia gastrica has often been rendered entirely consistent with good health. It is only after the compensatory digestive activity of the succus entericus is embarrassed by reason of an intestinal flora invaded by foreign irritative agents that the patient will have occasion for dyspeptic complaints.

Medical literature abounds in illustrative examples and my own experience at the Vanderbilt Clinic has brought me into personal contact with many more. One finds cases where achylia gastrica has been permanently present or persisted for years without baneful effects; others where the affection existed in persons too young for cancerous growths. In one man it lasted for twelve years with gain in weight and but few attacks of intestinal indigestion—a condition undoubtedly brought about by the action of the small intestine in vicariously assuming the function of the stomach.

Drs. Finney and Friedenwald[1] have cited a case of pylorospasm associated with a chronic gastritis simulating carcinoma in a man aged forty-eight years. The gastric secretion showed a true achylia and there was blood in the stools. The roentgen ray revealed a definite defect at the pylorus. In this case at least, the stomach chemistry was strongly supporting a diagnosis of malignancy. An exploratory operation, however, revealed a chronic gastritis together with a marked pylorospasm.

In a discussion on gastric disturbances Dr. Max Einhorn[2] alludes to the belief once current, that the absence of gastric secretion meant atrophy of the glands and consequent death. And when he found a man who had no gastric secretion he refused to accept the popular finding that the man had atrophy of the stomach and protested against such "promiscuous diagnosis."

Historically, the term achylia gastrica was first proposed by Dr. Einhorn in 1892 to designate a class of diseases in which no gastric juice is secreted. The affection is described as existing in the following forms: (a) Functional or nervous achylia, (b) Symptomatic, (c) Organic, (d) Idiopathic (Einhorn).

The term however does not imply the mere loss of free HCl, but also the existence of the following characteristic findings: (1) One hour after the Ewald test breakfast the aspirated contents are of the same appearance as when in the mouth before swallowing. I have found this to be quite characteristic. (2) The total acidity varies from 2-10 c.c. of $\frac{n}{10}$ NaOH. (3) The quantity of gastric contents one hour after the test breakfast is abnormally small—this also is quite characteristic except in the case of wet achylia. (4) The gastric contents slightly acidulated with diluted HCl cannot digest disks of egg albumen when placed in the thermostat; and milk similarly treated will remain uncoagulated—evidence that the secretion of enzymes is absent.

It might here be mentioned that the term achlorhydria, though often used interchangeably with achylia gastrica, implies only the absence of secretion of HCl. The use of "achylia gastrica" in that connection as meaning the total loss of HCl secretion independent of pepsin formation is, as Dr. Parker has pointed out, an unfortunate trend. That the amount of gastric secretion is not a determining factor in carcinous diagnosis becomes apparent on considering its wide variability. Forty per cent. of normal individuals have hypersecretion.

High strung patients who secrete HCl normally will often, under the influence of nervous excite-

ment and apprehension concomitant with the aspiration of a test meal, suffer the gastric secretion to be temporarily inhibited. In a recently published article Dr. J. L. Kantor[3] declares: "Experimentally it has been shown that in frightened animals the secretory as well as the motor functions are held in abeyance, so that one may meet with a case of retarded propulsion of the stomach contents as an instance of 'transient gastric retention'." Similarly, excitement and apprehension may bring about a 'transient inhibition' of HCl.

Hemmeter[4] calls attention to the rapidly varying states of secretion designated as heterochylia, occurring chiefly in cases of nervous dyspepsia, and cites instances of hyperacidity, hypoacidity, and anacidity observable in the same patient on the same day after identical test meals.

Dr. A. Goldman[5] laid stress on the possible finding of a Rheffus curve in gastric cancer as contrasted with a low or even very low titer in gastric ulcer. Thus while hyperchlorhydria is contributory evidence of gastric ulcer, it does not preclude the possibility of carcinoma; and achylia, though contributory in character as regards cancer, does not necessarily spell malignancy.

Dr. Rheffus[6] well classified the gastric secretory curves, placing at the head of his classification clean digestion, simple secretory variation. We thus may have clean subacidities, clean achylias which Rheffus justly assumes to imply a low or absent gastric curve, without any tangible evidence of mucosal irritation such as mucus, blood, pus, and so forth. Those curves are encountered in metabolic conditions such as gout, pellagra, and endocrine disturbances. In fact the inhibition of the gastric mucosa is thus established in almost any toxic state which inhibits the vagus or accelerates the sympathetic.

Moynihan[7] speaks of the stomach "as an organ full of sympathy for other sufferers"—metaphorically sympathetic ophthalmia. "Hardly any viscera connected with the intestine can be affected without the stomach playing its part in the disturbance also. This it does by pouring out an excess of secretion and by tumultuous and irregular activities. It so loudly speaks that its voice only is heard. The tears of sympathy are spoken of as hyperchlorhydria." Likewise, when a person is overcome by a strong emotional state, the stomach, responding to the shock transmitted, will suffer a corresponding cessation of its vital power. An interplay of vagatonia and sympathetic atonia is thus ever existent; and when for any reason the equilibrium is disturbed, the more dominant factor supervenes and holds unrestricted sway.

Further light on the limitations of achylia as a differential factor may be had from a consideration of non-cancer cases where the HCl is wanting.

In his publication on pernicious anemia Dr. Carr[8] presents the following summary: Gastric analyses were recorded in 57 cases, 53 of which showed no free HCl; 1 a free HCl of 2; 2 others of 7; the remaining case showed so much blood that acidity could not be tested for. In 93 per cent. of the cases examined the stomach contents showed no free HCl. Evidently achylia is an important clinical symptom of pernicious anemia.

Some authors call attention to the frequency of achylia in advanced cases of gall-bladder pathology, and its common association with syphilitic gastric ulcer. It is evident, therefore, that the absence of free HCl and its enzymes is a symptom common to many diseases and pathognomonic of no single one.

I wish here to make a plea for a more thorough search in the realm of chemistry for differentiating points. In this respect the test proposed by Wolff and Junghaus is very helpful though by many considered too elaborate, and unfortunately ignored. The test is that for dissolved albumin in the stomach contents as an indication of gastric cancer. Its underlying principle, as stated in Barker's monographic medicine,[9] is as follows: "When HCl and pepsin are absent from the stomach juice, one would expect no soluble albumin in the material aspirated one hour after a simple test breakfast. In simple achylia gastrica this expectation is realized; but in cancer of the stomach with absence of free HCl, there is often as much soluble albumin as in a normal stomach. This is accounted for by Wolff and Junghaus by (1) the action of ferments derived from the cancerous growth, (2) albumin secreted by the growth, and (3) diminished absorption due to secondary gastritis."

Smithies[10] has confirmed the value of this test, and among other conclusions states that "when carefully performed and interpreted, the Wolff-Junghaus test for demonstration of dissolved albumin in gastric extracts was positive or suspicious in 80 per cent. of our series of gastric cancer."

Friedenwald and Kieffer,[10] from a careful study of their cases conclude that the Wolff-Junghaus test "has its greatest significance in the diagnosis between simple and malignant achylias. Positive reactions are rarely observed in simple achylias, while they are frequent in cancer . . . . The test is positive in at least 83 per cent. of gastric cancer presenting an absence of free HCl, and in 72 per cent. of early cases."

The deduction therefore is warranted that the test is an immense aid in the diagnosis between grave and simple achylias and should be given the same weight as other tests.

From a number of cases treated at the Vanderbilt Clinic the following are selected as illustrating that age plays no great part as a causative factor in achylia gastrica.

A female patient twelve years of age was treated for universal psoriasis and presented symptoms which warranted a study to ascertain the status of her gastric chemistry, with resulting findings of a true achylia by repeated aspiration.

Male, fifty. Family history and previous personal history unimportant. Occupation, printer. Duration of symptoms, ten years. Chief complaints, epigastric distress, acid eructation, anorexia. Physical examination, sthenic, hyposensitive individual. Chest, negative. Abdomen of normal habitus, poor tone, no tenderness on superficial or deep palpation. Fasting contents revealed 4 c.c. of congo-negative fluid and no food remnants. *Ewald Test Breakfast:* Amount aspirated, 30 c.c., which separated into three layers—evidence of gases of fermentation. Free HCl = 0, combined HCl = 0, total acidity = 10. *Milk test* the following day uncoagulated. *Test for pepsin* (common method), negative.

While it is not within the scope of this paper to enter into a discussion of the medical treatment of achylia gastrica, the case mentioned pre-

sents such striking features from a dietetic viewpoint that it will be described more fully.

The patient was placed on a sparing and stimulating method of treatment with dilute HCl before, during and after meals. The symptoms complained of by him first abated in severity and finally disappeared, but recurred when he ceased taking the drops, upon his insistence on "getting well without the use of medicine." I put him on fresh pineapple juice, amounting to a pineapple a day, taken after meals in equal portions, with the result that the symptoms were again alleviated and the patient felt happy. Upon discontinuance of the pineapple treatment he suffered a full recurrence of symptoms. The alleviation of the symptoms brought about by the fresh pineapple juice is undoubtedly due to the proteolytic enzymes contained in the fresh pineapple.

Conclusions.—We have seen that the amount of gastric secretion is a factor of wide variability and that consequently an inference as to an individual's acidity based on a single examination of the stomach contents is unreliable. We have seen also that where true achylia is established it is often not incompatible with good health; and when accompanied by impairment of health the affection is not necessarily carcinoma. We are therefore inclined to believe with De Quervain, that achylia gastrica has no differential import.

It may not be unwise for the practitioner to attribute achylia gastrica to an advanced organic disease of the gastric glands—but only as a working hypothesis for further substantiation and not as a final pronouncement of a fatal prognosis.

SECRETIN, A DEFENSIVE FACTOR AGAINST GASTROINTESTINAL CANCER.*

BY ELLIOTT C. PRENTISS, M.S., M.D.,

EL PASO, TEX.

As advances are made in the science and art of medicine the ravages caused by one disease or group of diseases after another have been much reduced or eliminated, leaving a correspondingly high mortality in the end to diseases that are not preventable or curable. With this average lengthening of life cancer has naturally increased in frequency, but it has increased more rapidly than can be accounted for by that fact. It has been estimated that cancer has increased in frequency about 25 per cent. in the last ten years.[1] Other countries than ours show an increase of from 4.2 to 43.6 per cent., the only ones having a decrease being Ceylon and Switzerland. This has made cancer of even greater importance than before, as the increase is still going on.

Most cases of cancer are diagnosed too late for complete extirpation or are in a location that cannot be removed. Even when operation is apparently successful, in many cases all of the tumor cells have not been removed, and a recurrence or another primary growth takes place. Surgery in such cases is the best we now have, but it has failed. A medical cure must be our goal.

A study of the incidence of cancer in the various organs is of interest. The following statistics[1] are those recorded in the U. S. Registration Area, 1901 to 1910:

	Males		Females	
	Number	%	Number	%
Stomach and Liver	50,157	50.5	50,388	32.6
Rectum, Intestines and Peritoneum	11,980	12.1	16,751	10.9
Buccal Cavity	7,304	7.3	1,529	1.0
Skin	6,252	6.3	3,303	2.1
Generative Organs			35,587	23.1
Breast			22,190	14.4
Other Organs	23,690	23.8	24,598	15.9
Total, 40 years and older	99,383		154,346	
Total, all ages	109,299		173,369	

Gastric cancer furnishes about 38 per cent. of all cancer deaths. On looking over the table given we note that when we except cancer of the breast and generative organs of women, the remaining figures are much like those for males. Men are more subject to cancer of the mouth and skin, while those for the stomach, intestines, liver, and peritoneum remain about the same.

I will now summarize a large mass of statistics collected from the literature and which cannot be given in detail. About 70 to 73 per cent. of all cancers occur in the digestive apparatus below the mouth. Approximately 9 per cent. are esophageal, 0.5 per cent. hepatic, and 1.7 per cent pancreatic. Of all cancers primary in the intestines, only 2.5 to 3 per cent. are in the small intestine. Those in the small intestine are mostly in the duodenum and ileum, with a few in the jejenum. Seventy per cent. of those in the duodenum involve the papilla duodenalis, and most of the remainder are below the papilla. Carcinoma primary in the ulcer-bearing area of the duodenum is very rare. Mayo states that most of the cancers in the ileum are near, but not at, the ileocecal valve.

We note especially from the above that cancer is very much more frequent in the stomach than it is in the whole of the small intestine, and also that it is relatively very common in the esophagus and whole large intestine. We should try to find out the reason for this, for if we can discover it, something of therapeutic value may be deduced.

An interesting point worth mentioning here is the relative frequency of gastric and duodenal ulcer. Surgeons state that duodenal ulcer is of much greater frequency than gastric ulcer, but for purposes of argument here we will assume that they are of equal frequency. Taken in connec-

*Read at the Seventh Annual Session of the Medical and Surgical Association of the Southwest, Phoenix, Ariz., December 1, 2, and 3, 1921.

tion with cancer statistics this would seem to suggest that either ulcer is not a predisposing cause of cancer, or that there is some substance in the duodenal epithelium that prevents malignant change there.

Along this line two interesting observations have been made. One is that occasionally a gastric carcinoma will invade the duodenum, but the ulceration there will be benign, and the other is that occasionally a duodenal ulcer near the pylorus will spread up into the stomach and become malignant there. This fits in very well with the above conclusion. Another interesting fact is that cancer of the stomach seems to grow more slowly after a gastroenterostomy than it otherwise would, probably due to the presence of some chemical substance in the bile, pancreatic juice, or duodenal secretion that is antagonistic to cancer. This substance may be secretin.

What common factor is there present or absent in the esophagus, stomach, and large intestine that has its counterpart in the small intestine? Certainly not stasis, acid reaction, hydrochloric acid, bacterial overgrowth, or catarrh. The most important factor I can discover is that no secretin is present in the mucous membrane of the esophagus, stomach, and large intestine, and that it is present in the small intestine. Of course, there are also present in the lumen of the small intestine bile, pancreatic juice, and the ferments secreted externally by the mucosa, but they are not a part of the epithelial cell of the small intestine, and cancer of the papilla duodenalis, which is bathed constantly in bile and pancreatic juice, is more frequent than that of the duodenum.

The liver is the largest and most active gland in the body and infection is common in it, but primary cancer is rare. Secretin goes directly to the liver in the portal blood, and in the most concentrated solution possible. Primary carcinoma of the pancreas is three times as common as that of the liver, yet the gland is smaller and infection is less frequent there. Secretin reaches it in less concentration by the general circulation.

It has been demonstrated by physiologists that secretin, the internal secretion of the mucosa of the small intestine, is present in the duodenum, jejunum, and ileum to within two feet of the cecum. It is most concentrated in the duodenum and diminishes in amount from there down. In experimental work it is given intravenously, but Downs and Eddy[2] have shown that it has the same effect when given hypodermically, except that it begins more slowly and lasts longer. The preparation loses its power in 6 to 8 days, but they state that when mixed with 2 per cent. glacial acetic acid and dried, it will remain active for 6 months. It is, of course, then neutralized before using.

I believe that the dried extract is active over a longer period than 8 days, and have seen stimulation of biliary flow in two cases after operation, when a tube had been left in the gall-bladder. This should prove of value to surgeons in treating such cases. Physiologists state that secretin is destroyed by the HCl of the stomach contents, but it was found on gastric analysis in both the above patients.

It may be that before the conversion of a predisposing pathological process in the digestive tract into cancer there is an alteration in the character of secretin in the mucosa, or a diminution or even absence of it, thus breaking down the natural defense. I have not been able to find any record of examination of the mucosa of the small intestine for secretin after death from cancer, pernicious anemia, and other conditions. Such an investigation would be interesting to carry out, and may yield valuable findings.

The therapeutic value of secretin against cancer can be easily tested out on implanted rats, and I hope that it will be done. The oral administration of the dried extract to patients with gastrointestinal cancer is worth trying. This should not interfere with operation when it is advisable.

Conclusions.—1. Ulcers of the stomach and duodenum are frequent, as is also cancer of the stomach, but cancer of the duodenum is rare.

2. There is some substance present in the duodenal epithelium that prevents the conversion of duodenal ulcer into cancer.

3. Secretin is present in the epithelium of the gastrointestinal tract where cancer is least frequent, and absent where it is most frequent.

4. Secretin has a directly antagonistic effect against gastrointestinal cancer.

5. A secretin preparation can be used therapeutically and should be given a trial.

SPECIFIC GRAVITY AND ACIDITY OF URINE.

By M. W. LYON, Jr., M.D.,

AND

VERA B. TRAGER,

SOUTH BEND, IND.

In the laboratory of the Clinic, instead of determining whether a given specimen of urine is acid, neutral or alkaline by the use of litmus, a rough titration of the urine is made with N/10 NaOH, phenol-phthalein indicator, to determine the degree of acidity or the number of cubic centimeters of N/10 NaOH needed to neutralize 100 cubic centimeters of urine. The urine is titrated directly without first adding neutral potassium oxalate, which should be done in order to determine the true titratable acidity, owing to the presence of calcium and ammonium salts and monobasic phosphates. However, it is believed that the direct titration employed is sufficiently accurate for clinical purposes, if there is any real clinical value to be derived from a routine determination of the acidity of single samples of urine in the case of patients on their own choice of diet. In making the titrations it appeared that the degree of acidity was in large part dependent upon the height of the specific gravity figure. In order to determine the relation between specific gravity and acidity the figures for these were examined in 1,000 uranalyses, the results tabulated, and curves plotted. Only the analyses of

essentially normal urines, as indicated by lack of sugar, acetone bodies, albumin, and abnormal sediments, were examined. In addition to these, 50 analyses of urines containing acetone and diacetic acid, 13 of urines containing sugar, and 5 of urines showing marked nephritis were examined. Urines having an acidity of 10 or less, as determined by the above method, are neutral or faintly alkaline to litmus.

That the acidity of urine is, as a rule, a direct function of the specific gravity is shown in the chart. The numbers at the top are the average degree of acidity of the various urines whose specific gravities are represented by the numbers at the left. The curve made by uniting the dots by a solid line extends to right quite regularly with the specific gravity increase until at the extreme right

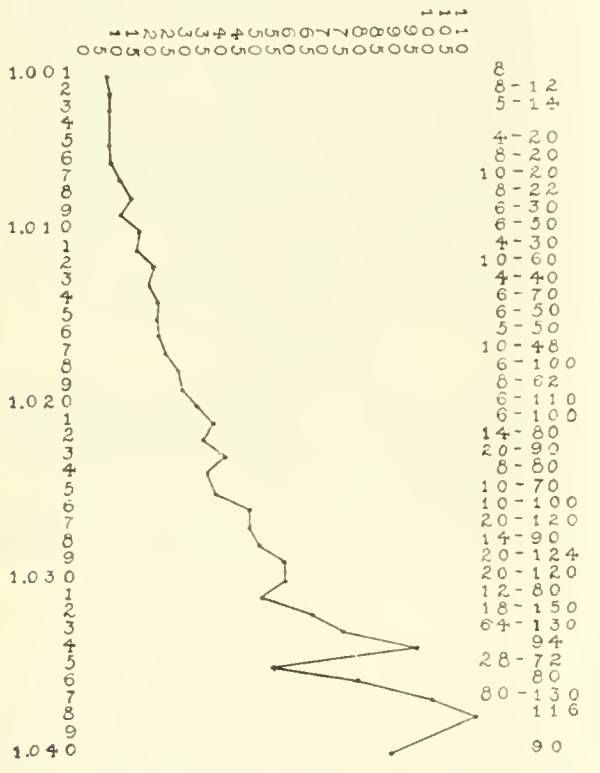

FIG. 1.—Curve showing the gradual rise in acidity of urines as the specific gravity increases. Numbers at the top are the average degrees of acidity observed for each degree of specific gravity as recorded by numbers at the left of the figure. Numbers at the right are the extremes of acidity as observed for each specific gravity as recorded at the bottom.

where it is irregular, owing no doubt to the small number of urines having a high specific gravity encountered among the 1,000 tabulated. The numbers at the right of the figure are the maximum and minimum degrees of acidity observed for each specific gravity indicated by the numbers at the left of the figure. These extremes are very great and there is a marked tendency for the minima to approximate a low figure, while the maxima become progressively larger as the specific gravity increases. The arithmetrical average acidity for the 1,000 specimens is 33.5. The arithmetrical average specific gravity is 1.0186. The ratio of acidity to the decimal fraction figures of the specific gravity is 1.8. The usual degree of acidity for any particular urine can be obtained approximately by multiplying the last two figures of the specific gravity reading by two. If the observed acidity is much above or below the theoretical figure, the urine is not necessarily pathological, but may be termed abnormal. Some are inclined to the view that high acidity of urine is something of an index of acidosis or an excess of acid salts in the urine. An examination of the chart shows that usually a high acidity merely indicates a highly concentrated urine. If the acidity in such a case is considered objectionable the simple administration of water will reduce it.

In order to determine whether there is a correlation between high acidity and acidosis fifty uranalyses in which acetone and diacetic acid were recorded in appreciable amounts were made. The acidity of each was divided by the last two figures of the specific gravity reading. The average of these ratios is 2.3 with extremes of 0.4 and 4.7. This shows that urines having acetone and diacetic acid possess an average acidity greater than normal. The test routinely employed for acetone is the well-known sodium nitroprusside-acetic acid mixture and ammonium hydroxide, that for diacetic acid the ferric chloride test. Acidity determinations, however, are of little value in diagnosing suspected acidosis as many urines containing acetone bodies possess low acidities and many urines with high acidities do not have them. The acetone and diacetic acid tests are simpler and more enlightening than acidity determinations. It is appreciated that acidosis may exist without acetone bodies being found in the urine. It is assumed that the fifty urines in which acetone and diacetic acid were found represented cases of acidosis. Most of them occurred in children, many of whom showed clinical signs of acidosis. It would be expected that urines whose high specific gravity is due to the presence of sugar would have acidities of relatively low degree. An examination of 13 uranalyses which recorded sugar in appreciable amounts and which did not contain acetone. indicated that this is probably true, although the figures are not striking. The acidity-specific gravity ratio in these thirteen cases is 1.3 with extremes of 0.4 and 2.6.

There are available only five uranalyses recording high albumin content and the presence of casts. The average specific gravity-acidity ratio in these is 2.1 with extremes of 1.0 and 3.1.

Conclusions.—An examination of 1,000 analyses of non-pathologic urines showed the usual specific gravity to be 1.020, the arithmetical average to be 1.0186.

The degree of acidity of urine increases directly with the specific gravity.

In normal urines the ratio of acidity to the last two figures of the specific gravity is 1.8, in urines from probable cases of acidosis, as shown by the presence of acetone and diacetic acid, the ratio is 2.3; in urines containing sugar the average ratio was found to be 1.3; in a small number of analyses in cases of marked nephritis the average ratio was found to be 2.1.

The determination of acidity in urines is of negligible value in detecting the presence of acidosis and of no value in excluding it; it has an important place in determining the results of alkali administration.

THE DIAGNOSIS OF ADENOIDS IN ADULTS.

As is known by their symptomatology, adenoids in adult subjects may be easily overlooked if one does not remember the possibility of their development. When a patient comes with symptoms of pharyngeal catarrh of long standing and obstinate to treatment, or if he complains of disturbances of hearing, an explanation of which cannot be derived from an examination of the ears, hypertrophy of the pharyngeal tonsil should be suspected. The only means by which a positive diagnosis can be made is by a posterior rhinoscopic examination and detection of the presence of adenoid growths. For that matter, examination of the rhinopharynx with the mirror should invariably be systematically made whenever anterior rhinoscopy, a laryngoscopy, or an examination of the ear is done. It is the necessary and indispensable complement. In children, adenoids make themselves manifest by such a group of subjective and objective symptoms that the diagnosis imposes itself, so to speak, without the necessity of resorting to posterior rhinoscopy, and a finger introduced in the pharynx will tell the tale if necessary. The same, however, cannot be said of adults, and if adenoids in them are not more frequently mentioned it is because posterior rhinoscopy is not practised often enough by the general practitioner. By this means a differential diagnosis will be readily made.

Reference to the palatine tonsils and their hypertrophy, which for a long time was thought to give rise to the accidents we now know are due to adenoids, need not be made. Difficulty in breathing due to obstacles in the nasal fossæ, such as polypi, synechiæ, deviations of the septum, chronic and hypertrophic catarrh, can be quickly diagnosed by the nasal speculum. It must be recalled that very frequently chronic nasal catarrh and hypertrophic rhinitis coexist with hyperplastic development of the pharyngeal tonsils, and, according to Raulin, the latter are paler than in true hypertrophic rhinitis. This is a point not to be disregarded in order to avoid unnecessary treatment of the nasal mucosa, which becomes progressively normal after the adenoids have been removed. When, by posterior rhinoscopy, the presence of a tumor is detected in the pharyngeal cavity, the questions of a fibrous polypus arises, and this is a somewhat delicate diagnostic point, of particular importance when the subject is from eighteen to twenty years of age. Of course, when the neoplasm is large and invades the adjacent cavities—the nose and orbit—the diagnosis is self-evident. On the other hand, if the growth is small, the diagnosis may be absolutely impossible, and the question can be settled only by a histological examination. During the early phase of development of fibrous polypi, an important differential sign is the frequent repetition of severe epistaxis, such as is never encountered in adenoids. From the viewpoint of direct examination, it is to be recalled that hypertrophy of the pharyngeal tonsil is seen as a more or less uneven mass, while nasopharyngeal polypi are smooth, more or less dark red in color, and rather large vessels are always seen on their surface. To the touch, adenoids are soft and irregular, and a bit of tissue can readily be removed with the nail. They have been aptly described as feeling like an earth-worm. A polypus is hard, cartilaginous, not very movable, with a polished surface. In elderly subjects an adenoid growth must not be mistaken for cancer. The latter has a rapid evolution, causes shooting pain, enlargement of the regional lymphnodes, and general cachexia. The growth is very anfractuous, ulcerated, and bleeds readily upon the slightest touch.

When removing adenoids in adults it is to be remembered that there is more bleeding at the time of the surgical act than in children, and that secondary postoperative hemorrhage coming on a few days later is more common than in young subjects. An operation should not be done during the menses or while coryza or an angina exist, no matter how trifling they may be. After their removal, the treatment should be directed to the cure of those complications that are prone to accompany the presence of hypertrophy of the pharyngeal tonsil.

NEOSALVARSAN IN MALIGNANT PUSTULE.

BOTH salvarsan and antianthrax serum have sufficed to cure some desperate cases of anthrax in the past few years, but the opinion is current that a bacteriemia due to the anthrax bacillus is beyond aid. Surgeons who advocate energetic local treatment claim that the serum alone is not sufficiently active to combat the full-fledged disease and that the outlook of the patient becomes very precarious. Both the old general mortality and the present-day mortality with surgery alone are in the vicinity of 40 per cent., while under modern conservative resources it is from 5 to 10 per cent. This low mortality is due largely to the possibility of early diagnosis and the resulting prompt treatment. Roux reports in the *Revue médicale de la Suisse romande* for February 1922, xlii, 2, the following case. The patient was a farmer and emergency butcher, who, called in to examine a beef which had just dropped dead, found the spleen of enormous

size. Anthrax was at once suspected and confirmed by the bacteriologist of the Canton. The butcher had carried the liver for some distance in his bare arms and a pimple appeared eight days later on the anterior surface of one forearm. He continued at his work of loading manure the rest of the day and by evening felt as if he was getting the grippe, a disease from which he had suffered in 1918. In the morning the arm was greatly swollen and the general condition poor, but having promised to kill a pig, he attended to the job and then collapsed. Taken to the hospital his condition was pronounced grave and a consultation was called. There were profuse diarrhea and vomiting with abundant cold sweats. The entire left arm was greatly swollen, with skin tensed to the limit. The malignant pustule on the forearm was the size of half a dollar. Blood tests showed the *Bacillus anthracis*, and inoculation tests on a guinea pig were positive. To ward off a possible tetanus complication an injection of antitetanus serum was given and five long incisions were made in the forearm. By the advice of Dr. Galli-Valerio both neosalvarsan and anti-anthrax serum were injected intravenously. These were repeated daily for several days and the patient received frequent injections of caffeine and camphor and drank nothing but champagne. From the first the patient reacted well and his mental state became favorable. He was without fever by the fifth day, left his bed on the fifteenth, and was out on the twenty-first. Recovery of his original strength was very slow. The arm was normal after fifteen days, but the left hand was somewhat crippled. It is thought that another two months or four months in all of convalescence will see a complete recovery. In accounting for the latent interval between handling the beef liver and the first outbreak of the carbuncle it will be necessary to suppose that the virus dried on the forearm and there remained until a chance scratch inoculated the patient eight days later. After the slight injury the development of the pustule was extremely rapid, a water blister being seen a few hours later. It seem incredible that the patient did not feel impelled to wash his forearms after handling the diseased liver, but this fatalism, or aversion to water, is rather characteristic of the peasant farmer.

THE INFECTIOUSNESS OF INFLUENZA.

A SPECIAL bulletin of the Division of Public Health Education of the New York State Department of Health cites new evidence of the extraordinary infectiousness of influenza at the beginning of an attack and of the importance of the common cold in relation to outbreaks of respiratory diseases. A local epidemic in a sparsely settled farming community on Long Island, at a time when connecting roads were nearly impassable and the people were largely cut off from nearby communities, made it possible to determine and study the source of the infection and the time and manner of its spread with almost the precision of a laboratory experiment. The following is the account of the origin of the epidemic as related in the Health Department's Bulletin:

On Friday evening, Feb. 10, the church people of this region held a "sociable" at one of the farm houses. There were fifty-one people present, and by Monday morning forty of them were sick with influenza of a fairly severe type. It was easy, afterward, to see what happened. The eleven year old son of the hostess had come home from school during the day and had gone to bed with a headache and fever. In the evening he could not resist the temptation to join the party, and he got out of bed, dressed and mingled freely with all the guests. Then he went back to bed, thoroughly ill with a typical attack of influenza. Undoubtedly he infected nearly every one in the social gathering. This was all the more possible because the party was held in two rooms of a house only thirty feet square, and there was great overcrowding. Influenza had occurred previous to the sociable in at least six families, with a dozen or more cases. From these the disease would perhaps have spread anyway, but the fact is indisputable that the actual spread was through the contacts of that unlucky Friday evening, and no one reported other cases than those directly traceable to this social gathering. All the cases in this outbreak were much alike. There was sudden onset, with headache and backache, fever and great weakness lasting seven or eight days. There were apparently no pneumonia cases, and all the patients recovered. In all the cases the "incubation period" was clearly fixed at from twenty-four to forty-eight hours after exposure.

The State Health Department sees in this outbreak striking confirmation of the following views: (1) Influenza at and just before its onset is extraordinarily infectious. (2) Every case of a common "cold," even if mild, should be isolated. (3) The public should realize the indefinite and possibly serious nature of a cold in the head. A "cold" may be almost any disease from a common and trivial cold to pneumonia; it may be caused by almost any germ from the as yet unknown virus of the common cold to some of the most virulent organisms known to medical science.

DIFFERENTIAL SURFACE TEMPERATURES.

THE phenomenon of difference of temperature of the two halves of the surface of the body is commonly mentioned only in hemiplegics, and the fact that such differences might exist in cases of visceral inflammation has attracted little if any attention. At least Pok, writing in the *Wiener klinische Wochenschrift* for February 9, 1922, xxxv, 6, makes no mention of any predecessor. His communication is apparently written to make good his claim to priority. As one of the staff of a gynecological clinic he deals only with conditions like unilateral annexitis, oophoritis, appendicitis, and tubal pregnancy. The patient should present evidences of a systemic inflammatory reaction, with localized pain or tenderness. One must not jump to the conclusion that any notable differences can be elicited by the thermome-

ter. The average excess on the affected side is slightly less than two-tenths of a degree for unilateral oophoritis. In uterine abortion there is no lateral difference of temperature and in differentiation between this affection and left tubal abortion, after the presence of a chill, etc., the excess of temperature of the left side over the right was in the latter case from one-tenth degree to more than one degree Centigrade. In the differentiation of appendicitis from acute left-sided abdominal conditions the higher temperature of the right side tends to exclude the latter. The author loses no time in the description of his technique of surface thermometry, but evidently takes several measurements during the day and is ruled by the average. His article hardly scratches the surface of such a potentially large subject, and he seems to have tested the method in but few cases before hastening into print.

Doctors and Wines.

THE showing of the recent questionnaire of the *Journal of the American Medical Association* that a number of physicians in the United States do not believe in the necessity of wine as medicine may be contrasted with some remarks on a similar subject by Dr. Cruchet, editor of the *Journal de médecine de Bordeaux* in the February 25, 1922, number (xciv, 4). A prominent champagne merchant in speaking of the endorsement by the profession of his product complained that while in private they gave him assurance of their support, they did not see the need of proclaiming it from the housetops. Others who lived in the champagne country, where all profited alike from the wine industry, thought their opinions would sound biased. Either of these excuses, according to Cruchet, is pitiful. One should be courageous enough to give his honest opinion and then stand by it. Mere local pride might influence a practitioner in the Gironde to recommend Bordeaux wine for all patients alike, and so on through each of the great wine-producing districts. A physician is believed to be an expert in these matters of wines, as he is or should be in mineral waters. His opinion should be given in good faith and without fear. He knows that in every one of the great French wine districts alcoholism is at a minimum; if he does not realize this he can easily convince himself. Drunkards are rare in Bordeaux, and when you find one he will be a brandy drinker. The doctor's motto, which would accord with the experience of the world, might be "fight alcoholism with wine."

Emboli and Embolic Gangrene of the Extremities.

EMBOLIC gangrene of the extremities from plugging of the main vascular trunks is extremely rare and it is very seldom indeed that cases are seen early enough to permit of the operation of embolectomy. The sources of these emboli are the aorta, heart, pulmonary and systemic veins, but in the latter case there must have been a patent foramen ovale. Embolism always predicates the antecedence of a thrombus in one of these localities. In order to obtain a better idea of the frequency and origin of emboli of the extremities P. Bull, the well known surgeon of Christiania, Norway, studied the autopsy records of the Rikshospital for the past 26 years, covering a material of 6,140 cases. (*Acta Chirurgica Scandinavica*, 1922, lxiv, 4.) The number of cases of embolism, discarding several doubtful ones, was but 15. The site was as follows: aorta, 2; common and external iliac, 6; external iliac and femoral, 1; hypogastric and femoral, 1; femoral, 3; popliteal, 1; subclavian and axillary, 1. Of the 15 patients 6 are known to have developed gangrene, 7 were exempt, and in 2 the result was uncertain. The next point to determine was the location of the original thrombus. In 13 of the 15 cases the thrombus formation was in the cardiac cavities and in the other 2 in all probability in the aorta. Of the thirteen intracardiac cases the left heart was the site in 11, while in the other two the right heart alone was the site. There is no mention of patent foramen ovale in these cases, but it must have existed. Thrombosis of the heart and aorta without consecutive embolism is not uncommon and there were 243 cases in the 6,140 autopsies. In all but 19 cases there was some lesion of the endo- or myocardium. The total number of cases of embolism, excluding those of the extremities, was 286 in the following order: lungs, 113; kidneys, 74; spleen, 60; brain, 32; intestines, 6; liver, 1.

News of the Week.

Smallpox in New York in 1921.—According to the February issue of the *Bulletin* of the New York State Department of Health, smallpox was reported from ninety-nine foci in the State during 1921 as against sixty-five for the preceding year. The total was 602 as compared with 281 for 1920. The disease was quite prevalent during the first half of the year, 86 per cent of the cases occurring during the first six months. The largest outbreak of the year occurred in Tonawanda and North Tonawanda, there being 37 cases in the former and 64 in the latter place. All of the outbreaks occurred in small cities, villages or rural towns, where vaccination is not practised unless it be as a result of a smallpox outbreak. In the nine first and second class cities of the State, where vaccination is a prerequisite to school attendance, no outbreaks occurred, and the disease rate for the year was only one-thirteenth of that elsewhere in the State, exclusive of New York City. Of the total 602 cases, 466, or 77.4 per cent., were never successfully vaccinated; 35, or 5.8 per cent., were vaccinated more than seven years previously; 21, or 3.5 per cent., were vaccinated within seven years, while in 13.3 per cent. no history was obtained.

National Research Council Announces Fellowship in Medicine.—Establishment of fellowships in medicine to increase the supply of qualified teachers in medicine in clinical and laboratory subjects and in curative and preventive aspects was announced March 23 by the National Research Council. The fellowships, supported by appropriations of the Rockefeller Foundation and the General Education Board, will be open to Americans or Canadians of either sex holding or qualified to hold degrees of Doctor of Medicine or Doctor of Philosophy from approved universities. The appro-

priations total $100,000 a year for five years. Successful candidates, to be known as Fellows in Medicine of the National Research Council, will be at liberty to choose the institutions or universities in which they will work. Correspondence concerning the fellowships should be addressed to the Division of Medical Sciences, National Research Council, Washington, D. C.

Drive for American Legion Camp Opens.—The American Legion, with headquarters in the Hotel Astor, New York, is conducting a campaign to raise a fund of $2,000,000 for a tuberculosis camp at Tupper Lake in the Adirondacks, which is being prepared to care for ex-soldiers. A site of 1200 acres has been acquired, with twenty buildings. It is expected that the camp will be prepared to care for 1700 men during the first year. Dr. Samuel Lloyd is treasurer of the campaign committee.

State Health Department Gives Health Talks By Wireless.—The New York State Health Department announces that Dr. Hermann M. Biggs, State Health Commissioner, will deliver health talks twice a week from the W.G.Y. station at the General Electric plant at Schenectady. The first of these lectures was delivered on March 24. The Health Department officials believe that the wireless will be a useful medium in disseminating the best possible medical advice on health subjects, especially to rural communities which have no physicians.

Free Clinics for Mental Diseases.—Forty free clinics for mental disorders are now conducted throughout New York State. During the past year nearly 5000 persons have attended these clinics, an increase of 34 per cent. over last year. Local newspaper publicity regarding the clinics is largely responsible for this increased attendance, the work of the clinics having thus been brought to the attention of those needing such service. More than 50 per cent. of these patients had never been under the care of the State hospitals.

War Strain Leaves Mark on Officers.—According to an informal report from the War Department, physical examination of regular army officers now in progress has disclosed clear cut evidence of physical deterioration due to the strain incident to the prosecution of the World War. An outstanding feature noted by attending surgeons in making the annual physical examination of all officers, including general officers, now required, was "the persistently large percentage of officers showing either excessively high or abnormally low blood pressure." Symptoms of physical deterioration noted by the staff of the attending surgeons included: Instability of the nervous system, characterized more particularly by affection of the vasomotor system; an unnatural tendency to worry, fatigability, low blood pressure and lowered resistance to all infectious diseases. The blood pressure of those officers who served in the A. E. F. who were over 45 years of age was materially raised, and in a majority of cases abnormally so, and in the case of younger officers, 25 to 30 years of age, was in the same degree decreased.

Public Health Officials Discuss Venereal Diseases.—A week's conference of physicians, public health officials and social workers was held in Chicago, beginning March 13, under the auspices of the United States Public Health Service. The conference divided its attention between consideration of the medical methods for curing the diseases and of social work to do away with conditions encouraging spread of them. During the week a number of clinics were given and visits made to dispensaries and hospitals.

Public Health Laboratory for Plattsburgh.—David Merkel of Plattsburgh has presented the city with $1,500 to be used for the establishment of a public health laboratory. The gift is to be a memorial to the donor's parents, Isaac and Jeannette Merkel. It will be situated at the Champlain Valley Hospital.

Hospital Notes.—Ground has been broken for a new $1,000,000 hospital, which the Sisters of St. Mary will erect on their site on Clayton Road and Belleview Avenue, St. Louis. The new building will be seven stories high and accommodate 200 patients.

The directors of St. Joseph's Hospital, Elmira, N. Y., announce that the construction of a new $150,000 hospital building will be commenced within the next two months.

The Newman Memorial County Hospital, Emporia, Kan., erected and equipped at a cost of about $300,000, was recently opened for the reception of patients.

A new $250,000 Biltmore Hospital at Asheville, N. C., will be started in the near future. The hospital will have 100 beds in addition to isolation wards, and will include in all eight buildings.

Work has been begun on additions to the Government Psychopathic Hospital at Lenwood, Ga. The cost of the additional buildings is estimated at $250,000.

Mrs. Frederick M. Thompson of New York has authorized the erection and equipment of a maternity annex to the Canandaigua Memorial Hospital, Canandaigua, N. Y. The contract has been awarded to the engineering firm of Elliot C. Brown & Co. of New York.

The Woodlawn Hospital, located at Fifty-fourth Street and Third Avenue, Birmingham, Ala., was formally opened on March 16. Dr. J. H. Stephens is the owner of the hospital, which is prepared to care for thirty patients.

A charter has been granted by the Secretary of State to the Sealy and Smith Foundation of the John Sealy Hospital, Galveston, Tex. The purpose of the newly incorporated foundation is the construction enlarging, remodeling, and equipping of the John Sealy Hospital and other hospital buildings in the city of Galveston connected with the John Sealy Hospital.

A new building at Sheboygan, Wis., has been completed and will be formally opened in the latter part of April for the housing of a group clinic. About thirty physicians, surgeons, specialists and nurses will constitute the staff of the new clinic.

The Board of the Virginia Baptist Hospital have awarded the contract for a hospital to be located at Lynchburg.

An addition to the Chambersburg (Pa.) Hospital has just been completed at a cost of $90,000.

A modern hospital for the treatment of cancer, to be known as "The Columbus Cancer Hospital," is to be erected at 340 East State Street, in that city.

This site has been leased by Dr. Charles F. Bowen for ninety-nine years.

The Board of Aldermen of New York City have authorized the Commissioner of Public Welfare to make improvements in the Sea View Hospital, Staten Island, necessary to accommodate tuberculous patients from the Fox Hills Hospital, recently abandoned by the Government. The United States Public Health Service has agreed to pay the city $3 a day for each such patient.

The city of Baltimore has acquired a site near Lake Montebello, upon which a hospital for contagious diseases will be erected at once.

The El Paso (Tex.) Masonic Hospital Association has received its certificate of incorporation. The association was formed for the purpose of purchasing the Rolston Hospital, the price being $130,000.

Dinner to Dr. Baker.—With the rounding out of twenty years of public service, the friends and admirers of Dr. S. Josephine Baker, Director of Child Hygiene, New York City Department of Health, are making plans for a testimonial dinner to be given in her honor at the Hotel Commodore on April 20. The committee, of which Dr. Henry Dwight Chapin is chairman, announces that many organizations have already signified their desire to cooperate and thus show their appreciation of the wonderful work that has been accomplished under Dr. Baker's guidance in the reduction of the death rate of mothers and babies and general work among the children of New York City.

Dr. Bertrand E. Roberts has been appointed epidemiologist of the State Department of Health, to succeed Dr. Edmund Boddy, resigned.

Dr. H. Earl Rogers has resigned his position as a member of the city health department of Dallas, Tex., and will enter the private practice of medicine in New York City.

Harvey Society Lecture.—Dr. Raymond Pearl, professor of biometry and vital statistics, Johns Hopkins School of Hygiene and Public Health, will deliver the ninth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, April 8, 1922. His subject will be "The Interrelations of the Biometric and Experimental Methods of Acquiring Knowledge; with Special Reference to the Problem of the Duration of Life."

The American Proctological Society will hold its twenty-third annual meeting at St. Louis, Mo., May 22 and 23, 1922, under the presidency of Dr. Granville S. Hanes of Louisville, Ky. The Society extends a cordial invitation to the profession to attend its public sessions.

Obituary Notes.—Dr. SAMUEL RAPP of New York died of heart disease at Atlantic City on March 19, at the age of sixty-seven years. He was graduated from Bellevue Hospital Medical College in 1879, and for more than forty years was attached to the Mount Sinai Hospital advisory staff. He was a member of the American Medical Association.

Dr. WILLIAM F. LEHMAN died at Chester, Pa., on March 3, at the age of sixty-three years. He was graduated from Jefferson Medical College in 1883.

Dr. CHARLES W. ARTHUR of Plattsburgh, N. Y., a graduate of the University of Vermont College of Medicine, Burlington, in 1865, died about March 5, at the age of seventy-eight years.

Dr. L. H. DAVIS, ship surgeon of the Munson Liner Pan-Americ, died of apoplexy aboard ship on March 12. Dr. Davis formerly resided in Millerton, N. Y., and served in the Medical Corps during the late war.

Dr. JAMES W. WARE, formerly of Bayonne, N. J., died at Cape May, N. J., on March 15 at the age of fifty-four years. He was graduated from Jefferson Medical College in 1895. He was at one time resident physician to the Shenandoah (Pa.) Hospital and a member of the staff of the Greenville (Pa.) Hospital.

Dr. R. B. HARRISON of Loudon, Tenn., a graduate of the Vanderbilt University School of Medicine, Nashville, in 1921, died of pneumonia on March 2, at the age of twenty-five years.

Dr. JOHN J. MAZZA of Bangor, Pa., a graduate of the Medico-Chirurgical College, Philadelphia, in 1910, died on March 12, at the age of thirty-three years.

Dr. CHARLES A. BEEBE, a retired physician of Fond du Lac, Wis., died at Chicago on March 6, at the age of fifty-nine years. He was a graduate of Western Reserve University School of Medicine, Cleveland, in 1882.

Dr. WILLIAM PALMER PATTERSON, a graduate of University and Bellevue Hospital Medical College in 1909, died of heart disease at his home in Newark, N. J., on March 21, at the age of forty-six years. He was a member of the American Medical Association, and attending physician at the Newark City Hospital.

Dr. THADDEUS MARSHALL BROOKS CROSS, a retired New York physician, died at the Peter Bent Brigham Hospital in Boston, on March 15, at the age of eighty-two years. He was graduated from Harvard College in 1863, received the degree of A.M. from that institution in 1866, and was graduated from Bellevue Hospital Medical College in 1868. He was formerly attached to the staff of Bellevue Hospital.

Dr. ANNA CRAIG died suddenly on March 21 at the State Hospital, Kings Park, L. I., at the age of sixty-two years. She was graduated from the medical department of the University of Michigan in 1893.

Dr. WILLIAM LAWRENCE CUTHBERT, retired, died at his home at Long Beach, Cal., on March 10, at the age of ninety-one years. He was a first assistant surgeon in the Civil War and first health officer of Long Beach in 1898.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

AMERICAN MEDICAL CITIZENSHIP VS. THE AMERICAN MEDICAL ASSOCIATION.

To the Editor of the Medical Record:

Sir:—My county society, the Medical Society of the County of Kings (N. Y.) does *not* believe that membership in a County Medical Society robs a doctor of his *right* or absolves him of his *duty* to warn his brothers in the profession, directly, or by addressing any and all the county medical societies in the country, in warning of danger which threatens from the "wreckers from without" and the "borers from within" the medical profession; and to use any means, consistent with American citizenship, to strengthen the medical salient of the American line of defense against the forces of disorder which have been flooding the State and national legislatures with measures prepared, ostensibly, for the "brotherhood of man" and really designed for his political control, through his most precious possession, *health*.

Where does *your* county medical society stand? What do you, as an American citizen, think of the attitude of the board of trustees and judicial council of the A. M. A. (*Jour. A. M. A.*, lxxviii, 7, page 516) in challenging the right of the advisory committee, made up of American medical citizens, members of their county medical societies, and fighting *your* fight against vicious miscalled "welfare" legislation which would rob you of your self respect and economic independence, impair the dignity of your order, the health safety of your people, and the security of the State and nation we are bound to sustain, either as individuals or banded together, as such medical advisory committee, to criticise and demand (*a*) change in the leadership and policy of the American Medical Association; (*b*) elimination of the Scientific Section bloc of fifteen non-representative, administration-created, administration-hand-pickable, and administration-controllable delegates which has the capacity to neutralize and nullify the will of fifteen States having one vote each; or New York and Michigan; or Ohio and Pennsylvania; or Illinois, Michigan, and Wisconsin; or Massachusetts, Missouri, California, and Minnesota; or any other combination of States totaling fifteen voting delegates; and (*c*) the maintenance of the board of trustees at nine members and the reduction of the term to two years (instead of three) and the election of four trustees one year and five the next in order to frustrate an attempt, begun last June and coming up for determination this year, to reduce the trustees to seven (making a closer corporation) and extend the term to seven years (perpetuating an oligarchy)? What do you and your county medical society know of the "team work" of leadership and policy through which there was forged by the Reference Committee on Legislation and Public Relations, sharpened by the chairman of the judicial council, and passed by a house of delegates suffering from "super-delegatosis," a weapon of offense against our profession and the people we serve, which was so used at the National Capitol, to confound those of us who were (*where the A. M. A. should have been, but was not!*) before the (Winslow) House of Representatives' Committee on Interstate and Foreign Commerce at the hearing on the Sheppard-Towner Maternity (Birth Control?) bill, opposing its enactment.

Do you realize that a resolution, opposing State medicine and defining its limitations, which had been adopted by the New York State Medical Society and indorsed by Illinois, Michigan, Massachusetts, and New Hampshire, representing more than one-fifth of the population of the nation (nearly 24,000,000 people), was deliberately scrapped, as was also a similar resolution prepared by a subcommittee of the Reference Committee on Legislation and Public Relations, and acceptable to the audience at the hearing, and that there was submitted "as a substitute for all resolutions," by that same Committee on Legislation and Public Relations, a resolution which, when amended by a motion of the chairman of the Judicial Council, which cut off the tail and added a coccyx, read and was adopted thus:

> *Resolved*, By the House of Delegates of the American Medical Association, that it approves and endorses all proper activities and policies of the State and Federal Government, directed to the prevention of disease and the preservation of the public health.

Do you realize that when Hon. Everett Sanders, of the Congressional Committee, said of that resolution: "That resolution is not a *condemnation* of any activity of the Federal Government, but is a *specific indorsement* of the activities and policies directed toward the preservation of public health, and this was in June, 1921," he realized (as you must) that the American Medical Association, through false leadership and policy and organized "team work" played right into the hands of the propagandists of the Sheppard-Towner Maternity Bill . . . "and now you know that they never can know and never can understand" the viewpoint of the rank and file (you) because they have acquired a contempt for the gullible, trusting, hero-worshipping medical-babes-in-the-woods, through whose admiration for their past performances in the field of scientific medicine these leaders have risen to positions of honor and acquired the power to subvert the function of the national medical organization to the purposes of the "wreckers from without," and that they are responsible to you and your county medical society, and to me and mine, for the natural consequences of their acts.

This was merely the culmination of a long series of incidents, covering several years, and yielding evidence of culpable disregard of the duty of guardianship on the part of individuals, acting as such and as "team-mates." Some definite shaping of the issues between the American medical citizen and the American Medical Association became imperative, and a medical advisory committee of American medical citizens was formed. Its personnel embraces men who have been active along the same lines as the present writer, whose work during the past several years in developing the power of organized medical citizenship, in the States of New York and New Jersey, by means of the professional guild idea and its capacity for making missionaries of hitherto docile medical practitioners and *sending them to their people with the facts*, was a material factor in changing the profession of medicine in New York State from a

"joke" (March 19, 1919) to an institution of civic force (April 7, 1920), because the legislators and their leaders and advisers "heard their master's voice" in November, 1919, when our enlightened and informed people spoke the language of *votes*.

This medical advisory committee asked the county medical societies of the country to adopt the resolution which follows and which was presented by me to my county society (the Medical Society of the County of Kings, N. Y.) in February, and made the special order of business of the March 21 meeting (and adopted):

Whereas, the public and profession are being sold out to: (1) Foundation control of "full time" medical education. (2) Lay board domination and the "closed shop" hospital. (3) Socialized state medicine, subsidized community health centers, and hospitals under political and university control. (4) Legislative dictation of therapy and fees. (5) Demoralization of medical standards by the expansion of cults. (6) Exploitation of the specialties by lay technicians.

Therefore, Be It Resolved, That all the delegates from the Medical Society of the County of Kings (N. Y.) to the Medical Society of the State of New York, and all such delegates who may be elected delegates to the A. M. A. meeting in St. Louis, Mo., May 22-26, 1922, are hereby instructed to vote for: (*a*) A change of policy and leadership in the A. M. A. pledged to the immediate abolition of the evils mentioned, and constructive protection of medical interests. (*b*) The repeal of multiple representation and plural voting privilege by the Section delegates. (*c*) The election of trustees for a period of two years; five trustees to be elected one year and for the next, to prevent the trustees from perpetuating oligarchical rule.

Be It Further Resolved, That copies of these resolutions be sent at once to the *New York State Journal of Medicine*, the *Journal of the A. M. A.* and the Medical Advisory Committee.

NOTE.—The secretary of the Medical Advisory Committee is F. H. McMechan, M.D., Lake Shore Road, Avon Lake, Ohio.

We are humble "Paul Reveres" trying to arouse you "Minute Men" to a realization of danger to you, your order, your people, and the State and nation. Just what is it that makes the medical salient the *locus minoris resistentiæ* of the American line of defense against the forces of disorder? Too much professionalism and too little citizenship. Too much reverence for past performances in scientific medicine and too little "checking" up of present conduct of medical affairs by those we have reased to leadership. The *Twelve* made the same mistake when they elected Judas Iscariot treasurer, because of his past performances in the field of finance.

JOHN J. A. O'REILLY, M.D.
405 UNION STREET, BROOKLYN, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 10, 1922.

Women Medical Students.—Several of the large teaching hospitals of London do not admit women as students, the excuse being generally that owing to the influx of those desiring to enter the profession of medicine since the war there has been no room. But these are by no means all the reasons, there are objections both on the part of teachers and men students to the admittance of members of the female sex. It is said that it causes embarrassment to the teacher to discuss before a mixed class certain medical subjects, such as venereal diseases for instance, and also embarrasses the men students. Discussion on the matter has been going on for some time, but has been brought recently to an acute stage by the decision of the authorities of the London Hospital, the largest in London, to admit women students no longer. The London Hospital was the only big medical school of the metropolis which allowed mixed classes. The ruling of the London Hospital has aroused quite a storm, which is fanned by the lay papers, and, of course, most diverse views are expressed. At a meeting of the governors on March 8 last of the Elizabeth Garrett Anderson Hospital for Women, Euston Road, London, opinions from the women's standpoint were freely ventilated. Mrs. Ogilvie Gordon, in alluding to the action of the London Hospital authorities, said it was a great misfortune that one of the finest and best metropolitan hospitals had decided to discontinue the admission of women students. The closed places in the Indian Empire would remain closed were it not for the medical women, and they would be needed presently too in the unhealthy places in the outposts of the empire to which boys were being sent and to which later the boys would have to go also. Mr. Gordon Pollock, chairman of the hospital, said he did not think they need take any notice of the action of the London Hospital. There must be something wrong with the institution if it could not get on with the women students. He had been told by a number of doctors that they found when there were women students in their classes the men put more zest into their work. They were a little afraid of the powers of work of the women students, who usually had a limited amount of money and had to get there by working all the time. When he first became interested in the Elizabeth Garrett Anderson Hospital there were only seven women on the medical register of England and Wales and now there were something like 2,000. That proved there must be some need for them. All of them appeared to be very busy and a number of them confessed to making quite pleasant little incomes. However, the point concerning which the controversy rages is not as to whether the female medical practitioner is needed; that point has been settled, she is needed, but as to the best means of educating her and the male student to the best advantage. Are exclusive or mixed schools most to be desired? The argument hinges on this point. It is stated in the *Lancet*, Oct. 23, 1920, in an annotation dealing with co-education in medicine that, according to the authorities of one of the mixed medical schools, if women are to become doctors and to work in conjunction with the present members of the profession on insurance and other committees, it is highly desirable that they should learn the same thing in the same place and not be segregated in schools of medicine for women only."

One feature of the situation seems to have been overlooked in the discussion, that all the largest and best medical schools are reserved for men students and that consequently women students are at a disadvantage in this respect. The only exclusive medical school for women in London is

that attached to the Royal Free Hospital, which is neither large nor prosperous. Now that the London Hospital has shut its doors to female students, practically all the large, well equipped London hospitals, with their wealth of clinical material and first-class teachers, are not available for women. As all questions of moment, this question has two sides, and it is difficult to pass a decided opinion on the matter. Time alone will show whether the results of the exclusive schools and the mixed schools, respectively, justify the policy of the former, although as has just been pointed out, the exclusive women's medical schools are in many ways considerably handicapped.

What Is the Influenza Problem?—The influenza problem is one which concerns the whole world, and, to speak frankly, seems as far from its solution as ever. Of course, the general public of all countries are exasperated at the comparative futility of the medical profession to deal successfully with epidemics of the disease, either from the preventive or curative standpoint, and especially from the preventive point of view. But, as said before, the disease is world-wide, and it may be added that the inability to control it is likewise world-wide. In *Health* for March 22 the following apt remarks are made with regard to this infection. It is not many years ago that we failed to control smallpox or plague, for example. Not long since we did not even know that bacteria existed. Knowledge must come gradually. Meanwhile, do not pour forth futile criticism; help the research which is daily striving for human good. It may be well to point out one or two essentials of this so-called problem. Actually there are many more than one. It is not known why influenza takes on a world-wide march at irregular intervals. The infection may periodically change its virulence, pass through a cycle of infectivity, but why? Attempts to associate it with meteorological conditions have so far failed, whatever the papers may say. We are not even certain that Pfeiffer's bacillus is the cause or even a cause. Bacteriologists have isolated it from many cases, but they have failed in the crucial test of inoculation in animals to reproduce influenza. Further, there is no characteristic symptom of influenza. It assumes many types. Have we any right to say these types all represent the same disease? Even upon the simple point of immunity conferred by a previous attack, evidence is absolutely discrepant. Why is one outbreak particularly fatal to one age period while the next deals death to a totally different section? Apart from all this, how are respiratory infections in general to be prevented under existing conditions of life? Truly, we do not know. Such a review is necessarily depressing, but it should be realized that influenza stands for an unconquered region of medicine so vast that the laying of blame to any professional organization and the dogmatic statements prevalent in certain quarters comes perilously near the ridiculous.

Presentation to Lord Knutsford, Chairman of the London Hospital.—An address was presented, on March 6 last, by the President, Vice-Presidents, House Committee and medical and surgical staff to Lord Knutsford to mark the completion of the twenty-fifth year of his chairmanship of the London Hospital and appreciation of the services he has rendered to that institution. Among those present and who gave testimony to his great services to the hospital was Lord Dawson, the well-known physician, who, speaking on behalf of the medical and surgical staff, said that between the years 1896 and 1903 the hospital buildings were modernized and recast, operating theaters and equipment representing all that modern knowledge could devise were created and thus rendered possible the high surgical skill for which the hospital was renowned. All these additions exemplified the alertness of the hospital under the chairman's inspiring leadership. This leadership found expression not alone in bricks and mortar, but in an infectious enthusiasm for medical progress and in determination that the London Hospital should be in the van of that progress. They rejoiced to think of that occasion, not as a farewell but a landmark of a great career. His enthusiasm, his vitality, his fun and his sense of humor had played no small part in its success. Lord Knutsford had differed on varying occasions from most of them, but never once had he failed in generosity and consideration. And who among them had not felt his kindness and sympathy on occasions innumerable? His understanding and help had encouraged many a junior in his early struggles. A Prince of Beggars, he had the instincts of the sportsman and the genius of the friend. He loved kindness, and, still more so, the doing of it. To him helpfulness was a privilege and the need his inspiration, and no small part of his service to the hospital had been his example of high and warm-hearted endeavor.

It may be added that Lord Knutsford is an example of what one man can do for an institution. The London Hospital is the largest in Great Britain and has one of quite the largest out-patient departments of the world. It is also one of the poorest. Its endowment is trivial and it is practically dependent on voluntary contributions. When Lord Knutsford, then Mr. Sydney Holland, took the reins of management twenty-five years ago the hospital was in a parlous condition. Almost wholly through his untiring energy and gift for organization he not only succeeded in obtaining sufficient money to conduct the hospital in a proper manner, but raised the money for the rebuilding scheme which cost nearly £1,000,000. In fact, at the present time the hospital is completely equipped and up to date in every department. Lord Knutsford, during the past few years, has struggled hard to maintain the services of the hospital, but the task has been too great. When it is considered that hospitals with large endowments are in difficulties, it is not a matter for wonder that the London Hospital, situated in the midst of the poorest district of London and with scarcely any income should be in a similar predicament. Lord Knutsford has thoroughly well deserved the tribute just paid him.

Women Doctors in Asylums.—At the recent conference on Lunacy Reform, convened by the Chairman of the Board of Control, the position of women doctors in asylums was made the subject of a somewhat stormy discussion. The opinion

of one of the medical superintendents is worth quoting. He said in part, that he had invariably found that the woman doctor was capable, well-informed, painstaking, energetic, and keen. On the other hand, he was compelled to admit that she had her disabilities, her limitations. Associating with her as he had done for so many years, he was afraid that her judgment was apt to be hasty and based on insufficient evidence; that she was often lacking in a sense of proportion, and, on reading her case book notes he had frequently observed that she gave undue prominence to comparatively unimportant details, while neglecting or failing to grasp essentials. It was extraordinary, but his experience had been that the patients and staff had not that confidence in her that they had in her male colleagues, and in cases of serious illness they preferred to be treated by the medical man. He would qualify this statement, however, for in one or two instances there had been brilliant exceptions to the general rule. This view was not entirely in unison with that of other speakers. One of these declared that women were rather apt to worry over things, and to be over-anxious, but that was not a bad quality. Another speaker held the opinion that women should certainly take their share in this work, and went so far as to say, that he saw no reason why they should not become medical superintendents. Mrs. Martyn, one of the speakers, said that women were demanding that in every mental hospital where there were women patients there should be one woman medical officer. She added, "Some people tell us that if men behave very well in this world, in the next incarnation they will be women."

Ophthalmological Congress.—This Congress will assemble at Keble College, Oxford, on the evening of July 5 and the meeting will be held on July 6 and 7. On July 6 a discussion on the "Significance of Retinal Hemorrhages" will take place, to be opened by Dr. C. O. Hawthorne and Mr. P. H. Adams. The Doyne Memorial Lecture will be delivered on the morning of July 7 by Mr. J. Burdon-Cooper, the subject being the "Etiology of Cataract."

3. Concerning the Type of Injury to Renal Epithelial Cells Which Increases the Susceptibility of the Cells to the Action of General Anesthetics. William deB. MacNider.
4. Acute Puerperal Inversion, with Report of a Case. Joseph P. Cohen.

1. Acute Pancreatitis.—Daniel Fiske Jones cites experimental and clinical evidence which leads him to the belief that there are probably two types of acute pancreatitis, with quite different etiology—namely (a) interstitial pancreatitis due to infection of the interstitial tissue, the infection coming frequently from the biliary system, and (b) pancreatic necrosis, a necrosis of the parenchymal cells, due to retrojection of bile into the duct of Wirsung or duodenal contents into the duct of Santorini. The treatment of the interstitial type, due to an infection from a cholecystitis, is cholecystectomy. The treatment of pancreatic necrosis is drainage of the fatty capsule of the pancreas and the pancreas itself. In addition, if the condition of the patient will permit, either the sphincter of Oddi may be cut, a choledocostomy or a cholecystostomy done, depending upon the condition of the patient and the condition of the gall bladder and ducts found at operation.

2. The Indications for Operation in the Treatment of Injuries Involving the Brain.—Donald Munro states that the indications for operation in injuries involving the brain are three: Compound fracture of the skull, depressed fracture of the skull, and a rise in the intracranial cerebrospinal fluid pressure. Patients who have received an injury to the brain do not develop symptoms and do not die from the fracture which may or may not be present in the bones of the head. They do develop symptoms and they do die as a result of the increase in intracranial pressure which accompanies the fracture, or which not infrequently is present in the absence of any fracture. The intracranial cerebrospinal fluid pressure depends on the relation between the secretory powers of the choroid plexus and the absorptive powers of the cerebral venous circulation. All cases that have received or are suspected of having received an injury to the brain, no matter how slight, should, as soon as they have recovered from their surgical shock, have the pressure of their cerebrospinal fluid measured, and the treatment should be based primarily upon this finding alone. If the intracranial pressure is measured, the symptoms and signs, such as pulse, blood pressure, respiratory rate, and mental state, commonly used as indications governing diagnosis, treatment, and prognosis, need not and should not be regarded in any other light than as confirmatory evidence.

3. Concerning the Type of Injury to Renal Epithelial Cells Which Increases the Susceptibility of the Cells to the Action of General Anesthetics.—William deB. MacNider has made observations on dogs which indicate that primary injury to the kidney develops in the glomeruli. The earliest evidence of secondary injury to the renal epithelium consists in a marked accumulation of stainable lipoid material in these cells and, especially, the secretory cells of the convoluted tubules. When naturally nephropathic animals are anesthetized by chloroform or ether, and the effect of these anesthetics on the kidney is contrasted with the effect of the same anesthetics on the kidneys of normal control animals, a parallel is found between the toxic action of the anesthetics for the two groups of animals and the amount of stainable lipoid that can be demonstrated in the stainable epithelium. In the kidneys of the naturally nephropathic animals, in which the amount of stainable lipoid has greatly increased in the renal epithelium secondary to the glomerular injury, the anesthetics induce an early degeneration and death of these cells and urine formation is arrested. In the normal control animals, in which only a small amount of stainable lipoid can be demonstrated in the loops of Henle, such degenerative changes do not occur, and these animals form urine during the period of anesthesia. The Meyer-Overton law would appear to apply to cells in this location as well as to the central nervous system.

11. A Case of Hypothyrosis in an Infant. Alvin E. Siegal.

1. Effects of Faulty Foods on Endocrine Glands.—Robert McCarrison, in the course of feeding experiments in animals, has observed that malnutrition, whether rising from complete starvation, from the incomplete starvation due to avitaminosis, or from star-

vation resulting from deficiency of proteins and calories, gives rise to enlargement of the adrenal glands and sometimes of the pituitary body with an atrophy of all other endocrine structures. The functional perfection of the adrenal glands is dependent upon the balance of the food and the quantity and quality of its vitamines. It was noted that in pigeons fed on mixed grain and butter, but without onions, that the incidence of goiter was 65 per cent. Free, unsaturated, fatty acid—oleic acid—is in certain cases peculiarly potent in respect to goiter production, while cod-liver oil containing 0.002 per cent. of iodine is peculiarly beneficial in respect to goiter prevention; both point to iodine as a common factor concerned in the result. So far as butter and oleic acid are concerned, an intake of iodine approximately proportionate to the intake of these fats in the food is requisite for the maintenance of normal metabolism, and for the normal functional perfection of the thyroid gland. A relative deficiency of iodine may be brought about by an excess of edible fat or of free oleic acid in the digestive tract. Faulty food permits the entrance into the blood of a stream of intestinal bacteria, which, acting on the thyroid, may cause congestion of the organ, desquammation of its acinar cells, and distortion of its normal acinar structure. Indeed, it is possible by the examination of the thyroid alone, with but a small percentage of error, to distinguish between those deficiently fed animals that have suffered from septicemic states in consequence of food faults and those which have not.

2. The Effect of Endocrine Derangement on the Dental Tissues.—F. W. Broderick points out that if the endocrine apparatus is thrown out of balance in the direction of calcium starvation, the reserve store of calcium is diminished, and fixation of lime salts in the teeth is interfered with. An upset in endocrine balance in childhood, youth, and pregnancy will be in the direction of calcium starvation. Calcium starvation will lead to a diminished calcium index in the saliva, with a lessened alkalinity of that secretion, thus directly leading to caries. Endocrine derangement, leading to a loss in balance toward calcium starvation, will tend to cause a condition of acidosis by lessening the alkali reserve of the body; in the compensation of this condition the calcium salts, together with other alkaline salts, will be used for acid neutralization, and therefore not available for hypercalcifying teeth. If the acidosis be more severe, built up and fixed inorganic lime will be torn away from bones and teeth to help build up this alkali reserve, and thus preserve life, lowering the resistance of the teeth to caries. Without this susceptibility to caries, exciting causes, i. e. food fermentation matter not at all, but if immunity be removed hardly will any reasonable care and attention preserve them entire. Endocrine derangement will account for all the conditions leading to dental caries, whether they may be diet, lack of vitamines, altered salivary secretion, or what not.

9. Anaphylaxis and the Endocrines.—Henry R. Harrower concludes that anaphylaxis, or protein sensitization, may involve the endocrine glands, and a part of the reaction connected with these idiosyncrasies may involve the ductless glands. Hypoadrenia of anaphylactic origin needs to be treated like adrenal insufficiency of any other toxic origin. Occasionally protein sensitization may be overcome by the establishment of an immunity, as is routinely done in the treatment of hydrophobia or the administration of bacterial vaccines. In vomiting of pregnancy, placental substance administered over a period seems to favor an immunity to placental proteins and a control of toxic irritability. Occasionally prophylactic measures bring about an anaphylactic reaction, particularly in patients already sensitive to other food proteins. Whenever a clinical hint attracts attention to protein sensitization, the endocrines should be studied and brought into the matter both from the viewpoint of diagnosis as well as treatment.

10. The Incidence of Syphilis in Hypothyroidism and Myxedema in Children.—Murray B. Gordon calls attention to several instances in the literature in which a hypothyroidism was probably produced a syphilitic infection as both conditions were coexisting and disappeared simultaneously under thyroid and antisyphilitic treatment. He finds that syphilis is not of great etiological significance in the majority of instances of myxedema and hypothyroidism in children. However, it is possible for syphilis to attack the thyroid gland with the production of these conditions. In a series of forty-two cases of hypothyroidism and myxedema in children both the luetin and Wassermann tests were performed with the result that 12 per cent. were found to be positive, an incidence of syphilis considerably higher than that placed by Jeans for the general infant population, which showed five to six per cent. of infants affected with syphilis and a higher percentage in older children.

4. Palliative Control of Gastric Crises of Tabetic Neurosyphilis by the Rectal Administration of Chloral Hydrate and Sodium Bromide.—Albert R. MacFarland reports that since he has used large enough doses of these drugs, and learned the safe interval of administration of this combination, he has achieved results at least as good as those with morphine in the majority of cases, and the grave risk of developing morphine addiction has been avoided. An aqueous solution of chloral hydrate and sodium bromide is prepared so that one-half ounce (15 c.c.) of the fluid contains 40 grains (2.6 gm.) of each drug. For persons weighing more than 150 pounds as much as 60 grains of each drug at one dose may be administered. The injection is introduced six inches into the rectum by gravity pressure, through a catheter. The administration of the chloral and bromide gives relief from both pain and vomiting for from two to five hours. In no instance has the development of an appreciable immunity to these drugs been noted. Gastric lavage seems to be a valuable adjunct to the treatment.

5. Desensitization of Hay-Fever Patients by Specific Local Applications.—George M. Mackenzie describes a method of preparing pollen extracts which contain from 75 to 150 mg. of nitrogen per 100 c.c. The extracts are standardized by content in nitrogen, a method first suggested by Cooke and Vander Veer. For routine use four strengths were used, containing respectively 0.01, 0.1, 1.0, and 10.0 mg. of nitrogen per 100 c.c. A group of 38 patients, 35 with late hay-fever, treated with ragweed extract, and three with early hay-fever, treated with timothy extract, were divided into three groups. Eight were treated by subcutaneous injections alone; 10 were treated by local applications alone, and 20 were treated by both subcutaneous injections and local applications. The routine method was to give the injections twice a week, beginning with the weakest of the four stock solutions, gradually increasing the amount and then the strength of the solution until several injections of 0.5 to 0.7 c.c. of the solution containing 10 mg. of nitrogen per 100 c.c. had been given. For the local applications the patient was given an ordinary atomizer and instructed to spray the nasal passages night and morning, beginning with the weakest solution. It soon became clear that the reactivity of the nasal mucosa could be greatly diminished by the spray alone. In several instances patients were eventually able, after eight to ten weeks of spraying, to use freely a solution 1,000 times stronger than the one which at the onset has caused symptoms when used in small amounts. In the series of patients given specific prophylactic treatment by this method, the results compared favorably with those in the series of patients treated by specific subcuta-

neous injections, but were less satisfactory than when a combination of the two methods were employed.

9. Blood Pressure Findings in Circulatory Disorders of the Extremities.—Bertram M. Bernheim states that in the last analysis the various groups of circulatory disturbances of the extremities—Raynaud's disease, arteriosclerosis, diabetes (with sclerosis), senility, thrombo-angiitis, etc.—exhibit many features in common, the treatment is unsatisfactory, and the end result the same. Blood pressure readings taken on patients suffering from a variety of circulatory disorders of the extremities indicate that, far from exhibiting a rise, many of them reveal a low pressure, extraordinarily low in certain instances, while most of them present a normal pressure. Once in a while a slight elevation is encountered. Almost never does one see a real hypertension. This is just the opposite of what one might have expected, in view of the fact that a compensatory elevation of blood pressure is frequently seen in generalized arteriosclerosis and in certain forms of heart and kidney disease. The relation of these findings to ischemic conditions of the legs may be interpreted in two entirely distinct ways. It may be argued, on the one side, that in circulatory derangements exhibiting obstruction to the blood flowing toward the lower leg and foot the blood pressure does not rise, the vis a tergo fails to increase, and so no opposition is offered to the further encroachment of the disease process. The result, unless successful treatment is given, is gangrene. On the other hand, it is just as logical to suppose that in the vast majority of disease processes affecting the blood vessels of the extremities there does occur a compensatory rise in the blood pressure, and that, as a consequence, the threatened and real gangrenes do not come to pass. Only where this rise fails to materialize do we see the gangrenes. The latter theory might well account for the failure to find these disasters among the many hypertension victims. It may be that in the blood pressure we may have the explanation of certain obscure features connected with the production of the threatened and real gangrenes. The blood pressure element in all cases of threatened and real gangrene is apparently of more importance than has heretofore been recognized. It may be that present methods of treatment, such as they are, will have to be revised, and a more rational therapy, one that conforms to the actual state of affairs existing, instituted.

3. Gamma Rays and Malignant Disease.—Reginald Morton has treated more than 300 cases by the Erlanger method during the past year and feels justified in making the statement that this is not only the best system of *x*-ray therapeutics yet devised, but is probably the most important recent contribution to the solution of the problem of malignant disease. He points out, however, that the system has its limitations; it is of little use where the general health is seriously impaired; no important success, for instance, has attended efforts to deal with carcinoma of the stomach. It is also of no help where the disease is extensive or after dissemination has begun. The conditions favorable to success are as follows: (1) The general health of the patient; (2) the lesion must be localized to a reasonably small area and treated before it has begun to invade widely the adjacent tissues, and before there is any distant dissemination; (3) the technique must be carried out accurately and completely at one sitting, so that every part of the lesion receives the requisite dose; (4) the health and well-being of the patient must be carefully controlled subsequent to irridiation. If all these conditions are present, it may be laid down, almost as an axiom, that the malignant growth will disappear, and with but a trifling disturbance of the patient's ordinary life. As to the relative advantages of surgery and radiology for the relief of victims of malignant disease, Morton believes that there are grounds for thinking that before many years surgery may become auxiliary to radiology. Speaking broadly, even now it is possible that radiology can do more than surgery under equally favorable conditions; it is at least significant that in the Erlangen Frauenklinik, where surgical methods have been definitely abandoned for cases of malignant disease of the female pelvis in favor of *x*-ray treatment, greatly improved results have been obtained. Evidence is overwhelming that radiology can be of the greatest assistance in dealing with malignant disease, and recognition of this fact should lead surgeons and gynecologists to seek the radiologist's cooperation immediately the nature of the case is determined and before any treatment has been applied.

5. A Case of Sclerema Neonatorum.—Eleanor Bourne reports this case which occurred in a new-born child. The clinical picture given by most writers is that the skin progressively becomes waxy, leathery, rigid, and adherent to the underlying tissues, the temperature falls, pulse becomes poor, food is not taken because the child cannot suck, all functions are impaired, the fontanelle becomes depressed, and the child dies in from two to ten days. In this case the typical symptoms were present. The treatment was based on the lines of overheating the child's bed to combat directly the subnormal temperature. Thyroid was given on the assumption that the symptoms were primarily due to acute functional failure (possibly transitory) of the thyroid. Rectal irrigations with sodium bicarbonate were given, partly to counteract acidity, and partly to remove toxins from the intestinal tract, the existence of intestinal stasis being shown by the passage of pure meconium as late as the fifth day. The relationship between intestinal stasis and thyroid insufficiency is shown by the common symptoms—complex of chilliness, inertia, headache and constipation, and pseudo-asthma. The relationship may constitute a vicious circle. Under this treatment the child was greatly improved when 6½ weeks old; at six months he was normal, except for weight, while at nine months he had reached the normal weight for his age.

6. The Application of the Methods of Correlation to the Study of the Urine.—Charles Powell White, believing that some light might be thrown on the composition of the urine and the process of excretion by the kidney by the application of methods of correlation, has computed coefficients of variation of different substances in fifty-two urines from twenty-two patients. The chief points suggested by this investigation are as follows: (1) The results obtained appear to favor most strongly the view that certain substances (sodium, potassium, chloride) are excreted in association with the water and hence through the glomeruli. Other substances (urea, uric acid, and sulphurous acid) are excreted independently of the water and therefore presumably through the tubules. Others again (phosphates, magnesium and calcium) appear to hold an intermediate position, possibly being excreted by both channels. This investigation thus supports the secretion theory rather than the filtration theory. (2) The association of urea with sulphuric acid and phosphoric acids is an interesting point which demands further investigation. (3) There is no indication of the excretion of uric acid as sodium urate, but there are indications of calcium and potassium urates. (4) Potassium appears to be excreted almost entirely as chloride, but some urate may be present. (5) Sodium is excreted as chloride, phosphate, and sulphate. (6) Calcium and magnesium are excreted as chlorides, phosphates and sulphates, and possibly also as urates. The chlorine was persistently above the mean. This suggests that the magnesium was absorbed and excreted as chlorine. (7) There are no indications of the excretion of alkali salts of ethereal sulphuric acids. The negative correlation between ethereal sulphuric acid and water requires further investigation. It seems probable that this method would lead to important results, but the labor involved is immense, as at least fifty specimens of urine should be used for the calculation.

7. A Case of Megacolon. E. R. Flint.
8. Gastroenterostomy and Some Dietetic Rules.

1. The Nature and Cause of Old Age Enlargement of the Prostate.—Kenneth M. Walker reviews the various theories to account for old age enlargement of the prostate, and concludes that it is impossible to explain it by any theory of chronic inflammation alone. Although enlargement may reproduce conditions favorable to the development of a neoplasm, the enlargement itself does not come into the category of true tumors. The condition is in the nature of a fibro-epithelial degeneration which finds its analogy in the female in serocystic disease of the breast. This degeneration may be regarded as an accident occurring in the progress of involution of the genital tract. The cause that determines the onset of the condition is unknown, although it is not improbably connected with a loss of endocrine balance occurring during this period. The writer's observations indicate that injections of extract of prostate in the human being do not produce any response in the way of alteration of blood pressure, respiration, etc. He has used both autolysit and commercial preparations of prostatic extract for this purpose and has never obtained a reaction that could be appreciated clinically. Incidentally, he mentions that he has found that prostatic extract, when employed as a therapeutic measure, is occasionally of use during the early phases of enlargement, but of little benefit in the later. Answers received to a questionnaire inquiring into the incidence of prostatic enlargement in the various countries of the world brings out the fact that prostatic enlargement shows a definite distribution that is anthropological rather than geographical in character. It very rarely occurs among Mongolians or Negroes. Generally speaking, enlargement is commoner among meat eaters and those leading the sedentary lives of cities than among vegetarians and frugal livers.

2. Metabolism of Children Undergoing Open-Air Treatment, Heliotherapy and Balneotherapy.—Leonard Hill and J. Argyll Campbell, with the cooperation of Sir Henry Gauvain, made these observations on children crippled with surgical tuberculosis and lying fixed in splints in bed and more or less nude, at Lord Mayor Treloar's Hospital, Hampshire. It was found that their metabolism on the average was increased 40 per cent. above the standard for the same weight of children confined in the closed calorimeter. After three months' treatment, including graduated exposure to open air and heliotherapy, their metabolism out of doors was 20 per cent. above that in well ventilated cubicles soon after admission. Children who had been treated for many months showed high metabolism in the out of door conditions, those who pigmented well in the sun giving about the same figures as those who did not pigment well, after making allowance for weight. The former gave the better figures for weight. It is considered that the rise in metabolism caused by heliotherapy *per se* is insignificant compared by that caused by exposure to open air. At the same time the value of heliotherapy as a factor toward the arrest of the disease is not disputed. Children on admission in well ventilated cubicles gave results about 20 per cent. higher than basal standards for closed calorimeters. It is considered that the open air conditions in the former were mainly responsible. The bodily tone and general condition of the children under the specially graduated treatment is remarkable when the long period of immobilization in splints in bed is considered. It is suggested that the treatment might be applied with advantage in other cases involving long confinement in bed.

6. Note on the Intrapleural Pressures in Artificial Pneumothorax.—James Lawton calls attention to a feature which has not, so far as he is aware, been noted and which deserves the consideration of those called upon to supervise the treatment of artificial pneumothorax cases, namely, the alteration which takes place in the intrapleural pressures with a change in the position of the patient. A consideration of the pressures in a number of cases investigated shows that there is a constant rise in the pressures when the patient is moved from the lateral to the dorsal position. The importance of this observation will be recognized when an attempt is made to reestablish a previous pressure. This obviously can only be done with certainty when the patient occupies the same position on both occasions. Emphasis must, therefore, be laid on the fact that any statement of intrapleural pressures must be accompanied by a statement of the position of the patient. Further, while the amount of the rise varied not only with the different cases, but in the same case, it was noted that the pressures were frequently doubled. In a few cases in which the pressures in the erect posture were investigated it was found that they approximated those found in the dorsal position.

Sexual Instinct and Erotomania.—Laignel-Lavastine states, following Freud, that the libido is the psychic phase of the sex instinct. In psychiatry the rôle of the latter is considerable. Sexuality colors delirium; its manifestations may become pathological from their intensity alone and may also be perverted. In connection with delirium with sexual content the author mentions the jealousy delirium of the alcoholic, which is known to the laity. "Erotic drunkenness" is the term used for the man who becomes infuriated by resistance to his approaches. This behavior has nothing in common with sadism, although suggestive of it. Satyriasis and nymphomania are hardly deserving of the term "excess of sexuality," being purely an expression of the much narrower genital instinct. Sexual perversion may be of so elastic a conception as to include concupiscence and everything outside of the desire for offspring. It may be conceived as making a game or sport out of a solemn function. The author gives his conception of erotomania, a term which is used very loosely. He means by it a psychosis in which a fixed idea predominates. It agrees in general with reasoning mania, which would have been a sufficient diagnosis to some of the older alienists, and the term monomania would have covered the condition with others. The cases cited by the author are complicated. One was that of a widow who had a supposed suitor. She conceived the fixed idea that a certain servant girl had been recommended only to keep her under observation and finally that the girl, the suitor, and others were conspiring to force her into marriage. In time she desired to spite the suitor for his supposed cowardly treatment of her and eventually shut herself up. She was finally interned. In other words, this woman although she may be said to have had "love on the brain" had no desire for any object of love and no love contacts of any kind, yet she had woven a most complicated systemized delusion about the supposed passion of a man for her.

Rationale of Mineralization in the Treatment of Cancer.—That some connection exists between the rate of cancer growth and the presence or absence of some of the normal salts of the body has long been felt, although data are hard to obtain. The apparent contradiction among data may be due to the fact that a rapidly growing cancer may show a mineral hunger, while in an old sclerotic cancer which is almost stationary there may be a deficit of the same salt. A. Robin, writing recently of silica, lime, and magnesia in connection with cancer, reports the results of certain experiments which show that cancer fixes these bodies to a notable extent. Since they doubtless are fixed only by the connective tissue which is antagonistic to cancer growth they may be regarded as assisting the natural defense.—*Le Bulletin Médical.*

Book Reviews.

PRÉCIS DE PARASITOLOGIE HUMAINE. Par M. NEVEU-LEMAIRRE, Professeur Agrégé des Facultés de Médecine, Chef des Travaux de Parasitologie a la Faculté de Médecine de Paris. Cinquième Édition Revue et Mise a Jour. Libraire Scientifique et Littéraire. Price, frs. 24.50. Paris: J. Lamarre, 1921.

THIS is a pocket size epitome of human parasitology that, so far as it goes, is more complete than any other book of its type with which we are familiar. After a few pages of general definitions the author takes up in systematic fashion all of the known human parasites. Chapter I on bacteria is very brief being scarcely more than a mention of the principal species. The bulk of the work is devoted to the fungi and the animal parasites. The principal genera and species are described briefly and a few words said concerning their pathogenicity and in some cases the treatment of the disease produced by them. The rarer, less important or imperfectly established species are each given a few lines sufficient to indicate their relative position in the scheme. So far as the mention of species is concerned the work is extraordinarily complete. There are numerous illustrations. No attempt is made to discuss cultural characteristics, methods of staining, etc. This edition has been thoroughly revised and the volume contains more material, though by changes in size of type it is actually smaller than the fourth edition. It should be very valuable as a handy book for rapid identification of fungi and animal parasites. We could wish that the author had been able to include in the text the references together with the names and dates in his listings of various species but suppose it would have added too much to the size and the cost of the book.

THE MEDICAL CLINICS OF NORTH AMERICA. Published bi-monthly by W. B. Saunders Company, Philadelphia and London. Price per year, $12.00. Volume 4, Number 6, May, 1921, Boston Number. Volume 5, Number 1, July, 1921, Chicago Number.

THE May number contains contributions from nineteen representative clinicians in Boston. The contributors are of such promience and their contributions so many that it is not possible to comment on each of them and not easy to select those of the greater importance. The ones that appealed to us as being most valuable are Christian's discussion of diuretics, Minot's presentation of two cases of anemia, Robey's talk on malignant disease of the lungs and Peabody's article on the vital capacity of the lungs in heart disease. Minot shows very well the method of reasoning that should be followed in the diagnosis of types of anemia and the futility of attempting to diagnose pernicious anemia solely by the examination of the stained blood smear. "Everybody" recognizes the truth of his conclusions but it is none the less necessary to emphasize them frequently.

In the July number Chicago contributes 272 pages of case reports and discussion from her foremost clinics. The article on pericarditis with effusion by Williamson is timely and thorough and gives us a new sign which should aid in its recognition. Bassoe's presentation of endocrine growth disturbance is interesting and well illustrated. Elliott shows what may sometimes be done in the treatment of myeloid leucemia. Gerstley reports a successful tonsillectomy in a thymus case and expresses his opinion that we have been too fearful of operating in these cases.

Both of these issues are good examples of the value of this type of publication when carried out in the proper way. The reader is presented with a brief discussion of a large number of subjects each of which is discussed with sufficient completeness to give him a fair idea of the topic and to stimulate him to further investigation of his own if he is interested in the subject.

COLLECTED PAPERS OF THE MAYO CLINIC, Rochester, Minnesota. Edited by Mr. M. H. MELLISH.. Vol. XII, 1920. Published September, 1921. Price, $12.00. Philadelphia and London: W. B. Saunders Company, 1921.

THE contributors to this volume number sixty, the majority of them workers at one time or another in the Mayo Clinic and also on the Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota, only eight of them being on the Foundation alone, and another eight in the Clinic alone. The contributions number 125, grouped under the headings: Alimentary Tract; Urogenital Organs; Ductless Glands; Heart; Blood; Skin and Syphilis; Head, Trunk, and Extremities; Nerves; Technic; and General. The wealth and variety of material contained in this volume of nearly 1400 pages are enormous and nearly every one, no matter what his special line of study, will find much here to attract his interest and increase his knowledge. A little out of the line of scientific communications, but of great interest is the account, by Dr. W. J. Mayo, of a trip to the principal capitals of South America with a description of the hospitals and medical schools in these countries. This paper and the article by Dr. Sharpe, recently published in the MEDICAL RECORD, reveal a field of intense medical activity in our own hemisphere which in the old days, when Berlin was the Mecca of the faithful, was unknown to us. A clear union with our neighbors to the south of us would no doubt be mutually beneficial and papers such as those mentioned will do much to promote this.

OBSTETRICS AND GYNÆCOLOGY. Edited by JOHN S. FAIRBAIRN, M.A., M.B., B.Ch. (Oxon.), F.R.C.P. (Lond.), F.R.C.S. (Eng.) Obstetric Physician, St. Thomas's Hospital; Lecturer on Midwifery and Diseases of Women, St. Thomas's Hospital Medical School; Physician to the General Lying-in Hospital, York Road, S. E.; Examiner in Midwifery and Diseases of Women to the University of Oxford and to the Conjoint Board of England; Member of the Central Midwives Board; Vice-president, Section of Obstetrics and Gynæcology, Royal Society of Medicine, etc. Price, $20.00. New York: The Oxford University Press, American Branch, 1921.

THIS is an encyclopedic treatise, or system, dealing with obstetric art and all matters relating to the diseases of women, written by a large number of contributors. Many of the latter are men known almost as well by name on this side of the Atlantic as in their own country, while the names of others, who are no doubt recognized as competent authorities by their British confréres, are not so familiar to their brethren in these specialties in America. The work is divided into seven parts, treating respectively of the Life History of the Female Reproductive Organs, Normal Reproduction, Abnormal Reproduction, The Infant, Diseases of Women, Public Health, Social and Medicolegal, and Operations and Other Therapeutic Procedures. It is impossible, in a notice of this length, to review all the articles or even one of the sections. The articles vary in importance and in satisfactoriness of treatment, as is invariable and to be anticipated in a work written by so many contributors, but we should say that, taken all in all, they are of an unusually high order of excellence. The work is intended more for the family physician, whose shadow, alas, is ever growing less, than for the specialist or consultant in obstetrics or gynecology, but even the latter will find a good deal to interest and perchance instruct him and may get some valuable hints from it that will help him famously in an emergency. The price of the book seems high, but thanks to the one-time German emperor and his advisers the cost of all medical books and every other necessity is high. There is an excellent index, filling forty-five of the 950 pages of the work.

DIATHERMY, ITS PRODUCTION AND USES IN MEDICINE AND SURGERY. By ELKIN P. CUMBERBATCH, M.A., B.M. (Oxon.), M.R.C.P., Medical Officer in Charge, Electrical Department, St. Bartholomew's Hospital, etc. Price, $6.00. St. Louis: C. V. Mosby Company, 1921.

THIS is a book of 193 pages and 44 illustrations. The eight chapters comprise an introduction, a historical note, accounts of production of current and installation, the physiological effects of diathermy, the elevation of temperature by diathermy, and the medical and surgical uses. The clinical discussion begins on page 65 and extends to the finish of the volume, numerous case histories being introduced. The author uses the Siemens model, Dean model, and the apparatus of the Medical Supply Association with Schall's portable. The latter requires a direct current, while the others are supplied by the alternating street circuit.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held December 20, 1921.

DR. SAMUEL BRADBURY IN THE CHAIR.

THE program of the evening was contributed by the Graduate School of Medicine of the University of Pennsylvania.

The Nature of the Wassermann Reaction in Relation to Its Clinical Value and Standardization of Technique.—Dr. JOHN A. KOLMER of Philadelphia made this presentation, in which he said, in part, that the Wassermann reaction occupied a very unique position among immunological phenomena. At first regarded as a specific reaction, it was now known to be biologically non-specific, but in most parts of the world this did not seriously reduce its diagnostic value in syphilis because the peculiar antibody-like substance in the blood or spinal fluid or both, and responsible for the reaction, was known definitely to occur only in syphilis and frambesia tropica or yaws. Infection with spirochetes of these two diseases resulted in the elaboration of a substance aptly called "reagin" by Neisser, which had the property of uniting or reacting with certain lipoidal substances, the resulting complex regarded as a precipitate by some investigators, being able to absorb or fix hemolytic complement in the test tube. This reagin was probably produced by the cells directly in contact with and stimulated by the spirochetes; it was first found, therefore, in the tissue juices of the chancre as recently shown by Klauder and the writer. As the spirochetes were disseminated through the body the tissues of various internal organs, including those of the brain and spinal cord, very probably participated in the production of this Wassermann substance or "reagin." It might be that the lipoids of the spirochetes were antigenic and induced the production of the "reagin," but so far all attempts to produce antibodies with pure lipoids had failed, and even if it were true, one would expect a certain degree of specificity on the part of these lipoids which had not been demonstrated. This view did not coincide with the present conception of the tissues usually concerned in antibody production in infectious diseases; there were no valid reasons for regarding this cellular reagin as a true antibody. In the first place, the amount to be found in the body fluids bore a more or less direct relation to the severity of infection, although this relation might not be clinically apparent if the spirochetes were active in tissues of minor physiological importance. In the second place, it might be present during the latent or resting stages of the disease in such small amounts as to escape detection, whereas, if it were a true antibody capable of forcing the spirochetes into these periods of latency it should be demonstrable in large amounts. For these and other reasons the Wassermann reaction was to be regarded as an index of the degree of infection rather than of immunity, and if this was true the phenomenon was unique, not only for this reason but likewise because of the peculiar nature of the reagin. This reagin had the power of fixing complement in the presence of a suitable suspension of lipoids. It was probably not itself a lipoid or identified with the lipoid content of serum or spinal fluid, although this phase of the subject was by no means a closed chapter. The important practical question was: Might similar cellular reagins be produced in diseases other than syphilis and frambesia capable of bringing about the physicochemical phenomenon of complement fixation in the presence of extracts of lipoids? When one remembered the many chances of technical error capable of involving every important element and phase of the test, the answer must be given with great caution. Furthermore, might not pregnancy, an intercurrent infection, a metabolic disease, and so on, stimulate latent foci of syphilitic spirochetes into activity with the production of reagin just as trauma might be provocative or stimulating? While not disclaiming the possibility of observing positive Wassermann reactions with a correct and acceptable technique in non-syphilitic diseases, Dr. Kolmer said he knew the clinician was not always infallible in his judgment, that syphilis could escape clinical detection and that these unexpected positive reactions were not always due to laboratory error. The final answer to the question could not be given, but he would venture the prediction that the answer would be negative and that as clinical and pathological knowledge of syphilis was developed, and more especially as the complement fixation technique was perfected, more and more emphasis would be placed on what might be called the "syphilitic significance" of these unexpected and weakly positive reactions with the sera of individuals regarded tentatively as non-syphilitic. A source of clinical error worthy of keeping in mind was that a positive Wassermann reaction did not necessarily mean that a particular lesion was syphilitic; for example, a tuberculous ulcer might occur in the larynx of an individual with latent syphilis and fail to improve with antiluetic treatment. False reactions might be due to the presence of insufficient amounts of reagin in the blood or spinal fluid or to technical errors. Therefore the technique of the Wassermann reaction should be as sensitive *as was possible with specificity.* Even then false biological reactions would occur for the very good biological reason that where "reagin" was practically absent from the serum and spinal fluid it could not be detected in the test tube. Again, it was worth while remembering that while "reagin" might not be present in the blood in sufficient quantities to be detectable, sufficient might be present in the spinal fluid for yielding positive results. The reason was unknown. In the writer's opinion, it was possible to avoid technical errors and greatly improve the diagnostic status of the test, and it should be the aim and purpose of serologists to evolve a test capable of correctly detecting the disease when this was not possible by clinical means; the Wassermann test failed in its ultimate mission and purpose if it failed to do so. During the past six years, with the assistance of his colleagues, Dr. Kolmer had been engaged in a series of investigations aiming to study every phase of complement fixation in syphilis for the purpose of building up a test possessing a maximum degree of sensitivity with the minimum possibility for yielding non-specific reactions. These investigations had been conducted without preconceived ideas and without bias, and had finally enabled them to build up a new complement fixation test for syphilis which he hoped others would find as satisfactory as they had, and that clinicians and serologists would at least consent to give it a fair trial alongside of their own technique. He had not called their test a standard test because it must earn that designation by common consent. A new antigen and many technical improvements had been included in order to give the technique five qualifications, as follows: (1) As high degree of sensitiveness as was permissible with practical specificity; (2) technical accuracy and uniformity in results, in so far, at least, as positive and negative reactions were concerned (slight variation in the degree of positiveness would occur, but these did no harm so long as the primary question of whether a serum did or did not yield a positive or negative reaction was answered); (3) yield a truly quantitative reaction in order to give an index of spirochetic activity and the influence of treatment; (4) be technically simple in order to reduce the minimum of error; and (5) economical of time and materials in so far as this was consistent with the best work. It was not a shortcut method and did not aim to be because too many sources of error required attention and correction to fulfill the primary aim of sensitiveness and specificity. Standardization was desirable if these aims were served and satisfied. Mere unification of results in Wassermann tests in different laboratories meant little or nothing unless the test was technically correct and as sensitive as was possible with practical specificity. He believed standardization was possible under these conditions.

Dr. JOHN A. FORDYCE said that Dr. Kolmer's wide experience with the Wassermann reaction, together with his knowledge of immunological processes, caused one to listen to anything he might say with much respect. His associations with Dr. Schamberg and other excellent clinicians had enabled him to carefully correlate the results of his Wassermann work with men of

wide experience. In this way he had been able to develop a technique which was perhaps as accurate as that by anyone at this time. It was a great satisfaction to learn that his views were so closely in accord with our own. For the last ten years in their public and private work, Dr. Fordyce said they had been endeavoring to develop a Wassermann technique on similar lines, that was, a careful correlation of the results of the test with their clinical work. Their knowledge of the disease had been enormously increased by the revelations of the Wassermann reaction. Its use had supplied proof as to the syphilitic nature of many conditions where it was only surmised as the etiological factor. The necessity of proper technique and proper standardization of method therefore was obvious. In answering the question as to what were the criteria of a proper technique, Dr Fordyce said in a general way it might be stated that a positive reaction should be obtained in known active syphilitic cases and a negative reaction in known non-syphilitic cases. The employment of the same technique over a period of years and the careful correlations of results with clinical observation was the best guide as to its value. Although the original claim that the reaction was a specific antigen-antibody one had not been confirmed, it was sufficiently specific to more than justify the claim as to its diagnostic value. The contradictory results obtained in the same patient from different laboratories were explicable in part by the different technique and especially by the different antigens employed. One laboratory using cholesterin reinforced antigens would report a negative reaction and another laboratory using crude alcoholic extracts with icebox incubation would obtain different results. These varying reports were found chiefly in cases of old infection or in treated cases. In recent syphilis it was the rule to obtain strongly positive reactions with both of these methods. The lesson to be learned from this varying reaction was that serum from suspected individuals should be tested by both of the methods in question. In making a survey some time ago of several hundred cases in which a discrepancy between the two methods occurred they found that about 50 per cent. were positive with the cholesterin antigen and negative with the crude alcoholic extract while the remainder were positive with the alcoholic extract only. As to other conditions which gave positive reactions which might lead to confusion, in yaws, a tropical disease, closely allied to syphilis in which the organism was morphological identical and the clinical picture in certain phases indistinguishable, the blood gave a positive reaction. In tubercular leprosy it was at times difficult or impossible to eliminate the possibility of syphilis because of the occasional occurrence of a positive reaction. During pregnancy a certain number of cases gave a positive fixation with cholesterinized antigen. In their clinic they found that in 25 to 35 per cent. of the patients referred to them by maternity hospitals because of a strongly positive reaction with cholesterinized antigen alone, a negative reaction was given with all methods when these patients reported several weeks after delivery and it continued so on repeated examination. It was frequently stated that in diabetes a positive Wassermann reaction was met with. They had occasion to examine many cases and were unable to corroborate this contention. They had also been unable to confirm the reports of a positive reaction in malignant disease unaccompanied by a specific infection as claimed by Warthin. Carcinoma of the mouth not infrequently developed on syphilitic soil. The accompanying lymph nodes sometimes showed syphilis. A long experience in the interpretation of the reaction had led them to modify considerably some of their former views. Some years ago a repeated negative reaction in the blood was looked upon as an accurate criterion of cure. They now knew that many such patients had a positive reaction in the spinal fluid while the blood remained persistently negative. Furthermore, a weakly positive reaction in a patient with a definite history of syphilis was an indication for further treatment. A reaction of this kind reported from an outside laboratory was usually considered negligible. Before this interpretation was placed upon it, the history of the patient together with the amount of treatment he had received should be carefully considered. In expressing an opinion regarding the question of cure or the absence of a syphilitic infection, the Wassermann reaction of the blood as well as of the spinal fluid should be carefully correlated with the previous history of the patient. He had often been aided in his interpretation of a Wassermann reaction by opinions from his colleagues as to the clinical findings which were present. In several cases an eye ground examination had shown the existence of vascular disease with degenerative changes in the presence of a negative blood. In some cases the vascular degeneration was a progressive one and was met with in the early stages of syphilis. It would therefore be fatal to such patients to state that the syphilitic infection had been cured. It was in cases like these, and similar ones with localized lesions, that they obtained a negative reaction in the presence of active disease. Some of these cases two or three years later might show evidence of hypertension and it was a question whether all syphilitics should not be under observation from time to time for a cardiac and ophthalmological examination, and whether their intensive salvarsan mercury treatment should not be followed up by iodides. The possibilities of error in the interpretation of the Wassermann were more numerous on the negative than on the positive side, and might briefly be formulated thus: The blood was negative in about 6 per cent. of late active cutaneous and sometimes in early malignant syphilis; in a certain percentage with cardiovascular syphilis; in certain localized progressive vascular affections of the eye. In congenital syphilis one occasionally saw infants with clinical findings of the disease, but serologically negative. The blood sometimes became strongly positive after treatment. In the following types of neurosyphilis the spinal fluid was often negative and the blood might be negative or positive: Vascular neurosyphilis abortive tabes and the late degenerative stages of the disease, sometimes in the terminal stages of paresis, epilepsy, in which cerebral gumma and syphilitic psychoses were usually accompanied by a negative Wessermann in the fluid. In summarizing one could say with a certain degree of assurance that a persistent positive reaction controlled in several laboratories meant active spirochetes in some part of the body. Autopsy findings in cases with a history of syphilis where death resulted from some intercurrent affection showed that in over 90 per cent. the aorta was the site of a lesion and that in over 40 per cent. the viscera were involved. A persistent negative reaction in the blood and spinal fluid after intensive treatment indicated cure in a great majority of cases, but since cured cases did not go to autopsy this statement was not susceptible of pathological proof; however, the subsequent histories of these patients with their marital history and healthy children supported this view. The exceptional cases on the negative side could not take away from the value of a negative Wassermann reaction, and neither could they be accepted as proof that syphilis was incurable. The pessimism of the pathologist as to incurability was largely based upon findings in patients who had been insufficiently or improperly treated. Strong clinical evidence was further met with in cases where symptoms relapsed while the blood remained positive. They had seen repeated relapses in interstitial keratitis while the blood continued positive and had noted their absence after the blood remained negative. Among the problems for the future to determine was the possibility of altering a Wassermann fast reaction. He found that in many cases treatment over a period of two or three years with proper intervals of rest would reverse the reaction to negative. In these cases mixed treatment was of decided value.

Dr. KOLMER, in closing the discussion, said that he had greatly enjoyed and had been instructed by Professor Fordyce's remarks. He stated that at the present time he was interested in applying his new complement fixation test in a study of those diseases which have been reported from time to time as yielding falsely positive Wassermann reactions in the absence of syphilis. Through the courtesy of the Surgeon General and Dr. Oswald Denney of the United States Public Health Service, he was able to study the sera of lepers with both the nodular and anesthetic types of the disease; so far the reactions had been uniformly negative, except in a few cases where syphilis was suspected clinically. Dr. Kolmer said that he believed that the

blood in leprosy yielded negative Wassermann reactions unless the patient was syphilitic. Dr. Kolmer stated that in late pregnancy he had observed the positive reactions mentioned by Professor Fordyce, which disappeared after delivery. He stated that he had not observed these reactions with the new technique, and believed that they might be due to the use of an excessive amount of cholesterol in the antigen. He stated that in the new antigen cholesterin was not used in amounts larger than 0.1 per cent. to 0.2 per cent. Dr. Kolmer stated he would not be surprised, however, to observe positive Wassermann reactions in pregnancy, and especially among women with latent syphilis in whom pregnancy might act in a provocative manner similar to the stimulation of syphilitic processes by trauma. Dr. Kolmer stated that time did not permit a discussion of the multitudinous technical details involved, but that he thought best results were dependent upon the use of a superior antigen and a primary incubation of sixteen to eighteen hours in a refrigerator at 6 to 10 degrees Centigrade.

The Diagnosis of Pulmonary Tuberculosis from the Standpoint of the Industrial Physician.—Dr. FRANK A. CRAIG of Philadelphia presented this contribution, in which he said it seemed hardly necessary to call attention to the importance of the early recognition of pulmonary tuberculosis among industrial workers, but he believed we could not lay too much stress upon this point for several reasons. First, the patient with tuberculosis which was recognized early, in the large majority of instances might regain his working capacity with the loss of a comparatively short period of time, while the patient in whom the disease became advanced before being recognized might only rarely regain his working capacity, with the loss of considerable time, even if he did not lose his life. In the second place the early recognition of tuberculosis was important from the standpoint of prevention, as the open, careless case of tuberculosis constituted a risk to his fellow workmen. In the third place the study of tuberculosis incidence rates in various occupations also possessed value from the standpoint of public health and occupational morbidity. For the detection of the disease in its early stages, in various industries, entrance examination combined with periodical reexamination of all employees would seem to be the only really effective method which we possessed at the present time. One plan that has been fairly generally employed by a number of industrial plants was that devised by Sochs, which consists in an entrance examination and reexamination of only those who showed suspicious signs at the first examination. The figures obtained under this plan showed a rather low incidence as compared to the rates which Mock gave in his recent work on industrial medicine and surgery. Among the police and firemen of Philadelphia they had found an incidence of positive tuberculosis of 1.43 per cent., and 2.31 per cent. if they included those markedly suspicious. These figures did not include any of those cases suspected of apical fibrosis, which were considered separately, but only those in which they had some good reason to suspect the presence of actual disease. They had thought that perhaps some scheme of selection might be devised by which cases which should receive a more detailed examination might be indicated by some means other than physical examination. Every chest would by this methods be examined, but special attention would be given to those cases which showed some certain indication of this disease. With the hope of developing some such plan they had studied the cases of tuberculosis which were encountered in the examination of the police and firemen of Philadelphia, which was conducted by the Phipps Institute of the University of Pennsylvania. The diagnostic standards as set up by the National Tuberculosis Association were not applicable to these industrial surveys, as they were based, to a considerable extent, upon the history of the patient. In this survey weight, temperature, pulse, and blood pressure were tabulated in 132 cases of tuberculosis. These cases were divided into five groups as follows: Suspected tuberculosis; possible tuberculosis; probable tuberculosis; arrested tuberculosis; definite tuberculosis. As a result of their experience in this survey they believed that for the early detection of pulmonary tuberculosis there could be no question that the carefully conducted health survey was the most valuable means at our command, especially valuable being the entrance examination combined with periodic reexaminations of the entire force. The tuberculosis incidence rates which appeared in the literature as the findings of medical examiners in their studies of numerous industrial bodies were so lacking in uniformity, and were so infrequently unaccompanied by qualifying, defining or explanatory information that they were almost valueless for comparing the findings of one industry with those of another. It would seem as though some standardized method for reporting such cases was definitely needed before it would be possible to establish average tuberculosis rates for various occupations. The conclusions drawn from this survey were as follows: (1) The examination of large bodies of men for the presence of pulmonary tuberculosis presented many, but not insuperable, difficulties, and in each case the diagnosis must rest upon a careful correlation of all the findings. While the most important information was that gained by a physical examination of the patient, including inspection, palpation, percussion and auscultation, there were other methods of study which possessed considerable value in the formation of a diagnosis. (2) The *history* of the case was of the utmost inportance, but was seldom obtainable in the study of large groups of men. (3) In the routine examination of large bodies of men the recording of *temperature* seemed to be of questionable value, although it might prove invaluable in the study of individual cases. (4) From the standpoint of tuberculosis the recording of the *pulse rate* offered very little if any information of value. (5) Loss of weight was a finding of considerable value and one which was readily obtained. The age and height must be taken into consideration in studying the weight of the individual. (6) Systolic *blood pressure* which was below the normal for the age of the patient was a very suggestive finding. The recording of the blood pressure should be included in the study of every large body of men for many reasons.

Dr. HAVEN EMERSON said he had not come prepared to discuss the paper, but he could not refrain from saying a few words, since the paper brought up some very interesting points in regard to the advantages of periodical physical examinations and the discoveries a physician made whenever he took a group of people who thought they were well and submitted them to a rigorous medical examination. The New York City Department of Health in 1914 instituted physical examination of its employees, and it was a surprise to find so many cases of undernutrition, overnutrition, incipient tuberculosis, cardiac disease, high blood pressure, previously unsuspected diabetes, etc., as were revealed among these 3,000 people who were supposedly well. As a result of these examinations and advice given to employees there was in three years a reduction from 5 per cent. to 2 per cent. of the number of days of absences from work on account of sickness. Examination of a group of college students presumably in the best of health always elicited a large number of cases of tuberculosis. The campaigns waged in a national way for prevention of tuberculosis, cancer, mental hygiene, etc., all depended for their results upon the early detection of disease in presumably healthy people. Dr. Emerson said he agreed with most things Dr. Craig had said, but he could not agree that it was impracticable to take time to examine the chest among industrial workers unless there was a loss of weight or some other particular disturbance suggesting the possible presence of tuberculosis. It was possible and necessary to make a thorough examination of the chest in every employee if a good service was to be offered. He did not see how any employer of people or any physician who had supervision of an industrial group could square himself with his conscience without seeing that the chest was examined in every instance. Without such an examination he assumed responsibility for failing to discover conditions that might lead to serious disease and to fatalities. With reference to Dr. Craig's classification, it was a pity to introduce new terms when we had the admirable classification made by Turban. If one adhered to the classification that was advised by the National Tuberculosis Association he was readily understood by everyone. The dispensary committee organized by the New York Academy of Medicine felt very

strongly the necessity of supplementing dispensary service for the sick with a service for the presumably well where people who thought they were well but did not know how sick they were might receive the benefit of a thorough physical examination and be referred to a physician for treatment if they were found in need of medical attention. In the first 100 persons examined there was a large collection of the early stages of disease not recognized by the persons who had these conditions. A physician was hardly worth his salt if he could not beat the patient to the disease. If the physician could not recognize the early stages of disease before the patient did he was little better than the patent medicine man. The old principle was to wait until the patient complained and then start treating something the patient had detected himself. The periodical medical examination was pushing back the boundaries of medicine to the stage where one could accomplish curative treatment. Periodical medical examinations would do more to prevent sickness than any other single resource of preventive medicine. It was the foundation stone of all activities in the way of public health work. Our aim should be a physical examination for every individual at least once a year, oftener under the age of five, and always after complete apparent convalescence from any acute febrile or infectious disease.

Dr. CRAIG, in closing the discussion, said he did not wish to be misunderstood in regard to the examinations. Every one of the firemen and policemen was given a complete examination of the heart and lungs, but there were some cases in which something more seemed necessary. For instance, should a certain man's temperature be taken every afternoon, or should a man have an *x*-ray examination? There were cases that needed more attention than the routine examination. He did not wish to leave the impression that any of these men were slighted for all were carefully examined. In regard to the question of terminology, Dr. Craig acknowledged that it was a mistake to make a new classification. He had often remarked on the lack of standardization of classification in published works, and he was guilty with the others.

The Need of Social Service in Private Practice.—Dr. H. R. M. LANDIS, M.C., U. S. A., spoke informally on this subject. After apologizing for what he termed a rather trivial presentation, he said it was hardly necessary to recall that in 1905 when Richard Cabot introduced social service in connection with hospital work, it was viewed with skepticism. However, its usefulness soon came to be recognized, and today there were few hospitals in the country that did not have social service departments. This method having once come before the public it developed very rapidly. This was not the first time that the method had been employed. It developed as far back as 1880 in England where it was used among the insane. The plan had two advantages. It placed the physician in possession of information he would not have otherwise, and then the medical work must be well done if the social service work was to be as effective as it should be. The medical profession as a whole had not seized upon social service work with the avidity one might have expected. It happened to him quite a number of times each year that an individual presented himself and asked his advice. He would state that he had been told that he had tuberculosis and had been to consult an eminent authority who had given him advice that he could not carry out. The difficulty in those instances was that the physician giving the advice had no knowledge of that patient's background or of his financial resources. Perhaps he was advised to go to some place in the far West, an undertaking his resources would not stand. He might not even have the railroad fare. The Southwest had been flooded with tuberculosis patients with no financial means and no means of self-support, and eventually they became public charges in a community where they were complete strangers. Formerly the family doctor and the general practitioner had the opportunity to know the background of those men. The relations of the family physician with his patients was vastly different from those of the purely medical consultant. The patient consulted the family physician about all sorts of things, many of them not medical at all, and in that way the family physician learned the social and financial background of his patients. Then very often the giving of this impractical advice was simply due to carelessness. The consultant was in the habit of advising people who were able to carry out his advice, and then when a man came to him who had succeeded in some way or other in getting together enough money to pay his fee, he gave him the same advice he was in the habit of giving his well-to-do patients, and the man could not carry out the advice. Dr. Landis said that at the sanatorium with which he was connected many patients came from outside of Philadelphia. They came seven out of ten times with moderately advanced lesions, the type of case utterly unsuitable for that institution which took only incipient cases. Patients were sent who ought to be put in bed. It happened to be his duty to explain to those patients that they could not be admitted. The idea that they could not be admitted was utterly foreign to them and when told that the institution could not accept them they received a shock they should have been spared. These patients had usually been sent by a physician and the explanation that they could not be admitted was usually followed by a letter from the physician taking him to task something like this, "If this patient is not a suitable case what sort of a case would you take anyway?" "Surely this patient has tuberculosis and is in need of care." The physician should provide himself with the knowledge of the type of cases an institution cares for and should not give the patient an idea he was going to be admitted unless he knew definitely that the patient was suitable for admission to that institution. It would be better if the physician would simply send the patient for examination and then the admitting physician after examining the patient, could send his findings to the physician who had referred the case and the patient could then take up the matter of the course to be pursued. That was where the advantage of social service came in. When a patient came to a dispensary and the physician found that he was suffering with tuberculosis he was turned over to the social service department and the social workers saw that he was placed in the proper place without any of the disagreeable features that had been referred to. Another feature of the care of private patients that required consideration and where there was need for tactful handling by the trained social service worker was in the private floors of general hospitals. Dr. Landis said he knew of no place where there were more annoyances than on the private floors of hospitals. These annoyances ranged all the way from trivial irritations of the patient to those of serious consequence. Another place where tactful handling was much needed was in the admitting room of general hosiptals. We were trying to teach the people that the hospital was a place not only for the ill but that its function was to educate and serve the community. Yet, if a person became ill and was shipped off to a hospital, he was first interviewed by a clerk, who inquired his name and address, and the name and address of the person to be informed if all did not go well with him; he was then asked to pay in advance and was ushered to a waiting room, where, after waiting indefinitely, someone came along and asked him whether he was Mr. So-and-So and told him that the doctor would see him. By that time the patient's frame of mind was such that he did not care much what happened to him. No doubt hospitals lost many handsome subscriptions by the tactless way in which they received private patients. A great deal of this was a hospital problem and a problem of those attached to hospital staffs, but it was also a problem that concerned the physician dealing with patients outside the hospital. This lack of knowledge of the patient's background was something that we had lost in getting away from the family physician. Too often in sending the patient from specialist to specialist and in the private wings of the general hospital we had lost sight of the fact that this patient was a human being.

Dr. C. E. FORD said he could not agree with Dr. Landis that it was necessary to apologize for his presentation. He thought the sort of service advocated by Dr. Landis was a very important socio-economic endeavor. His work was confined to industrial medicine and for that reason he had a very keen appreciation of its value. In medical practice in industry one met a great many tuberculosis patients and it was felt that the

treatment of sickness not arising out of the occupation should be referred back to the private physician, but it had been found that the attitude of the private physician, practising in industrial districts, was such that it was necessary in many instances for the employing company to take charge of and hospitalize tuberculosis patients, pay their hospital bill and support the family in the manner in which they were accustomed to live during the period that the patient was in the hospital. This, of course, was a tremendously unfair burden upon the employer, but the attitude of the physician toward these cases by reason of failure to appreciate the social phases of the disease and give instructions accordingly, made the assumption of this burden necessary, if the patient was to be saved and made a self-sustaining social unit. There were many groups to which social service in private practice was valuable. It was of value not only to the employee but the employer as well. Dr. Ford cited numerous instances of cases that he had met. For instance, among a group of men recently pensioned was an individual 73 years of age—a master mechanic for a short time and assistant superintendent and employed continuously for 53 years; his wife was living—two adult children independent; his disability was senility. He had no money, no property and his life's savings were represented by $200 in Liberty bonds. A second case was that of a man 67 years of age, employed 30 years, wife living, 4 children—disability, senility. His resources were a $900 equity in the house in which he lived and nothing else. A third case was that of a man 62 years of age, wife and 8 children—total resources $60. Dr. Ford emphasized the fact that these men presented evidences of medical neglect; that these individuals were worthy was indicated by their prolonged period of employment which of itself was a warranty of character. Economic conditions were such that workmen employed continuously and having large family responsibilities were unable to secure the best that was offered in medicine, and it appeared that social service properly directed would be of inestimable aid to the physician as well as make a definite contribution to the standard of living of industrial workers. Socially minded medical men must devise some means of reaching this type of deserving citizens who constituted the bone and sinew of our country. The problem must be solved by the medical profession instead of leaving it to some irresponsible allied group. Medical men must be the leaders in these activities rather than allow the responsibility to rest with untrained inexperienced non-medical social workers.

A Prolonged Study of the Degeneration of a Myocardium.—Dr. James E. Talley of Philadelphia made this contribution,which was illustrated by lantern slides. He said he would feel that he should apologize for presenting only one case were it not for the fact that the patient had been observed and studied over six years. The patient discovered in 1910, while in China, that she had a slow pulse, the average was about 40, sometimes it was as low as 36, and occasionally as high as 50. She gave a history of an attack of fever thought to be malarial but it was suggestive that the fever began three months after she had given birth to a child; a latent infection was a possibility; she had had diphtheria, measles and attacks of tonsillitis; for some years she had had a cystitis, not due to the colon bacillus but to a Gram positive bacillus. She had five healthy children living, one had died in infancy. In 1916, she returned to this country and had been under observation since. From 1916 until about a year ago, the ventricular rate was 40, occasionally somewhat higher but never less than 36. She had an aortic systolic murmur not well transmitted and a systolic murmur at the apex that was well transmitted. There were no diastolic murmurs. The teleroentgenogram showed the heart much enlarged, especially in its transverse diameter. There was evident mitral disease, myocardial disease and persistent slow pulse. The patient's symptoms were not as severe as had been expected; she had had two fainting spells when the trouble first began. After returning to this country she conducted a school for the children of missionaries and took care of her own five children. She broke down under this strain and had to give up her position. For some six years her condition has remained practically the same, she remained much of the time on one floor, but went down to meals and since complete disassociation with flutter appeared, she had apparently been able to walk a little farther than formerly. There was only one threatened circulatory failure in which she developed slight edema of the legs, and her liver became slightly enlarged. This readily subsided. Electrocardiographic studies during these years showed that her slow pulse was due to a nodal rhythm, the impulse arising in the node or in the neighborhood of the node. About a year ago the patient first showed auricular flutter and complete heart block, the average ventricular rate being 30 to 32, the auricular rate from 220 to 240. Recently, at one sitting he was able to secure curves of transient right and left branch bundle block alternately; some weeks later the curves showed right branch bundle block alone. The curves were interesting, showing at one time auricular flutter, complete disassociation, branch bundle block, alternation, and premature beats. The question of varying ventricular complexes in a given patient had been dwelt upon by many writers, among them Hart, Cohen and Oppenheimer. Lewis had reported a case of temporary obstruction of the right bundle; Mathewson of the left. The latter had also reported transient obstruction occurring alternately in the right and left branches. Wilson in one patient was able to produce a curve of branch bundle block by vagal stimulation. Three theories had been advanced to explain this intraventricular variation in conduction. One was a shifting of the center of impulse formation, the second was that the impulse pursued a different course in its distribution and the third was a variation in the rate of conduction.

Dr. T. Stuart Hart said that in this most interesting presentation Dr. Talley had shown some very extraordinary and unusual electrocardiograms. Perhaps the most unusual one was the occurrence of auricular flutter with complete spontaneous heart block. Of course, it was quite common to see block with auricular flutter when digitalis was being used, but otherwise it was exceedingly unusual. Dr. Talley's presentation of alternating right bundle branch block and left bundle branch block was also a very unusual phenomenon. Dr. Hart recalled that he had had the opportunity of reporting such a case some years ago. It was published in *Heart*. In this case there was a ventricular paroxysmal tachycardia; at that time the phenomena were called extrasystoles arising alternately from the right and left sides of the heart; now we could interpret it as an alternating bundle branch block. One could not study the curves as closely as one could wish during a presentation of this kind, but there were one or two clinical features that were of interest. A study such as this of Dr. Talley's was the kind that we needed if we were going to make advances, not merely the presentation of a case that showed one particular feature but one that had been followed through years and showed the course of events. The study of cardiac disease was comparable to that of cerebral localization; we were beginning to localize processes in different parts of the heart. In cerebral localization the neurologist could say here is a small tumor and he could say it had extended thus and so far as the arms, the legs, the facial muscles were affected. Here was a series of definite processes in the heart which were being localized just as the neurologists were localizing the growth of a tumor in the brain. This had been a great help to the neurologist because it had made surgical intervention possible under certain conditions. Then it was also a help because if the growth arose from a particular structure he knew that it was probably of a particular nature. In the same way this localization of cardiac functions shows that with certain effects certain cardiac tissues are involved and therefore certain medication indicated, while with different effects such medication would be contraindicated. As to the etiology in this case of Dr. Talley's one would say from the nature of the disturbance of heart function that most probably the etiological factor was lues, whether the Wassermann was positive or not. One other point of interest was that with all these wonderful curves she had little cardiac insufficiency. It would seem that the reason was that there was considerable blocking of the main bundle which was in itself a protection feature, since it kept the heart slow and was therefore a great help to the efficiency of the heart.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of North Carolina.

Raleigh, June 20, 1921.

(*Continued from page* 480.)

PRACTICE OF MEDICINE.

1. Differentiate typhoid fever from aestivo autumnal fever, first week.

2. Name types of malarial fever. (*a*) Cause of each. (*b*) Give briefly treatment of each. (*c*) Why is it so important each case should be treated until cured?

3. Give synonyms and early symptoms of tabes dorsalis, etiology, and treatment.

4. (1) Give symptoms of pernicious anemia. (*a*) Blood picture. (*b*) Prognosis. (*c*) Treatment. (2) What is found in blood of leukemia that is characteristic that is not found in normal blood?

5. Give exciting cause, diagnosis and treatment of cerebrospinal meningitis.

6. Define the following signs and name condition in which each is found: Kernig's sign, Romberg's sign, Dalrymple's sign, Skoda's sign, Von Graefe's sign.

7. Give differential diagnosis between membranous croup and spasmodic croup, and give treatment of each.

8. What is Bell's palsy? Where is lesion found, symptoms and treatment.

9. Discuss briefly gastric ulcer and give treatment.

10. Name some indications and contraindications of gastric lavage.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. Define: (*a*) *Obstetrics.* (*b*) *Gynecology.* (*c*) *Pediatrics.*

2. What are the diameters of the normal female pelvis at the superior strait expressed in centimeters? What are the causes for variations from the normal measurements? What is the effect of these variations from the normal upon the act of normal labor?

3. Tell in their usual sequence the symptoms and signs of normal pregnancy, both subjective and objective.

4. How would you treat a central placenta prævia associated with a transverse position of the unborn child and associated with severe hemorrhage?

5. Describe: (*a*) Precocious menstruation. (*b*) Delayed menstruation. (*c*) Menorrhagia. (*d*) Metrorrhagia. (*e*) Amenorrhea. (*f*) Vicarious menstruation. (*g*) Dysmenorrhea. (*h*) Climacteric.

6. Describe in detail the secondary repair of a median perineal laceration involving the sphincter ani muscles.

7. Give the etiology, symptoms, diagnosis and treatment of carcinoma of the uterus.

8. Give the differential diagnosis between cholera infantum, acute ileocolitis and chronic ileocolitis.

9. Outline a plan for the successful treatment of a case of enuresis in a child five years of age.

10. Name the incubation period of: (*a*) Diphtheria. (*b*) Scarlet fever. (*c*) Pertussis. (*d*) Measles. (*e*) Varicella. (*f*) Epidemic parotitis.

Note.—Each question will be counted as eight points on the total. The practical examination will have a value of twenty points.

ANSWERS.

PRACTICE OF MEDICINE.

1. *Typhoid fever (first week).* The bacilli can be isolated from the blood. This is absolutely conclusive, but may be difficult.

Aestivo-autumnal malaria. Blood examination will show the presence of the plasmodium.

2. Types of malaria.—(1) *Benign tertian,* caused by the Plasmodium vivax; (2) *Quartan,* caused by the Plasmodium malariæ; (3) *Malignant tertian,* or *Aestivo-autumnal,* caused by the Plasmodium falciparum.

Each case of malaria should be treated until cured, because unless this is done relapses will occur, and the patient will eventually become a gamete carrier, and thus be a "carrier" and transmitter of infection.

3. Tabes dorsalis. *Synonyms.*—Locomotor ataxia, Posterior spinal sclerosis. *Early symptoms.*—Lightning pains; loss of knee-jerks and deep reflexes; Argyll-Robertson pupil; Romberg's sign; difficulty in urination; optic atrophy; paresthesia.

Etiology.—Syphilis; and the disease is more common in the male sex and in adult life.

Treatment.—"The recent demonstration of the syphilitic nature of locomotor ataxy tends to strengthen the position of those who advocate specific therapy in its treatment. But even the most modern methods of administering salvarsan (intrathecal injection of salvarsanized serum) appear at best to have only a temporary effect, and to show little advantage over efficient mercurial inunction. The best cases for specific therapy are those in which the ataxia has rapidly followed the initial lesion (two years or so), and where the case is seen early. Other methods of treatment are largely symptomatic. The general health must be maintained by tonics, especially iron; diet should be nutritious; and rest, or exercise stopping short of fatigue, must be ordered according to circumstances. Lightning pains may be treated with antipyrin, phenacetin, or aspirin; chloride of aluminum, three to four grains thrice daily may be given where these fail, and morphia is often necessary. Similar treatment must be used in the various crises, and in the gastric form gastric sedatives may also have some effect. Where they make life intolerable, division of the appropriate posterior nerve-roots has been practised with some success. For the ataxy the best treatment is a systematic re-education of the muscles under the control of sight, on the system introduced by Fränkel, beginning with the simplest exercises and movements, and passing gradually to the more complex. Massage is also of considerable use."—(Wheeler and Jack's *Handbook of Medicine.*)

4. Pernicious Anemia. *Symptoms.—Pernicious anemia* begins insidiously, with languor, muscular weakness, and pallor; palpitation of the heart, dyspnea, attacks of syncope, and edema may follow. The pulse is large and soft, hemic murmurs are often present; later on a remittent fever may develop, together with nausea, vomiting, diarrhea, anorexia, and disorders of vision. The weakness progresses.

Blood Picture.—The blood shows a low specific gravity, the hemoglobin is rarely more than 50 per cent. and may be much lower; the color index is increased; the red corpuscles are greatly reduced, the average number being a little over 1,000,000; poikilocytosis is pronounced; nucleated reds are generally present; and the leucocytes are decreased both absolutely and also with regard to the polynuclears.

Prognosis.—Unfavorable.

Treatment.—"Fresh air, rest, and a diet as liberal as the digestive powers of the patient will permit are requisite. Warm salt baths and massage are valuable adjuvants to internal treatment. The teeth should receive careful attention. If there be gingivitis or pyorrhea alveolaris, antiseptic mouth washes should be used at frequent intervals. Arsenic is the most valuable drug. It may be given in the form of Fowler's solution, the dose being gradually increased from 2 or 3 to 15 or 20 minims three times a day. Iron is rarely of service. Bone-marrow is sometimes efficacious. Inhalations of oxygen have been recommended. Appropriate anthelmintic remedies should be given, of course, in the cases in which intestinal parasites are present. Digestive disturbances are often benefited by the administration of diluted hydrochloric acid and a bitter."

In *leukemia* myelocytes may be found.

5. Epidemic cerebrospinal meningitis. *Etiology.*—The *Diplococcus intracellularis meningitis.* Sporadic cases may be due to the pneumococcus, streptococcus, colon bacillus, typhoid bacillus, bacillus of influenza, or gonococcus; but the epidemic form is always caused by the *Diplococcus intracellularis.* It enters the system through the mucous membrane of nose, mouth, or pharynx, and reaches the meninges by way of the lymphatics or the circulation. The disease may be conveyed by "carriers." *Diagnosis* is made from (1) the symptoms, (2) Kernig's sign, and (3) lumbar puncture. *Symptoms*—The onset is generally sudden, with headache, rigors, stiff neck, opisthotonos, vomiting, mod-

erately high (102° F.) and irregular fever, full and rapid pulse, herpes, photophobia; convulsions, delirium, monoplegia or hemiplegia, enlarged spleen, retracted abdomen, and disturbed reflexes may be present. *Kernig's sign* is obtained (if the thigh is flexed at right angles to the abdomen, the leg cannot be fully extended on the thigh, as it can in health, owing to the contraction of the flexor muscles). By *lumbar puncture*, some of the cerebrospinal fluid may be withdrawn and examined for the presence of the diplococcus.

Treatment includes the use of Flexner's serum (injected into the subarachnoid space after about 40 c.c. of the spinal fluid has been withdrawn). The patient is to be kept in a dark room, with his head elevated (but not flexed) and an ice bag applied to head and spine. Nutrient enemata may be required; both bowels and bladder need to be watched. Nervous symptoms may demand an opiate or chloral; urotropin is said to be of service.

6. *Kernig's sign.* The patient lying on his back, with his thigh flexed upon the abdomen, the leg cannot be completely extended. It occurs in meningitis.

Romberg's sign. The patient standing with his eyes closed and his feet close together, his body sways. It occurs in tabes dorsalis.

Dalrymple's sign. The palpebral slit is abnormally wide. It occurs in exophthalmic goiter.

Skoda's sign. On percussing the chest a tympanitic sound is heard above a consolidation in lobar pneumonia or above a pleural effusion.

von Graefe's sign. The eyeball does not move downward with the upper eyelid when the patient looks down. It occurs in exophthalmic goiter.

7. *Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick, tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

Membranous croup is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacilli or streptococci.

Treatment of diphtheria. The patient should be in bed and isolated; the family should be quarantined; infected articles should be soaked in some antiseptic solution and then boiled; a milk diet is indicated; the nose and throat should be kept clean by the use of some mild antiseptic solution; calomel in divided doses should be given to keep the bowels open; tincture of the chloride of iron is indicated; and early administration of diphtheria antitoxin in adequate doses (3,000 to 10,000 units) must be given at once; if there is no improvement within twelve hours, the dose must be repeated.

Treatment of spasmodic croup. The patient should be put in a bath of hot water, or hot cloths should be applied to the neck; an emetic dose of ipecac should be given; a saline should be administered; and bromides in small doses should be given at bedtime for a few nights.

8. *Bell's palsy* is paralysis of the facial nerve after its exit from the stylomastoid foramen. The lesion is found either in the stylomastoid foramen or in the peripheral fibers of the nerve.

Symptoms.—"When the nerve is affected after it leaves the stylomastoid foramen (Bell's paralysis), the affected side is immobile, smooth, and expressionless. The eye cannot be shut, and usually waters freely. The attempt to smile or to whistle brings out the contrast between the two sides. Articulation of labial consonants is defective. The food collects between the cheek and teeth, owing to buccinator paralysis. The skin of the neck cannot be voluntarily moved (paralysis of the platysma).

Treatment.—"Remove if possible any pressure on the nerve by causing absorption of inflammatory products. Where the cause is syphilis, use specific remedies. Treat any ear disease, surgically if need be. In rheumatic cases apply a blister over the point of exit of the nerve and give diaphoretics and a smart purge. Maintain the tone of the paralyzed muscles by massage and by a moderately strong faradic or continuous current applied for about a quarter of an hour several times daily, the positive pole being on the nape of the neck. Iodide of potassium may be given internally. The peripheral type is usually very amenable to treatment. In obstinate cases an anastomosis may be made between the spinal accessory or hypoglossal nerve and the distal portion of the facial; but the operation is a severe one, and the improvement produced is often only partial."—(Wheeler and Jack's *Handbook of Medicine.*)

9. GASTRIC ULCER. *Etiology.*—Injury, bacteria, hyperacidity of gastric juice, changes in the blood or blood-vessels of the stomach; it generally occurs in young people (20 to 30) and is apt to be associated with chlorosis. *Symptomatology.*—Pain, localized in stomach, coming on soon after a meal, and of a sharp or cutting nature, and often relieved by vomiting; hematemesis; tenderness over the stomach; the condition is generally improved by starvation or by a milk diet; analysis of gastric contents shows an excess of free hydrochloric acid; there may be "occult" bleeding, which can be recognized by the benzidin test. Prognosis is guardedly favorable; hemorrhage and perforation are apt to be fatal complications; relapses are common; the mortality is about 10 per cent.

It is to be *differentiated from* cancer of the stomach, duodenal ulcer, gastralgia, gastritis, pylorospasm, hypersecretion, cholecystitis, cholelithiasis, and renal calculus.

Operation is indicated when the hemorrhage is copious and recurrent, when medicinal treatment has been given a fair trial and no cure has been made, when after apparent cure a relapse has occurred, when perforation occurs, when adhesions about the stomach interfere with the proper performance of its functions.

The treatment consists largely in rest in bed, liquid diet and sometimes rectal alimentation only. The rectum should first be irrigated with lukewarm water, and the following nutritive enema may be given: Milk, ℥8; yolks of 2 eggs; sodium chloride, ʒ1; claret wine, ʒ1; and a tablespoonful of aleuronat flour. Hematemesis will require absolute rest and abstinence from food and drink. Thirst may be relieved by sponging the lips and tongue with ice water. Ice-bags may be applied over the affected area, and ergotol (♏20) with morphine (gr. ¼) may be given hypodermically. Later light diet and silver nitrate may be administered.

10. GASTRIC LAVAGE. *Indications.*—"Aside from diagnostic purposes lavage must be performed—(1) when there is stagnation of food in the stomach; (2) whenever large quantities of mucus are present in the organ; (3) after poisoning by the ingestion of alkaloids (morphine, atropine, cocaine, etc.) into the stomach; (4) in postoperative ileus.

Contraindications.—"These comprise all conditions in which introduction of the tube is not permissible, as for instance, hemorrhages, ulcer of the stomach, aneurysm, poisoning by strong acids or caustics: great general debility." (*Reference Handbook of the Medical Sciences.*)

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. *Obstetrics* is that branch of medical science which treats of the physiological and pathological processes which arise, either directly or indirectly, from impregnation; and it is concerned with the necessary care and treatment of the woman and child.

Gynecology is that branch of medical science which treats of the diseases peculiar to women.

Pediatrics is that branch of medical science which treats of the diseases of children.

2. *The diameters of the normal female pelvis, at the superior strait,* are:— (1) *antero-posterior,* 11 centimeters; (2) *transverse,* 13½ centimeters; and (3) *oblique,* 12¾ centimeters.

Variations in the above may be due to age, lack of development, disease. The *effect of these variations* may be to hinder, or entirely prevent the normal termination of the pregnancy; as a result various procedures may be necessary, such as the use of forceps, version, cesarean section or some other operation, mutilation or death of the fetus, the termination of pregnancy before the usual period; further, the prognosis is worse for both the mother and the fetus.

3. *Subjective signs of pregnancy,* in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements. *Objective signs of pregnancy,* in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growh of the uterine tumor.

4. The patient should be anesthetized, the physician's hand should be made to pass right through the placenta praevia, a podalic version should be performed, and one leg of the fetus brought down; this will act as a plug, and stop the hemorrhage; the anesthetic may then be discontinued and the patient be allowed to deliver herself as in an ordinary breech presentation; or the traction may be continued and the fetus delivered rapidly.

5. *Precocious menstruation* is menstruation at a much earlier period than is usual.

Delayed menstruation is the appearance of menstruation at a later period than is usual.

Menorrhagia is excessive menstruation.

Metrorrhagia is uterine hemorrhage between the usual menstrual periods.

Amenorrhea is the absence of menstruation.

Vicarious menstruation is the periodic loss of blood from other channels instead of the usual flow from the uterus at the menstrual periods.

Dysmenorrhea is unusually painful menstruation.

Climacteric is the period of life when a woman ceases to menstruate.

6. "In 'complete' lacerations—those of the *third* degree—through the sphincter ani to the rectum, the rectal tear is first stitched with *catgut* sutures (a short, curved needle being used) and going through the rectal wall only. The sutures are tied on the inside, so that the knots are on the mucous membrane of the bowel. They begin from above and come down to the sphincter ani, the cut ends of which are drawn out with a tenaculum while the sutures penetrate them. These *catgut* sutures need not be removed; they will digest in the tissues and disappear of themselves. The posterior wall of the vagina is next sutured with fine silk, from above downward toward the hymen. Finally, skin sutures through the perineum itself, including muscles of the pelvic floor, are passed. The sutures (preferably of aseptic silk) are passed with a moderately curved needle about two inches long, as follows: Beginning at the posterior end of the laceration (that nearer the anus), the needle enters the skin near the edge of the wound and follows a circular course until its point appears at the very bottom of the laceration (a finger of the other hand in the rectum guarding against its penetrating that canal); it then enters the opposite side of the laceration at the bottom of the wound and comes out of the skin opposite its point of entrance, having followed a similar circular course to that pursued on the other side where it first went in. The ends are *loosely* tied or secured by catch-forceps, until the requisite number of sutures are passed in a similar manner (half an inch apart), when the wound is again cleansed, the vaginal plug removed, and the sutures tied tightly enough to coapt the parts without injurious constriction, the order of succession in tying being that in which the sutures were passed.

The silk sutures may be removed in about a week. Antiseptic dressings are applied as after an ordinary labor, extra care being taken to keep the wound aseptically clean by daily irrigation with the creolin solution." (King's *Manual of Obstetrics.*)

7. *Etiology of cancer of the uterus:* "The causes of cancer are unknown; the predisposing or favoring conditions are as follows: (1) *Age*—the disease occurs most frequently between forty and fifty. The extreme limitations are between eight and seventy-six. (2) *Heredity*—an apparent predisposing cause. (3) *Social state*—more frequent among the poor and ignorant. (4) *Race*—relatively rare among negroes. (5) *Trauma of labor*—laceration of the cervix a possible predisposing cause. (6) *Endometritis and endocervicitis* are said to be favoring conditions."—(Dudley's *Gynecology.*)

The presence of *early* uterine cancer may be deduced from the presence of an irregular uterine hemorrhage, an offensive discharge from the vagina, and sometimes pain in the pelvis. A microscopic examination may aid in the diagnosis.

Later, the tumor is noticeable, and the patient shows the characteristic cachexia; the uterus may be curetted, and the scrapings examined microscopically. Metastatic growths may be noticed in the pelvis. The growth (if on the cervix) is friable.

Treatment, to be of any value, depends on an early diagnosis. If the cancer is diagnosed quite early, before cachexia and metastasis are present, and before any other structures are involved, complete hysterectomy may prolong the patient's life.

8. *Cholera Infantum.* "The disease sets in with vomiting, which is incessant and is excited by an attempt to take food or drink. The stools are profuse and frequent; at first fecal in character, brown or yellow in color, and finally thin, serous, and watery. The stools first passed are very offensive; subsequently they are odorless. The thin, serous stools are alkaline. There is fever, but the axillary temperature may register three or more degrees below that of the rectum. From the outset there is marked prostration; the eyes are sunken, the features pinched, the fontanelles depressed, and the skin has a peculiar ashy pallor. At first restless and excited, the child subsequently becomes heavy, dull, and listless. The tongue is coated at the onset, but subsequently becomes red and dry. As in all choleraic conditions, the thirst is insatiable; the pulse is rapid and feeble, and toward the end becomes irregular and imperceptible. Death may occur within twenty-four hours, with symptoms of collapse and great elevation of the internal temperature. Before the end the diarrhea and vomiting may cease."

Acute enterocolitis.—"There is evidence of an inflammatory alteration of the intestinal wall, usually of the lower ileum and large intestine. The mucous discharges continue, mingled with food residue and often streaked with blood. Pus cells are numerous under the microscope. The temperature remains elevated or may be remittent. After two or three weeks the symptoms gradually subside, the stools become fewer in number, and the fecal character returns. In other instances the severe involvement of the intestines seems evident within a few hours of the onset, with abdominal pain, vomiting, and fever. Blood and pus may be present in nearly every stool. Tenesmus is frequent and prolapsus ani is not uncommon. In severe attacks the prostration is marked, the tongue is dry, the mouth covered with sordes, and death may ensue in a few days from profound sepsis, or if the acute stage is survived, the case may continue desperately ill for weeks, gradually recover, or die from asthenia.

Chronic ilcocolitis.—The signs of active inflammation subside; there is little pain or fever, but more or less mucus remains in the stools. The general condition of the child suffers. There is a continuous loss in weight; the skin is dry and hangs in folds; nervous symptoms are always present. There may be stiffness and contraction of the extremities, with opisthotonus. The progress of the disease is irregular, marked by short periods of improvement. Death is often due to a relapse, to asthenia, or to bronchopneumonia."—(Osler's *Practice of Medicine.*)

9. *Treatment of enuresis.*—"The physician must find, if possible, the principal reason for incontinence, by an examination of the urine, together with a general and local physical examination of the patient. More than one cause will often be found present. Highly acid, scanty urine may be relieved by a free administration of water together with an alkali, such as the acetate or bicarbonate of potash, five grains of either thrice daily. Where overirritability of the detrusor is the principal cause, belladonna in full physiological dose, by its action on unstriped muscular fiber, will usually diminish functional activity and thus correct the condition. For a child of five years, grain 1/400 atropine sulphate or the tincture of belladonna, ♏ v. may be given late in the day, and the dose increased until there is dryness of the throat and flushing of the skin. If the incontinence is not relieved when the drug is pushed to its full effect, it will not be necessary to

continue it very long. Where there is evidence of weakness of the sphincter, nux vomica or strychnine and ergot will act in strengthening its tonicity and stimulating the nerve centers. From 5 to 10 minims of fluid extract of ergot and 5 minims of the tincture of nux vomica may be given thrice daily, well diluted in water, to a child of five years. Unlike belladonna, these remedies may have to be continued for several weeks before the full benefit is obtained. Occasionally good results will be obtained by a few hypodermatic injections of ten drops of the fluid extract of ergot directly into the ischiorectal fossa. Suppositories, containing half a grain of ergotin, may also do good in this class of cases.

"The general hygienic treatment is always important. A simple, unstimulating diet, with a light early supper is desirable. Restriction in the amount of fluids, especially late in the day, may be tried. General tonic treatment, such as the use of large doses of the syrup of the iodide of iron will relieve certain cases. Cold bathing, and plenty of fresh air will act as adjuvants. Sometimes a change from one bed to another will bring at least temporary relief. The children should be taken up late at night and early in the morning, and placed upon a commode to prevent the bladder from getting too full. Punishing these children is unavailing and usually makes the matter worse by upsetting the nervous system."—(Chapin and Pisek's *Diseases of Children.*)

10. *The incubation period* of *diphtheria* is about 2 to 5 days; of *scarlet fever*, is about 3 to 7 days; of *pertussis*, is about 10 to 14 days; of *measles*, is about 10 to 18 days, usually 14; of *varicella*, is about 14 to 20 days; of *epidemic parotitis*, is about 10 to 20 days, usually 14.

(To be continued.)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

INTESTINAL PROTOZOA OF MAN. By CLIFFORD DOBELL and F. W. O'CONNOR. 211 pages with illustrations. Price, $4.50. Published by William Wood & Company, New York.

DISEASES OF THE EYE. By GEORGE E. DE SCHWEINITZ. 832 pages with illustrations. Price, $10.00 net (cloth). Published by W. B. Saunders & Company, Philadelphia.

MENTALLY DEFICIENT CHILDREN. By SHUTTLEWORTH and POTTS. 320 pages with illustrations. Published by P. Blakiston's Son & Company.

AN ESSAY ON THE PHYSIOLOGY OF MIND. By FRANCIS X. DERCUM. 150 pages. Published by W. B. Saunders & Company, Philadelphia, Pa.

LA GOUTTE ET SA CURE HYDRO-MINERALE. By MAURICE LOEPER. 144 pages. Price, 7 francs. Published by L'Expansion Scientifique Française.

THE TREATMENT OF ORDINARY DISEASES. By BEVERLEY ROBINSON. 132 pages. Published by American Medical Publishing Company, New York.

THE PATHOLOGICAL GALL-BLADDER. By ARIAL W. GEORGE and RALPH D. LEONARD. With illustrations. Price, $10.00 net. Published by Paul B. Hoeber, New York.

LEHRBUCH DER GRENZGEBIETE DER MEDIZIN UND ZAHNHEILKUNDE. Vol. 2. By JULIUS MISCH. 672 pages with illustrations. Published by F. C. W. Vogel, Leipzig.

CLINICAL TUBERCULOSIS. By FRANCIS M. POTTENGER. Vol. 1, 707 pages with illustrations. Vol. 2, 725 pages with illustrations. Price, $15.00. Published by C. V. Mosby Company, St. Louis.

THE VITAMINS. By H. C. SHERMAN and S. L. SMITH. 273 pages with illustrations. Published by The Chemical Catalog Company, New York.

VACCINS ET SERUMS. By Dr. APERT. 282 pages. Published by Ernest Flammarion, Paris.

Miscellany.

An Italian Appreciation of Virchow.—The *Riforma Medica* for January 2, 1922, xxxviii, 1, contains an account of Virchow in connection with the one hundredth anniversary of his birth. The editor feels certain that this mark of honor has the approbation of all Italian medical men and the article itself is written by a well known Italian, Dr. Aievoli. This action by the editor is hardly open to the accusation of Teutonic propaganda, nor is there any mention of the fact that the deceased antagonized with might the Prussianism of his day. The political and other extramedical activities are not mentioned, and the scientist is presented only in his role of pathological anatomist including the authorship of his epoch-making works and editorship of his *Archive* and *Jahresberichte*. He was the teacher of the distinguished Italian pathologist von Schroen, and may in turn be visualized as the successor to the mantle of Morgagni. The author quotes to some extent from the address of Professor Orth last October in Berlin, in which it was stated that Virchow had in his life attended 500 medical meetings while the number of his personal contributions was 122. Virchow was first and last a morphologist, so that the many dynamic and humoral activities of the present day represent very decided departures from the foundations laid by him.

Napoleon's Alleged Attempt at Suicide at Fontainebleau.—In a recent secular article in a prominent French periodical there is an attempt to revive an old legend that Napoleon once sought death by poisoning. This report seems to have originated among the servants of the great man, but it is known that one of these (Ali), who was quoted to that effect, was not with him at Fontainebleau. This narrows down the testimony to one Hubert, who was the emperor's valet at the latter place. The narrative was in part as follows: The emperor had sat up until 4 A. M. writing letters to the empress, but for some reason changed his mind and threw them in the fire. Believing himself quite unobserved, he went to a commode on which were kept glasses, a teaspoon, sugar bowl, and a carafe of water. The sugar bowl chanced to be empty. The emperor was seen or heard to pour water in one of the glasses and stir with the spoon. This could be explained by the fact that the order was to keep some syrup in the glasses, so that the emperor naturally thought that he was sweetening his drink. After having stirred for a time, he called Hubert to summon several notables who were presumably in the building. His face and bearing were calm. When the dignitaries had arrived he told them that he had swallowed poison in a moment of weakness as a result of his military reverses, and then had Hubert fetch the surgeon Yvan, and the latter at once administered an emetic which acted with some difficulty. After about six hours the emperor claimed to feel himself again. This account of Hubert differs in some respects from that of Baron Yvan, son of the surgeon. Apparently it is impossible to determine whether this was a bona fide case of attempted suicide or one of the emperor's dramatic coups. According to the Baron, his father was very sceptical.—*Le Progrès Médical.*

CANCER AND ENDOCRINE DISEASE.

BY SEELYE W. LITTLE, M.D.,

ROCHESTER, N. Y.

THE average physician is apt to skip tables in medical articles. I regret to say that this article contains one table and that the table is an essential part of the article. Incorrigible table-skippers should, therefore, skip the article along with its one table.

The table confirms and emphasizes several important facts not generally appreciated by the medical profession; it nullifies some statements which have become hereditary in succeeding generations of text-books; and it demonstrates some facts which, so far as I know, are here presented for the first time. There may well be slight inaccuracies in the figures presented owing to the innumerable transfers and additions required in the compilation of the table. In essentials, however, the table may be relied upon as accurate.

It would have been easy to present many other tables to substantiate various statements in the text, but I refrain. It will be a pleasure to send references, figures, tables, etc., to anyone who may be interested.

The figures for 1919 are not included because they were not available until after the table had been made up, and because the 1919 figures are merely repetitions of the others, showing precisely the same characteristics. The 1919 figures are larger, of course, but the ratios hold steady as shown.

The relative frequency of incidence, as modified by sex, of the three endocrine diseases discussed and of cancer; the parallels and the ratios shown to exist between cancer and the three ductless gland disorders; and the persistent steadiness of it all year after year—these things cannot be coincidence only. Also it seems not to have commented upon, in searching for a cancer "lead," that in general women have endocrine disorder oftener than do men; probably because the fact is not generally appreciated. Nor would it be of any special significance except for what is here brought out concerning the curious relationships between cancer and the only endocrine diseases listed in the U. S. Reports.

Deaths from Cancer and from Diabetes in Registration Area of United States for Age Period 40-59 *and Age Period* 60-79

	1915			
	Cancer		Diabetes	
Age	40-59	60-79	40-59	60-79
Males	7,960	11,286	1,671	2,265
Females	13,601	13,383	2,010	3,033
	21,561	24,669	3,681	5,298
Ratio (approximate)	7 to 8		7 to 10	

	1916			
	Cancer		Diabetes	
Age	40-59	60-79	40-59	60-79
Males	8,452	12,130	1,811	2,385
Females	14,544	14,452	2,168	3,204
	22,996	26,582	3,979	5,589
Ratio (approximate)	7 to 8		7 to 9.8	

	1917			
	Cancer		Diabetes	
Age	40-59	60-79	40-59	60-79
Males	8,742	13,035	1,872	2,519
Females	15,262	15,051	2,095	3,287
	24,004	28,086	3,967	5,806
Ratio (approximate)	7 to 8		7 to 10.2	

	1918 (Year of influenza pandemic. This table is exclusive of deaths among military and naval forces.)			
	Cancer		Diabetes	
Age	40-59	60-79	40-59	60-79
Males	9,258	13,514	1,879	2,389
Females	16,029	16,379	2,103	3,143
	25,287	29,893	3,982	5,532
Ratio (approximate)	7 to 8.5		7 to 9.7	

1919 Ratio—Cancer, 7 to 8.6; diabetes, 7 to 10.1.

The first point to be emphasized is that there are actually more cancer deaths during the age-period 60-79 than during the age-period 40-59. Yet in the 40-59 period there are about three times as many people as in the 60-79 period. Diabetes has the same characteristic, and both diseases have it year after year. The ratio of deaths in one period to deaths in the next period is marvelously steady year after year for each of the diseases respectively; for cancer the greatest variation is from a ratio of 7 to 8, to a ratio of 7 to 8.5, and the greatest for diabetes is from 7 to 10.2, to 7 to 9.7; giving for each disease the same maximum variation—0.5. This means, among other things, that each disease consistently maintains the even tenor of its own particular gradually rising death rate from one twenty-year age period to the next, does this year after year; that not even a great pandemic with a high death rate could seriously affect the ratio of deaths in the two periods in the case of either disease, though it did bring the total number of deaths from each disease below the total which one might confidently look for under average conditions. Beyond a doubt many deaths from cancer and from diabetes were forestalled by death from influenza or pneumonia in the year 1918. Many other diseases had a slightly lowered death rate in that year.

In spite of text-books and popular medical opinion, diabetes, like cancer, is commoner among women than among men—persistently, regularly, year after year; and, like cancer, the ratio of diabetes deaths among men to diabetes deaths among women remains fairly constant year after year. That diabetes is commoner among women than among men is a fact which the writer was anxious to verify long before he had any large-scale mortality statistics to work with; because from his study of cancer in connection with ductless glands he was logically con-

vinced that it must be so. Premises and logic being perfect, the conclusion must be correct. At any rate, it was agreeable to find a reasoned conclusion thus verified.

Besides cancer and diabetes there are other diseases which are preeminently old-age diseases. Death rates for old-age populations are, of course, enormously high, but there are only a few diseases the death rates from which are always remarkably high in old age as compared with their death rates at other age-periods, and at the same time diseases which furnish yearly a large total number of deaths among the aged in comparison with their total number of deaths at other age periods; and diseases which also year after year regularly account for a large number of deaths among the aged not only in the relative sense but in the literal sense. Such diseases as influenza and pneumonia we may dismiss as irrelevant. Their old-age death rates are very high, but not steady from year to year as are the rates for cancer and diabetes. There is, however, one general class of diseases which notoriously are old-age diseases, which have enormously high old-age death rates, gradually increasing rates, and rates steadily maintained year after year. A very large proportion of old people regularly die from these diseases. They are: Apoplexy, chronic organic heart diseases, chronic "rheumatism," "asthma," chronic bronchitis, and chronic nephritis. These are all diseases of one general type commonly known as the degenerative diseases of old age. These too are irrelevant to this discussion. One reason among many is that they are not at all partial to women—the contrary rather. Obviously neither the infections nor these other diseases have any relation either to cancer or to diabetes save that all have unusually high death rates among old people. Our table shows plainly now that cancer and diabetes are in a class by themselves and wonderfully alike as regards sex incidence, steadiness of high death rate from age 40 onwards, persistent gradual increase in death rate, each maintaining the same relative rate of increase, and in other particulars.

But there is much more than this. Up to about age 20 both diseases are comparatively rare; both occur as often in one sex as in the other, and each tends to run a rapid course; what fluctuations in sex incidence and in death rates there are from year to year at this age period are practically alike in the two diseases. From age 20 onwards each is predominantly a disease of women, without a break, to extreme old age. From each disease the greatest absolute number of deaths in any one five-year period is, among men, the age period 65-9; among women, the age period 60-64. (1918.) This last parallel is not always so precise as in 1918, but it is always a very close parallel. There is no other known disease at all comparable with cancer and diabetes in all the above noteworthy parallels; there is none at all comparable in any two or three of the above parallels, save two diseases which are exactly parallel in every important respect except frequency. These two others are comparatively rare diseases but *they are both ductless gland diseases*. More of these two others later.

Here then are four diseases each of which has precisely the same unusual and characteristic combination of features steadily maintained from infancy to extreme old age, a combination so peculiarly their own as to place them together in a class by themselves, and so foreign to other diseases as to exclude every other known disease from that particular class. Three of the four are known to be ductless gland diseases; *the fourth is cancer*. There are of course other ductless gland diseases besides these three; but none is qualified to enter the particular class mentioned. (For example, acromegaly is a ductless gland disease, but for obvious reasons it is never a disease of early life.) One of the four besides cancer invariably presents in its later stages pathological new-cell growth of embryonic character, as will be shown presently. Each one of the four is unmistakably a separate disease entity while all four unmistakably belong to the same general class; just as scarlet fever and chicken pox are separate disease entities belonging to the same general class.

If cancer is a disease in the same class with three well-known ductless gland diseases, why is it that cancer does not regularly present symptoms plainly referable to dysendocrinism? *It does*—invariably; and it presents far more such symptoms than does diabetes, for example. What endocrine symptoms, may I ask, does diabetes present? Sugar in the urine means neither diabetes nor endocrine disorder necessarily; nor does absence of sugar from the urine necessarily mean neither diabetes nor dysendocrinism. The one invariable characteristic of true diabetes is faulty carbohydrate metabolism of endocrine origin, a fact not even yet realized by the average practitioner to whom diabetes is still for all practical purposes "sugar in the urine" because that is the one common outstanding spectacular symptom of the disease, which he insists upon seeing (in a test tube) before saying "diabetes." Diabetes begins before sugar appears in the urine.

Likewise, and to a greater degree, for most medical men *a* cancer is cancer simply because it is the one essential outstanding spectacular manifestation which he always has insisted upon demonstrating (and still does) before he will say "cancer"; for most medical men *a* cancer is the disease cancer —"at first"! And why not from the beginning to end? "Well, towards the end, you see, there are constitutional symptoms—anemia, waste of body tissues, cachexia, and all that." What about such clinical phenomena as the following? Highly specialized body cells which have reverted to embryonic type; which defy the whole organism by reproducing their kind indefinitely and in every instance; which, from the beginning to the certain end, thrive and flourish the better as all other body cells become weaker and less capable of performing their proper work; which thus appear and thrive with steadily increasing frequency year after year without a break from maturity to extreme old age, the increase being slight from year to year during early adult life but greater and greater year after year from mid-life onwards; corresponding precisely to the biological truth that a normal cell begins to die when it stops growth or development, or both, slowly at first but with increasing rapidity as time passes; thus, when an individual is physiologically completely matured, he at once begins to die in like manner. But if in such an individual there happens

to be even a single body cell of embryonic type, such as those under consideration, there is no physiological reason why it should die along with the dying mature body cells; on the contrary there is every reason why it should thrive, and it does;—What about such clinical phenomena as those just mentioned? Are those embryonic-like cells when few in number not only a cancer but "a purely local disease," while the same cells or their progeny when numerous are still a cancer (or cancers) but are not by any means the sum-total of the same disease? And what caused those abnormal cells to appear in the first place? And why do they appear with increasing frequency as age advances, pari passu with the increasing rapidity with which physiological death of the normal body cells takes place? And if we "cure" cancer by cutting out a cancer while it is still a "purely local disease" what's to prevent the "purely local disease" appearing again from the same cause which accounted for the first attack? (This happens occasionally! How about it?) Is it claimed that a beginning cancer is not only a cancer, and the sum-total of the disease cancer, but also is or contains the cause of itself in its dual capacity as a pathological new growth of body cells and as a purely local (at first) disease? This must be claimed by anyone who claims that total removal of a beginning cancer cures cancer. No disease is cured unless its cause is removed or otherwise rendered harmless. Yet no one can claim that this is done, as regards cancer, by the removal of a beginning cancer unless he also claims that the unknown cause of cancer is known to be included within a cancer, "at first." Why does the bulk of medical authority persist in this "local disease at first" nonsense? Cancer from start to finish is demonstrably a constitutional disease though I do not propose to repeat here a demonstration which has been made repeatedly by myself and others.

Cancer begins before there can be a cancer; and the disease must necessarily be caused by something or other which must sooner or later in every case account for the appearance of a cancer, and must account for the inevitable death of every cancer patient who is untreated, for the death of most of those who are treated on the local-disease-at-first plan, and for all other known cancer facts including those shown in our table.

There are present in every individual certain essential-to-life organs which are also essential to normal cell growth and development, to normal functioning and normal metabolism of certain highly specialized cells, and therefore to general normal metabolism of the body as a whole. Like all other organs they fail as age advances. These organs belong to the class appropriately called by Noël Paton 'regulators of metabolism"; lacking such control, embryonic cells remain embryonic cells to the end of the chapter; lacking such control, a highly specialized cell which became highly specialized only because it formerly had such control, cannot remain highly specialized in function and, consequently, it must eventually lose its physical characteristics as a highly specialized cell or it must perish; a functionless cell does one of two things—it "reverts to type" or it undergoes the "atrophy of disuse." This suggests a good lead for those seeking the essential causative factors of cancer.

If dysendocrinism is at the basis of cancer it is obvious that long before a cancer could appear there should be some lesser symptoms than a cancer of the gradually increasing dysendocrinism long before the dysendocrinism had reached a point which made a cancer possible. It may well be asked, therefore, why there are no such premonitory symptoms if dysendocrinism has anything to do with causing cancer. The answer is simple: there *are* such symptoms. At this point experience tells me that a flood of questions comes: "Who says so?" "How do you know?" "What are they?" "Why hasn't someone else noticed and called attention to any such symptoms?" "Why don't such symptoms become more and more marked as the disease progresses?" etc. etc.

Categorically I will answer the above questions in order.

I say so. I've seen them whenever I look for them. See next paragraph. Many others have noticed and called attention to such symptoms. They do.

Very often before a cancer appears, always after it appears, a cancer patient shows unmistakable symptoms of dysendocrinism which become more and more pronounced as the disease advances. In this place I mention only two such symptoms and invite any physician to look for them and thereby convince himself that one or both of them often precede by months the appearance of a cancer. I select these two because they are easily detected and one does not have to be an expert endocrinologist in order to believe that they are produced by something or other going wrong in some ductless gland or other. (1) High blood-sugar ratio, with or without (generally without) glycosuria; (2) Abnormal pigmentation. High blood sugar ratio without glycosuria often means a beginning diabetes; perhaps oftener, after age 50, it means beginning cancer; try it and see.

Gradually appearing skin pigmentations, freckle-like, often appear as old age comes on; due, doubtless, to the normal physiological aging of certain ductless glands. At any rate it seems to be a perfectly normal old-age phenomenon. But abnormal or unusual or very marked pigmentation always suggests ductless glands to the clinician, especially when appearing rather suddenly and when it cannot be accounted for by external causes such as sunburn, *x*-ray, etc.

Not rarely one may observe in aging people a rather sudden marked increase in size of existing old-age pigmentation, or a suddenly appearing crop of new spots, or both. Such unusual sudden increase in old-age freckling frequently precedes by several months the appearance of a cancer which by no means is always a skin cancer—indeed, most frequently not a skin cancer. And often one may observe a rather sudden appearance of old-age freckling before it is normally due; this also is often a forerunner of a cancer. Likewise in persons of any age the sudden increase in intensity or extent of pigmentation in a long-existing abnormality of the skin—a mole for example—more often than not presages a cancer of the skin at that point. Here again any physician who will may convince himself.

In passing it may be of interest to learn that in

many cases I have caused such abnormal pigmentations to disappear through proper endocrine therapy; and I like to think that thereby I have "cured" cancer before there was a cancer. I have certainly, in like manner, caused may typical so-called precancerous lesions to disappear; and thereby certainly prevented the appearance of a cancer at such sites just as well as though I had caused them to disappear by cutting them out. I choose to believe, however, that by this method of removal I have done far more than can be accomplished by cutting out "precancerous" lesions. In my opinion I accomplished the removal by removing the cause, *i.e.* by supplying what the failing ductless glands could not supply; and in my opinion I "cured" cancer before there was any cancer. All this and all other statements as of fact I am prepared to prove to the satisfaction of anyone who can see and who will see.

A minor but suggestive fact which has a bearing on our thesis is this: Fat people are, generally speaking, more likely to have cancer than thin people; likewise they are more likely to have diabetes. At and after mid-life women are more likely to put on fat than men. Women are more liable to cancer than men, and more liable to have diabetes. Fat people, overworked metabolic machinery, and ductless gland failure fit nicely into the picture, and constitute in themselves an harmonious trio.

Besides diabetes there are but two other diseases which are listed in the U. S. Mortality reports and which are at the same time known to be ductless gland disorders: Addison's disease and exophthalmic goiter. I have not placed them in my table for several reasons; chiefly because neither is preeminently a disease of old age. A flaw appears in my argument here, apparently. I have rather more than hinted that ductless glands naturally and normally fail along with all other organs as age advances; that premature endocrine failure, or too rapid failure in the old-age period instead of the normal gradual failure, provided such failure occurs in an essential-to-life ductless gland, fills the bill in accounting for the fact that cancer, like diabetes, appears more and more frequently year after year from mid-life to extreme old age. Why, then, shouldn't Addison's disease increase in frequency as age advances? For the simple reason that Addison's disease is generally a result of *tuberculous* disease of the adrenals. Tuberculous disease lessens in frequency as age creeps on. Incidentally it might be mentioned that "cancer families" are generally "tuberculous families" to a greater degree than they are "cancer families." Again, the Adrenals are two ductless glands, but one of which (the cortex) is essential to life. Why do we not have an increasing number of deaths from non-tuberculous-caused cortex failure, then, from mid-life onwards as we should according to my argument? In other words, the cortex surely fails more and more as age advances, and where are the necessary corresponding old-age deaths caused by failure of this vital organ? Where are the old-age deaths from non-tuberculous-caused Addison's disease? There were less than 100 deaths from Addison's disease after age 59 in the whole Registration Area; that would not account even for the deaths naturally to be looked for as the result of the inevitable *normal* failure of the cortex along with other vital organs in old age. Lethal old-age of the cortex surely "gets there first" sometimes. (There were over 12,000 deaths in the Area in 1918 listed as deaths from old age.") Much less can the 306 deaths (for all ages) recorded in the Area in 1918 as deaths from Addison's disease account for all the deaths that must have been caused by *abnormal* failure of this vital organ, whether such failure was due to tuberculous disease or not. We know that the islands of Langerhans thus abnormally failed in 1918 many thousands of times because we know one thing at least that results therefrom, viz., diabetes. Suppose that glycosuria were excluded from the symptom complex of diabetes, would there have been 12,800 deaths in the Area listed as caused by diabetes, *i.e.* by a disordered ductless gland? Even with the spectacular, easily found, test-tube symptom we used to write "diabetes" on death certificates as we do now; but a few years ago the word was only a tag meaning "sugar going through"; diabetes was "sugar going through," a disease named from its one spectacular symptom. Now the word means "disordered carbohydrate metabolism caused by failure of the islands to function properly." In the old days there were no deaths recorded as being due to disordered islands of Langerhans. Diabetes was frankly only a convenient tag; now it is a silly misnomer for an endocrine disease. Right here it is important to realize that microscopically proven very extensively damaged islands by no means necessarily result in diabetes or in "sugar going through." I am prepared to demonstrate that a patient may die, said patient's islands being found at autopsy plainly disorganized to a degree incompatible with continued life, said patient never having had glycosuria during the last three years of life (the urine having been repeatedly tested), said patient's death certificate reading, as "cause of death," "Cancer of Stomach," said cancer being duly found at autopsy. All of which proves that seriously disordered islands do not always mean diabetes.

Where are all the deaths from cortex failure? Addison's disease cannot possibly account for them. And we haven't even an Addison's disease to account for deaths that must be due to lethal failure, from mid-life on, of one or two other essential-to-life ductless glands. It is incredible that such deaths never occur. There were in 1918 in the Area some 65,000 deaths, etiology unknown. They were all tagged "cancer"—but let us get on.

Addison's disease, Graves' disease, diabetes, and cancer have the following characteristics in common: More deaths among females than among males (did you know that fact as regards Addison's disease?); number of deaths increased from year to year at a pretty steady rate for each disease respectively (except for the year 1918, the grippe year, when deaths from diabetes and from Addison's disease fell below the 1917 figures, owing doubtless to grippe often getting in ahead of diabetes and of Addison's disease in the epidemic of 1918; many diseases, cancer among them, showed a slight slump that year in like manner); much rarer among Negroes than among Whites, relatively to population (has pigmentation anything to do with it?); abnormal skin pigmentation quite fre-

quent; changes in blood composition, though not necessarily the same either in kind or in extent in any two of the four (but note next paragraph); invariably as each disease progresses there are progressive disturbances in nutrition and in metabolism as a whole, though not necessarily, again, disturbances of the same sort in any two of the four; death from any one of the four diseases is preceded by what is called "cachexia"—as a rule in cancer and in Addison's disease, frequently in diabetes, not rarely in Graves' disease.

Addison's disease commonly, perhaps always toward the end, exhibits the symptom of a *pathological new growth of cells of fetal type.* Cancer commonly, perhaps always toward the end, presents the symptom of a pathological new growth of cells of fetal type which is so like the Addisonian new growth that it is actually called "Addisonian"! I refer of course to nucleated red blood cells. These embryonic-like blood cells are not collected together but travel about each by itself in the blood stream; and they do not appear until the disease is pretty well along. So, obviously, in each disease, the new growth scattered about in the blood stream is a mere symptom and cannot possibly be a purely local disease—not even at first; obviously likewise a cancer is a totally different thing because it does not float around loose in various parts of the body—at first; and besides a cancer is always—at first—a purely local disease including all symptoms thereof! That is a thoroughly established truth—an axiom really!

We have four diseases, three of which are of endocrine origin and the fourth of unknown origin. The unknown quantity in every instance resembles the known quantities in many peculiarly distinctive characteristics, while it resembles no other class of known diseases in like manner. There are many other features common to cancer and to endocrine disorders besides the few barely outlined above. I am fully prepared to account for every proven cancer fact on the basis of dysendocrinism being the factor, or at least *a* factor, without which cancer is impossible; to do this without insulting either cancer facts or endocrine facts. This may seem like a case of exaggerated ego. As you please; but try me on any cancer fact. Remember, I do not say here that dysendocrinism is the basic cause of cancer; I say that dysendocrinism can account logically for all known cancer facts; freely admitting that something else may account for them better and that there may be actually no etiological connection at all between disorders of the ductless glands and cancer incidence.

But even granting the exaggerated ego, isn't the matter worthy of serious investigation? One thing is certain: Any theory of cancer, or none, as a working basis for treating cancer, would reduce the cancer death rate just as rapidly as does treating cancer on the theory that cancer is at first a purely local disease and is therefore curable by total early removal of cancers. We have been working on that basis with increasing zeal for many years. Death rate for cancer in 1920, highest on record.

This article is designed simply to stimulate possible readers to do a little thinking.

EXOPHTHALMIC GOITER: THE PROBLEM OF RECOVERY.

BY ISRAEL BRAM, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN CLINICAL MEDICINE, JEFFERSON MEDICAL COLLEGE.

THOUGH on the offensive with respect to operative mortality and *immediate* clinical results in Graves' disease, surgery is still more than ever on the defensive with respect to justification of operative procedures and the completeness and permanency of recovery. It is the contention between the various schools of treatment and the scarcity of clinicians who understand the disease and its victim that render the treatment of such a patient an almost unmanageable task; when, in truth, the prognosis in the usual instance of Graves' disease should be far better than that of the usual instance of pulmonary tuberculosis—and recovery should be far more conclusive.

In this paper we are not concerned with toxic adenoma or hyperthyroidism, which indicates a state of thyroid hyperactivity superimposed upon an old-standing nontoxic goiter, and in which thyroidectomy, removing the causal adenoma, cures the patient. We shall here discuss exophthalmic goiter or Graves' disease, an affection of widespread etiological, clinical and therapeutic implications. The following deductions are based upon a prolonged, intensive observation of this disease, with a record of over four hundred* nonsurgical recoveries. It is the hope of the writer to imbue the reader with the importance of *permanent recovery* rather than *transient improvement* in the sufferer from Graves' disease.

The Pro and Con of Operative Mortality.—A recent patient of mine had made arrangements with a prominent surgeon in Philadelphia to be operated on. Being of an analytical nature, happily married and rather fond of life, he asked: "Now, doctor, you are a good surgeon, and I will probably live through the operation. Thus far I am convinced. But will I get well of my sickness? I must be reasonably certain of this before I enter the hospital." The surgeon, an honest, frank gentleman, informed him that statistics showed a large percentage of improvements, but as to complete recovery, time only could tell. "If you cannot give me more assurance than that, and if *you cannot show me surgical cures of my sickness*, you shall not operate on me!" He left the surgeon then and there, and after three months of nonsurgical management, this patient is rapidly becoming a normal individual. All evidences of the formerly typical Graves' disease are gone, excepting a still very slight exophthalmos which bids fair to disappear within the next two or three months. This is one of many similar instances that could be cited. The low operative mortality rate in exophthalmic goiter, in perfectly appointed clinics, is *surgically* fortunate. *Clinically*, it is unfortunate, in that its coercive influence causes hopeful

* This figure represents the number of patients discharged from active treatment up to July, 1920. These patients were followed up for from one to nine years to confirm the completeness of recovery. Patients seen with toxic adenoma, those under active treatment, and those seen in consultation but under the care of their family physician are not included in the above figure.

patients and many hopeful busy practitioners to put a blind faith in the knife as a remedial measure in this disease. Improvement in surgical technique and lowering of operative mortality rate are not *per se* good reasons for operating. The *rationale* of thyroidectomy should not be based upon the fact that only two or three in a hundred die of the operation. It is not justified even if many patients surviving operation are improved, if this amelioration of symptoms is incomplete and temporary. The patient rightfully expects but one result for the risk undergone and the resulting scar, and that is, an unequivocal *cure*—a complete, permanent, subjective and objective restoration to health, happiness, and utility. Surgery does not produce this result in exophthalmic goiter. Moreover, the mortality rate, were a broadcast average taken, is still genuinely high. Thyroidectomy of the hyperplastic thyroid is replete with peril, and is one of the most difficult and dangerous of surgical procedures, the *average* mortality rate of which is considerably in excess of 10 per cent. In my observations I find that in clinics where thyroid work is merely incidental to general surgery, a 50 per cent. mortality in Graves' disease is occasionally met with. Even in ligations, death occurs where it is least expected. If it is true that "a patient dead is 100 per cent. dead," we begin to dread lest in the very next patient scheduled for thyroidectomy "something goes wrong."

The Inconclusiveness of Thyroidectomy.—Aside from the operative mortality, the shock, and the well-known dangers and sequences associated with surgery of the hyperplastic thyroid, to all of which the patient is subjected without the substantial reward of clinical recovery, the *multiplicity* of operations, regarded by surgeons as necessary in a goodly percentage of patients, is not only an added peril to life, but diminishes the prospects of final recovery. This multiplicity of operations is dependent upon clinical relapse, but the surgeon usually ascribes its need to lack of "subtotality" of the original thyroidectomy. That the thyroid substance left by the surgeon sooner or later increases in size by cellular proliferation until there is again a fair-sized goiter, is not only seen clinically and in the postmortem room, but is proved through animal experimentation. Leo Loeb,[1] for instance, confirming the results of Halsted's experiments, found that after the subtotal extirpation of the thyroid in guinea pigs, the remainder of the gland showed hypertrophy in course of time. The piece of hyperplastic thyroid tissue left *in situ* still hyperfunctionates—still heeds the call of the uninfluenced, activating etiological factors which require the assistance of an *entire* thyroid gland for compensation, and soon this organ endeavors to become entire again through regenerating proliferating processes. Often the regenerated thyroid mass exceeds in size the dimension attained before operation, when the surgeon again feels "in duty bound" to operate. Surgical attack of the hyperplastic thyroid is physiologically, pathologically, and clinically inconsistent. It is the almost unanimous opinion of endocrinologists throughout the world, that though the disease asserts itself largely as a thyrotoxemia because of thyroid hyperactivity, the direct pathogenesis is of *pluriglandular* nature, the thyroid hyperactivity occurring merely as a link in the chain of events in which the thymus, suprarenals, pituitary, parathyroids, pancreas, and gonads play no small part. In brief, Graves' disease is a generalized neuro-endocrine[2] dysfunction, in which thyroid hypersecretion plays its part not causally, but sequentially. Thyroid hypersecretion is no more the main factor in the clinical picture of this affection than is splenic hypertrophy of typhoid fever the main factor in typhoid. The hyperactivity of the thyroid, whether the organ be enlarged or no, and the enlarged spleen, are results, not causes, of their respective affections. Each is a *constituent* of the syndrome of which it forms a part, and it is just as irrational for surgery to attack the thyroid in Graves' disease as it is to attack the spleen in typhoid fever.

Again, the thyroid responds to physiological demands, increasing in size and function during puberty, adolescence, pregnancy, and the menopause. The thyroid responds to pathological demands made upon it by infections, focal and general, psychic trauma, and glandular disturbances elsewhere in the body, frequently resulting in a decided increase in size and structure of the organ. In each case the thyroid performs an important duty—that of defending itself against irritating influences and dysfunction elsewhere, and in this defense the element of thyroid compensation and hypertrophy in the interests of bodily integrity is vital. It is just as absurd surgically to attack this compensating protecting organ resulting from the pathological demands, as it is to operate on it because of the physiological demands.

Irrelevant Analogies of Surgery.[3]—The surgeon occasionally asks: "Why remove diseased tonsils, and fear to remove a diseased thyroid?" Remove all of a diseased tonsil, and your tonsillectomy is complete and satisfactory; leave a part, and we are in course of time confronted with the need for another operation, the remaining portion having served as a root for the regeneration of the removed tissue. Remove the thyroid, however, and you ruin or kill your patient through the resulting myxedema. Leave a portion in order to conserve the life of the patient, and as with the lingering portion of diseased tonsil, sooner or later the entire gland is regenerated, and we have again a full-fledged example of hyperplastic thyroid. Again, "Why remove a diseased appendix," the surgeon argues, "and hesitate to remove a diseased thyroid?" The analogy is erroneous for (1) appendicitis is a local disease while Graves' disease has a widespread etiology, symptomatology, and physiological relationship; (2) the appendix is a vestigeal organ while the thyroid is a vital organ and must not be tampered with; (3) the appendix, in appendicitis, is the seat of germ activity while the hyperplastic thyroid is not infected; (4) operative removal of the appendix renders the patient well and healthier than ever, while the total removal of the thyroid means a slow death from cachexia strumipriva and partial removal does not cure exophthalmic goiter. It is obvious that, logically speaking, the surgeon is on the horns of a dilemma.

Opinions of Other Clinicians.—Let us examine the views of other observers interested in this subject:

Leonard Williams[4] insists that a large percentage

of patients with exophthalmic goiter could be successfully managed nonsurgically.

S. P. Beebe:[5] "The present low mortality of thyroid surgery in competent hands has been obtained at the cost of many unfortunate victims, as a rule."

Lewellys Barker:[6] " . . . It must be remembered, however, that even after surgical operation upon the thyroid gland, patients who have had Graves' disease with diffuse hyperplastic goiter, rarely regain perfect health. They require close medical supervision for a long time, often for the whole of life . . ."

F. B. Scott:[7] "That brilliant craftsman, the thyroidectomist, should become an anachronism, a tradition only of the dark days that are gone; and medicine, strong in physiological and philosophical faith, should resume her peaceful sway."

J. M. Pearson:[8] " . . . Strictly speaking, he (the surgeon), in the last event, does not *cure* the patient. To take away an offending portion of the body can in no sense of the word be considered the equivalent of restoring its integrity or causing the peccant portion to resume its orderly function."

Solomon Solis-Cohen:[9] "In Volume lxv (1911) of *Guy's Hospital Reports*, Dr. Hale White records the results of an attempt upon his part to trace the history of patients discharged after medical management during the last twenty years, and he finds that in about 80 per cent. the recovery has been permanent. In my own personal and consultation practice I have had the opportunity to observe a number of patients for periods varying from a few months to twenty-five years after apparent recovery from nonsurgical treatment. In but one instance has there been relapse, and in no case had death occurred from any condition with which Graves' disorder could be causatively associated."

Robert McCarrison:[10] "In four out of eleven 'cures' effected by operation at St. Thomas' Hospital, there was no evidence of Graves' disease found on microscopical examination (Mackenzie), so that in 36 per cent. of these cases which were classed as 'cures' we must admit either an error in diagnosis or conclude that the thyroid gland does not share the usual evidences of Graves' disease in a very much higher proportion of cases than has hitherto been supposed . . . the practice of operative interference with the thyroid gland in all cases of Graves' disease at sight and without applying all the resources of our art in the detection of its cause, as is now a very common custom, is one which cannot be too strongly deprecated. I am convinced that . . . the number of cases in which thyroidectomy is performed will become smaller and smaller, and its practice, except in cases which have baffled the most painstaking investigation, will ultimately be abandoned."

David Marine:[11] " . . . We must look for the essential cause of exophthalmic goiter outside the thyroid. . . . From the standpoint of pathological physiology, this overactivity of the thyroid seems primarily a purposeful or compensatory reaction due either to the exhaustion or partial loss of the regulatory control over oxidation processes normally exercised through the sympathetic nervous system."

W. V. P. Garretson:[12] "The extirpation of a hyperactive thyroid gland is in most instances absolutely contraindicated and is a procedure based upon ignorance of glandular function. That gland is overactive in an effort to compensate for a deficiency of function elsewhere in the endocrine gland chain. The intimate interrelationship of glandular function teaches us that hyperactivity is a compensatory effort to offset hypoactivity elsewhere. In the case of the thyroid it usually indicates an ovarian or suprarenal gland exhaustion. Artificially supplying the deficiency under proper conditions will effect the desired results."

Russell, Millet and Bowen:[13] ". . . Although both Goetsch and Woodbury claim clinical improvement in almost all their cases following thyroidectomy, in no instance had their patients been followed over a period exceeding nine months. Furthermore, we do not feel that the degree of subjective improvement reported is sufficiently striking, in the absence of careful control by direct personal observation and the repeated use of function tests, to justify any dogmatic statement on this most important point. Particularly is this true since the physiological effect of operation and the recognized value of a subsequent rest period might together be sufficient to produce a definite, if temporary, amelioration of symptoms. We must not be unmindful of the danger of hypothyroidism developing in these cases as a result of thyroidectomy. As far as we know, no report has yet been published of basal metabolic estimations following these operations."

C. F. Hoover:[14] "I have been unable to see any justification for amputation of part of the thyroid gland as a direct treatment for Graves' disease."

And here are a few expressions from thyroid *surgeons:*

Carrington Williams:[15] "Group III (exophthalmic goiter) are improved by surgical treatment; the prognosis, however, is not comparable to what may be expected in Group II (toxic adenoma). We believe that the best results claimed in treating exophthalmic goiter have been due to operations on cases in Group II which is not exophthalmic goiter. The converse, however, is true—that is, that poor results are in cases which we would classify in Group III."

J. T. Mason,[16] of Seattle, commenting on "Mistakes Made in One Hundred Thyroidectomies," remarks: "Ligation will often precipitate a severe attack of hyperthyroidism. There is always a reaction; this is especially true following ligation. The collateral circulation is unquestionably restored within a few days. . . ." The probability is that to the shock of the ligation procedure there is added a collateral circulation which not only compensates but frequently over-compensates nature's desires for thyroid vascularization.

"Dr. Crile some years ago made the statement in reference to cases of hyperthyroidism (with exophthalmic goiter or not), that he thought it necessary after thyroidectomy that the patient be sent to a convalescent home in the country for six months if cure was to be permanent. He then went to work to say that such patients made as great an improvement without thyroidectomy as did those who had been operated on."—Tom A. Williams.[17]

Charles H. Frazier:[18] "How little is known today of the function of the thyroid even though sur-

geons have been removing them by the thousand! How many physicians still question the propriety of operating for toxic goiter and assume a skeptical attitude as to the reported results of surgical interference! It is my own belief that the present status of surgical therapy is but a stepping-stone to the development of some method of arresting the toxic functional disturbances of the gland and that eventually other measures, perhaps nonoperative, will be forthcoming, that will deal with the cause rather than the effect of deranged function and by removing the cause, break the vicious circle."

C. Capezzuolo,[19] in a review of the literature on the results of operative treatment of exophthalmic goiter, including his own experience, states that surgeons might find, on examination of patients some time after operation, many patients relapsed who had been reported as cured. Though a surgeon, this author insists that a course of medical measures should be tried repeatedly, and that the patient be impressed with the importance of cooperation in treatment.

André Crotti:[20] "One may think the distinction between these two forms of goiter devoid of interest. Therein lies the mistake, for the distinction between them is of great clinical and prognostic value. The thyrotoxic nodular colloid adenoma responds to surgical treatment far more readily and safely than the parenchymatous one." This is a subtle way of stating that the toxic adenoma is a relatively safe surgical risk, but that in the thyroid swelling of Graves' disease surgical interference is replete with disaster. We heartily agree with Dr. Crotti.

The Basal Metabolism Argument.—In a recent discussion on the floor of a Philadelphia Medical Society,[21] it was shown diagrammatically that after thyroidectomy in exophthalmic goiter the basal metabolism rate was very much reduced; after *x*-ray treatment the rate was reduced to a lesser degree, but there was no reduction following the administration of quinine hydrobromide. In this mechanical, mathematical, cold, offhand fashion, surgery was glorified as successful, and nonsurgical treatment as a failure, in the therapy of this disease. These patients, in whom the emotional element plays a leading etiological, clinical, and therapeutic rôle, were regarded as "cases"—the human element was forgotten, and cold, lifeless figures were juggled to the advantage of statistics. We admit that a reduction of some of the secreting thyroid substance, whether through the knife or the *x*-rays, yields a reduction in basal metabolism in a goodly percentage of "cases"; but this is temporary and is not "cure"; on the other hand, we refuse to entertain the idea that the casual administration of quinine hydrobromide is synonymous with a rational regimen of nonsurgical management of Graves' disease. Such hasty generalizations as give rise to the aforementioned statistics are responsible for the still prevailing chaotic status of the therapeusis of this disease.

Clinical Differences Between Thyroidectomized and Non-Thyroidectomized Patients.—Complex as may be the task of managing to a successful outcome an unoperated patient with exophthalmic goiter, the task is infinitely more difficult, though usually finally successful, in one whose thyroid has already been tampered with one or more times by surgery. In a previous paper,[22] I pointed out that the main clinical differences between the two types of patients are as follows:

1. The course of the disease in a patient surviving operation is usually more chronic, the bodily tissues becoming more firmly settled into morbid physiological function.

2. This confirmation of morbid tissue habit, asserting itself in hyperexcitability and excessive catabolism, leads to greater degenerative changes than are observed in less chronic (nonoperated) patients.

3. These changes, occurring in the circulatory system, account for the numerous instances of cardiac decompensation seen in operated patients.

4. The changes often show a predilection for the central nervous system, as evidenced by the greater predominance of insanity in operated than in unoperated patients.

5. Not infrequently the thyroid gland itself is the site of marked postoperative degenerative changes, leading to the symptomatology of the so-called "burned-out" goiter. Thus, a subject of thyroidectomy may, within a few months, present evidences of both hyperthyroidism and hypothyroidism, merging sooner or later into the complete clinical picture of myxedema or cachexia strumipriva.

6. Taking the foregoing factors into account, it is evident that the difficulties of the endocrinologist in the management of an operated case are at least twice as great as in a case not interfered with by surgery; in fact, the obstacles to complete restoration of health at times appear insurmountable.

What the Thyroid Means to Us.—"The thyroid is not essential to life, but it is synonymous with making life worth living."—George W. Crile.[23] If this is true, then the surgical removal of five-sixths of the organ deprives the patient of five-sixths of that which is responsible for making life worth living. The claim that the patient can get along with one-fifth or one-sixth of the thyroid tissue originally given him by Nature is fallacious. Though this may appear to be true during sleep and during moments of wakefulness akin to sleep when body and mind are at a low ebb of activity, and are, so to speak, hibernating, a normally active individual requires all his thyroid structure and function in order successfully to compete physically and mentally with his fellow men. If we were endowed with a kind of supernatural vision, we should see the thyroid serving as a physiological barometer, indicating every physical and mental stress and strain essential to the onward march of civilization. Not only are patients with lessened thyroid substance unequal to normal physical and mental demands, but since this organ plays an important rôle in immunizing processes of the body, a person possessing but a fraction of his thyroid is especially prone to infection.

The Solution of the Problem.—In Graves' disease, "the etiology of which is as elusive as the fountain of youth, the symptomatology of which is as varied as the colors of the rainbow, the syndrome of which is seemingly characterized by more vicious circles than are seen elsewhere in the domain of medicine—in brief, in this disease presenting so great a confusion of structural, functional, and psychic features for study that the keener the observer the

greater the problems still unsolved"[2]—is it any wonder that the patient is a burden to the general practitioner? Is it to be marvelled at that the general practitioner, often finding himself incapable of managing his charge, and unacquainted with an internist especially trained and skilled in this work, turns the "case" over to the surgeon? The busy practitioner, though hopeful, does not expect cure through the surgeon's efforts—his experience in previous instances teaches him that the most to be expected from surgical effort is temporary improvement. But he is thankful even for this, as the responsibility for holding on to such a patient is great.

It is not the clinical cure that gives to surgery its present position in the therapeusis of exophthalmic goiter; it is its lowered *operative mortality* and the scarcity of understanding internists. This is an age of particularization. Specialization is still in the making, is still seeking to eliminate the term "incurable" from the vocabulary of the medical profession. Exophthalmic goiter is quantitatively and qualitatively as difficult a subject, presenting problems as many and as grave, requiring as much training and skill, as any specialty extant. With the development of such a clinician—a scientist capable of ferreting out all predisposing and exciting etiological elements in a given subject of Graves' disease irrespective of the time and pains involved—who can apply the necessary remedial measures whether they be prophylactic, dietetic, hygienic, medicinal, electrotherapeutic, psychotherapeutic, singly or in combination, as indicated after a careful individualizing analysis—in brief, with the appearance of an internist who, through years of patient observation can understand and speak the language of subjects of Graves' disease, there will be a cessation of surgical interference in this affection. Exophthalmic goiter will then cease to be the dread disease that it now is, and recovery will be but a matter of time.

Percentage of Nonsurgical Recoveries.—Does nonsurgical treatment of exophthalmic goiter yield 100 per cent. of cures? There are three classes of patients who are obviously unsatisfactory:[24] (1) Those who are evidently moribund. (2) Those who have developed a definite form of insanity, especially patients requiring physical restraint in order to overcome destructive tendencies. These patients are to be regarded as instances of mental aberration requiring chiefly the services of the psychiatrist. (3) Those patients who, after several weeks of observation, are discovered to be noncooperative. It is well to regard the first few weeks of treatment of any patient as probationary, and if, in spite of properly applied mental appeal, the patient is untruthful and otherwise unfair in obedience to orders, rather than court failure, the patient may as well be refused further treatment.

In brief, the properly equipped internist, after eliminating those who are moribund, the insane, and the noncooperative, all of whom constitute approximately 10 per cent. of patients who apply for treatment, should obtain close to 100 per cent. of cures. All things being equal, the prognosis in Graves' disease is excellent; recovery is complete and lasting, and the patient, taught how to "carry on" and imbued with a healthy philosophy of life, becomes and remains stronger in body and mind than ever before.

PYELITIS: ETIOLOGY AND PATHOLOGY, WITH ESPECIAL REFERENCE TO INTERNAL THERAPY.

By W. C. K. Berlin, M.D.,

Denver, Col.

Anatomical and postural environments of the kidneys in man are, no doubt, the principal predisposing etiological factors in the occurrence of infections of the kidney pelves. The anatomical structure of the kidney pelves constitutes the first step in the predisposing cause of localized infections in this area. The pelvic base being larger, narrows down to the outlet at its junction with the ureters, forming a funnel shaped cavity. The pelves are located midway on the inner or ventral border of the kidneys. The postural environment of the kidneys is the second and most important

factor in the predisposing cause of pyelitis; in fact, it is the postural associated with the anatomic factor that completes the predisposing cause. The postural factor consists in the fact that the long axis of the kidney is parallel or perpendicular in the erect position to the long axis of the body or trunk and the short axis as well as the direction of the pelvic outlet are horizontal to the long axis of the body or trunk.

The postural environment being admitted as a predisposing factor, it is conceivable that drainage is not free and unobstructed if the body or trunk be maintained continuously in an erect or perpendicular, *i. e.*, sitting or standing, position. In this position the pelvic outlet being placed considerably above the lower segment of this funnel shaped cavity, forms a pocket, which exercises all the prerogatives of maintaining a cavity poorly drained two-thirds of the time. The cavity may permit the collection of urine which is maintained in a state of stasis. Static urine in this as in any other similar environment tends toward chemical and bacterial decomposition with the consequence of lowered tissue resistance producing in fact a "locus minoris resistancæ" which may permit infections in such a location. The remaining one-third of the time, when the body is in a horizontal or reclining position, is the only opportunity in which complete drainage of the pelves may be established, except in certain occupational pursuits which require much stooping and bending. Occupational environments may explain satisfactorily the relative frequency of the occurrence of pyelitis in the female whose occupational environments are not generally of the more violent stooping and bending character.

Notwithstanding the combined predisposing anatomical and postural factors associated with the kidneys, it is doubtful if infection of the pelves of the kidneys could occur without an exciting cause,[1] however insignificant, and one which may be of a specific nature, that is, bacterial selective action in setting up inflammation of the kidney pelves.[2] This exciting cause may be located in any part of the body. The immediate exciting etiological factor in the occurrence of pyelitis, preceded by a bacteremia, is no doubt from a focal area of infection such as may follow a general or local gastro-intestinal stasis, causing faulty digestive processes favoring fermentative changes and producing autointoxication through toxic split protein products, all of which encourage excessive multiplication of the intestinal bacterial flora and which are, no doubt, responsible for severe bloating and thinning of the intestinal walls, which condition favors and makes possible the migration of bacteria, possibly of an elective type[3] from the intestinal contents or other foci to the lymph channels and finally to the blood stream; or the foci may be of the more circumscribed type found in areas intimately associated with the gastrointestinal tract such as cholecystitis, gastric or intestinal ulcers, appendicitis, prostatitis, pyosalpingitis, etc., or the more classic foci occurring in or associated with dental, tonsillar and nasal areas or sinuses and from which bacteria also find their way into the blood stream, thus causing distant infections by metastasis because of this bacteremia. More rarely ureteral structures or ascending infections from the urinary bladder may be classed as exciting causes.

Having now established, practically, a predisposing as well as an exciting cause and the bacteremia for the metastatic connecting link between the two, we now have the resulting pathological picture of a pyelonephritis secreting pus and exfoliating pelvic epithelial cells together with the usual decomposed urinary débris from poorly drained areas.

Treatment.—The first essential is to locate and remove, if possible, the exciting cause. This step having been inaugurated the treatment of the resulting bacteremia and pelvic infection is the second consideration. Because of the fact that the kidneys are remote from the gastrointestinal tract, and therefore not easily influenced by the oral administration of remedial agencies and because local applications through the ureter-cystic-ureteral route to the pelves, as well as biological therapy, have not proved satisfactory, it would appear that a more direct and effective method of treatment would be desirable. Pursuant to this desire, the intravenous application of remedial substances was inaugurated and the following preparations were used: (1) Hexamethylenamine in 20 c.c. negative pressure ampoules, containing 20 gr. of the chemical; (2) a 20 c.c. negative pressure ampoule containing sodium iodide, 28 gr.; creosote and guaiacol, each ⅛ gr., in slightly alkaline normal saline. For the sake of brevity this latter will be referred to as "Solution Sodium Iodide Compound," both these preparations were manufactured by a Denver company specializing in ampoule medication.

These substances when applied intravenously, doubtless enter into the general scheme of metabolism and are subject to the same osmotic processes that occur to food or any other material that may enter the blood stream and which carries corrective substances to all tissue cells by anasmotic action, and reversely the elimination of waste matter from the same tissues is by cataosmosis. The final disposition of such remedial substances, when administered intravenously, is by elimination almost entirely through the secretory organs and especially the kidneys by means of a cataosmosis. And it is at this point, as well as in the blood stream, that the therapeutic action of these substances is most pronounced. That the favorable results obtained in the treatment of a number of infections of the kidney pelves warrant the use of the vein for applying therapeutic measures in pyelitis may be confirmed, in a measure, by citing the essential facts of a few rather typical case histories selected from a number of patients so treated.

Case I.—Mrs. A. L. B., age fifty-two; married; children; housewife.

Previous History: Negative up to January, 1919, at which time present illness began.

Examination: Tall, moderately fleshy woman of brunette type; skin showing evidence of jaundice; articulations of hands, feet and knees painful, inflamed and enlarged. Hands, arms, feet, ankles and legs up to knees edematous and skin glistening. Heart moderately enlarged, compensating, with aortic or second heart sound accentuated. Abdomen tympanitic. Urine: sp. gro. 1022, alkaline in reaction, bile tinted and heavy with sediment. Albumin, trace. Nuclealobumin, trace.

Centrifuged at 3,000 revolutions per minutes for three minutes, showed 20 per cent. débris. Microscopic examination showed the preponderance of this sediment to be composed of pus cells; other cells indicated the presence of a pyelitis.

Diagnosis: Tentatively, chronic arthritis complicated or caused by a cholecystitis or pyelitis.

Treatment and Management: The introduction of a strictly regulated diet and systematic plan of elimination. The intravenous administration of sodium iodide compound. These injections were repeated every other day from January 23 to March 25, 1921. Improvement in all the enumerated conditions was soon apparent and continued until suspension of treatment. At this time the symptoms of jaundice, edema and the glistening skin were absent. Heart sounds and size more normal; symptoms of intestinal fermentation and intoxication improved or absent. Urine: light brown color, sp. gr. 1018, neutral reaction; albumin of both types absent; centrifuged sediment, one-half of 1 per cent. wet. Pain and swelling of the joints much improved. Patient formerly suffered a total disability, now walks with aid of crutches and gets in and out of bed without help.

September, 1921: Patient is maintaining her improved condition.

Case II.—D. C., age nine, female, white. Family history, negative.

Personal History: Normal child up to first part of August, 1919, when patient began complaining of discomfort over hypogastrium and in urinating. These symptoms increased in severity in spite of all treatment administered, and the patient finally became bedfast, suffering great discomfit, loss of weight, and almost continuous desire to urinate. June 20, 1920, patient was removed to hospital and urine segregated by physician then attending. Urine from the right kidney was found to contain pus. Failure to catheterize the left ureter made a diagnosis of this kidney doubtful. Following the segregation the bladder was irrigated twice a week, and an autogenous vaccine of *B coli* and *M. catarrhalis* was administered with good results, and the patient resumed her attendance at school. On December 20, 1920, the patient was again returned for a second segregation for diagnostic purposes. At this time it was reported by the parents that both ureters were successfully catheterized and both specimens contained pus, guinea pigs were inoculated, and later a report was rendered giving positive findings of a tuberculosis infection. However, on the fifth day following the segregating operation, the patient suffered a violent hemorrhage from the bladder, which was followed by total loss of bladder function and she was compelled to wear a diaper continuously up to February 1, 1921. Due to the urgent advice to have the child submitted to surgical interference a decision was made to change medical attendants.

The patient first came under observation February 2, 1921. She was of average height, emaciated; weight, 51 lbs.; languid; color of skin was of a yellowish-green and very anemic in appearance. Physical findings were negative, except that abdomen was tympanitic. Urine: Sp. gr. 1010; alkaline, and heavy with sediment. Filtered urine gave decided test for nucleoalbumin. Unfiltered specimen centrifuged at 3,000 revolutions per minute for three minutes registered 45 per cent. sediment, chiefly pus cells; other cells indicated pelvic inflammation.

Management: The patient having been allowed, heretofore, unrestricted use of food luxuries and confections, was limited to a well regulated plain nourishing diet; systematic elimination was established by natural, if possible, or forced processes, both of kidney and alimentary tract.

Therapy: The intravenous administration of sodium iodide compound, alternating with a selected dose of hexamethylenamine, 31 gr. in 20 c.c. ampoules, one or the other of these being injected daily from February 2 to February 21, 1921, when iron cacodylate, 1 grain in 2 c.c. ampoule, replaced the hexamethylenamine injections. March 15, 1921, a few doses of an autogenous vaccine were administered in place of the iron. These with the iodine solution were administered up to March 30, 1921, when tuberculin "O. T." in increasing doses, together with iron cacodylate, was administered intravenously every third or fourth day; the iodine solution was used as an interval treatment at this time. This routine was maintained through April and May to June 1, 1921.

Results: February 2, 1921 (before treatment). Urine, centrifuged at 3,000 r.p.m. for three minutes in graduated tube, registered 45 per cent. sediment, mostly pus. February 3, twenty-four hours after sodium iodide compound intravenous injection, sediment registered 9 per cent. February 4, twenty-four hours after hexamethylenamine solution, sediment registered 5 per cent. February 5, twenty-four hours after sodium iodide compound, 3 per cent. On this date, bladder function has been reestablished, excepting at night, sufficient to permit the patient to enjoy the comforts of a toilet; a little later on the child was able to resume her attendance at school. On June 1, 1921, after about four months of sustained management and treatment, the patient's condition was as follows: Gain of two pounds in weight. Symptoms of anemia absent, color of skin better. Patient moves with celerity, appetite good, severe tympanitic condition of abdomen absent. Urine: light straw color; sp. gr. 1016, alkaline; sediment 2 per cent. in graduated tube. Patient able to control bladder four to five hours when awake.

The patient's parents declaring their intention of visiting in the East at this time, the opportunity of visiting the Mayo Clinic was accepted and the child was submitted to their laboratory régime. A most thorough examination was made, particular attention being given to the pathology of the kidneys, which were found to be negative as far as a general or local tuberculous infection was concerned.. Original cultures made from the segregated urine was said to have contained growths of colon bacillus and *M. catarrhalis*. Cultures taken after one month's treatment gave *M. catarrhalis* only.

August 26, 1921, patient is maintaining improvement and gaining weight. Urine: Light straw color; sp. gr. 1014; slightly alkaline; albumin and sugar absent. Centrifuged specimen registers less than one-half of 1 per cent. sediment in graduated tube.

October 15, 1921, weight 58 lbs.

Case III.—Mrs. J. T. B., age forty-five, white, housewife. Physical condition good, but anemic. Was under observation and treatment in 1919 and 1920 for colds and symptoms of rheumatoid arthritis. April 22, 1920, patient submitted to panhysterectomy. On the fourth day of convalescence, suffered a chill followed by high temperature and accompanied by severe pain over left kidney area, radiating downward and inward. Apparently hot packs, oral medication, local application of silver compounds to the pelvis of the kidney and dietary measures failed to control the condition.

May 25, 1921. The patient again came under observation.

Examination: Physical findings negative, except abdominal tympanitics. Temperature 103° at 4 P. M.; pulse 110, thin and tense; complaining of severe pain over left kidney area and radiating downward. Urine: Sp. gr. 1010, alkaline; color, yellowish white and loaded with débris. Albumin and sugar tests negative in filtered specimen; a small trace of nucleoalbumin. Centrifuged specimen, unfiltered, at 3,000 r.p.m. for three minutes showed 50 per cent. sediment. Microscopical examination showed this to be mostly pus cells; the character of other cells and débris indicated inflammation of the kidney pelvis.

Management: Diet was limited to nonprotein foods, except that contained in a vegetable diet. Elimination, both alimentary and urinary, established and maintained.

Treatment: The intravenous administration of sodium idodide compound, alternating with solution of hexamethylenamine, 31 grains or less, according to degree of bladder irritation; one or the other being administered daily up to June 29, when the hexamethylenamine solution was replaced by the intravenous administration of iron cacodylate, 1 grain in 2 c.c. solution; the iron cacodylate and iodide solutions were alternated at increasing intervals up to June 15.

Results: May 25, 1921, 4 P. M : Temperature 103°; pulse 110; sediment in centrifuged urine, 50 per cent.; sodium iodide compound administered. May 26, 4

P. M.: Temperature 99°; pulse 100, character improved. Pain greatly lessened. Hexamethylenamine solution administered. May 27, 4 P. M.: Temperature 98.3°; pulse 100, improved in character. Hot packs dispensed with; very little pain. Patient sleeps and rests well. Urine: Sp. gr. 1012; color, light straw; slightly alkaline reaction; albumin absent in filtered urine; centrifuged unfiltered specimen registered 4 per cent. sediment in graduated tube. From this time on the patient's condition gradually improved, under the same or similar management and treatment. The injections were administered at longer intervals.

June 15: Temperature normal since May 27; pulse 81, good quality; pain over kidney area absent. Physical condition improved, gained weight, color of skin normal, appetite good, sleeps well. Urine: Sp. gr. 1016; light straw color, transparent, clear; albumin absent; centrifuged specimen, 1 per cent. sediment. Improvement was gradual up to about November, 1920, at which time, because of a fear of a return of the trouble, she underwent the Fowler operation for the correction of the postural environment of both kidneys. September 20, 1921. Patient continues to enjoy good health. Urine: Sp. gr. 1016; light brown straw color; acid to litmus paper; albumin absent; sediment, trace only.

Case IV.—Miss M. J. T., age twenty-four, white, dentist's assistant.

Previous History: Negative, in good health up to about September, 1918, when difficult breathing was experienced on mild exertion, increasing gradually until patient could not run or walk fast; also experienced difficulty going into the higher altitudes of the mountains.

Examination: October 1, 1920, anemic; abdomen tympanitic; cardiac hypertrophy and heart not compensating; mitral murmur and aortic second sound accentuated. Urine: Sp. gr. 1012; light straw color; alkaline in reaction; serum albumin, 4 per cent. wet; microscopic examination showed granular and hyaline casts, moderate percentage of pus cells and other cells indicative of kidney pelvis irritation.

Management: Diet limited and systematic elimination established. October 6, 1920, daily intravenous administration of sodium iodide compound instituted.

Results: October 15, breathing improved; heart sounds improved; hypertrophy diminished; abdomen less tympanitic. Urine: Sp. gr. 1017; neutral reaction; light straw color, clear; albumin, 2 per cent.

November 15: Breathing almost normal on exertion, i.e. running, climbing stairs, etc.; abnormal heart sounds absent; cardiac hypertrophy scarcely above normal; tympanitic condition of abdomen much improved; color of skin normal; physically stronger. Urine: Sp. gr. 1018, slightly alkaline; dark straw color, clear; albumin, slightly in excess of 1 per cent.

December 5: Physical condition good, heart sounds normal, difficult breathing absent. Urine: Sp. gr. 1016; neutral to litmus paper; straw color, clear; albumin, 2 per cent. Because of aversion to hygienic discipline and system, and an aversion to further intravenous treatment, the patient was referred to Dr. O. S. Fowler, genitourinary specialist. After *x*-ray examination of kidneys and pelves and the gastrointestinal tract, a 90 degree rotation and suspension (Fowler's operation) of the kidneys, for better dainage, was done.

July 1, 1921, patient apparently in perfect health; former physical findings absent. Urine: Sp. gr. 1022; slightly acid reaction; light amber color, clear; albumin absent; sediment absent.

Case V.—J. H. E., age fifty-five, male, white, physician. Previous history negative up to January, 1920, when bladder irritation was experienced, gradually increasing. The urine was cloudy and gave a strong growth of colon bacillus. Cystic irrigation with different solutions, and especially plain warm water, gave temporary relief. About July 1, intravenous injections of solution of the sodium iodide compound were administered every other day, alternating at different intervals with hexamethylenamine solution, covering a period of about two months.

Results: Prompt and early relief from pain and frequent desire to micturate while under treatment. X-ray examination disclosed imbedded urinary calculi, which were removed, resulting in complete recovery.

Surgical interference, which must be considered mechanical in its nature, may be conservatively advised when the condition in the pelves of the kidney persists, however modified by improved management and treatment, or if it shows a disposition to relapse after apparent recovery. This mechanical change is accomplished by altering the postural aspect of the kidney rotating the long axis of the kidney from a perpendicular through and describing an arc of about 90° to or approximating a horizontal position in respect to the long axis of the body. The kidney is then suspended or fixed in this new position. This change from the normal anatomical position to a new postural environment causes the outlet of the pelves of the kidney to describe an arc similar to that of the long axis of the kidney, and in this new postural environment to point directly downward, which is the essential object arrived at, namely, to eliminate the predisposing cause of pyelitis by making it possible to secure free and unobstructed drainage of the pelves of the kidneys.

In view of our present knowledge of the exciting cause of the pathological condition it would be practising conservatism to reserve surgical interference for a later or a "last resort," otherwise the exciting cause would be disregarded and permitted to continue, and endanger the health and life of a patient to a greater degree from the prevailing infections than from pyelitis. Under proper management and treatment the exciting cause may be eliminated, in which case the postural environment as a predisposing factor in the etiology of pyelitis becomes almost negative in importance and, no doubt, curable by this improved therapeutic method.

Summary—I. The anatomical and postural environments of the kidneys are the chief predisposing factors causing pyelonephritis.

II. Intestinal stasis,—autointoxication, and autoinfections, from different foci or other obscure pathological conditions, are no doubt the immediate cause of pyelitis.

III. In metastasis the blood stream is the means of transmitting the infection to the pelves of the kidneys.

IV. Intravenous injections of selected solutions may exert in some cases a curative influence by attacking the bacteria either in situ or in transit through blood stream.

Jubilee of Ramon Y Cajal.—On February 25, 1922, the first steps were taken in the direction of honoring Dr. Ramon y Cajal of Madrid. The meeting was summoned by Recasens, Dean of the College Faculty, and a committee has been chosen which represents the whole of Spain. The date is fixed at May 1.—*La Medicina Ibera.*

MEDICAL ANTHROPOLOGY.*

BY EDWARD PREBLE, M.D.,

NEW YORK.

OUR anatomies are descriptive rather than biometric and our physiologies are general and experimental rather than human in scope. Works on general anthropology take cognizance principally of racial differences and are largely restricted to special subjects like anthropometry, craniology, dentition, pigmentation, hair structure, etc. The natural result of this limitation is that a vast body of verifiable facts and other data either escape attention altogether or are so widely scattered as to be inaccessible at short notice. In 1888 the distinguished physiologist Vierordt collected the recorded biometric data of man under the designation of "Anatomical, Physiological and Physical Tables and Data," the last edition being published in 1906. It is now antiquated and since it is merely a collection of figures is completely lacking in human interest. For a work of such importance it is but little known and apparently has never appeared outside of Germany.

For many years in connection with medicoliterary research the author has been jotting down odd figures and facts which every medical practitioner should know or at least know where to find quickly. In not a few cases he has located special information only after much pains. He has collected about 4,000 of these data and is convinced that the time is ripe for publication of a special volume with the title "Medical Anthropology" or "Human Biometry." Such a book might form a basis for a course of study to be affiliated with Forensic Medicine or possibly taught in the first year of the curriculum.

The following paragraphs show the scope of such a book and under each head are given a few sample data.

Anthropometry: Weights, Surfaces, and Volumes.—While there is a redundancy of figures on total weights there is little enough on the weights of individual segments of the body and the entire subjects of surfaces and volumes are but scantily represented. The superficies of an average man is 19 or 20 square feet, while the total volume in c.c. must agree closely with the weight in grams because the density of the body is so nearly that of water. If we select an adult of average dimensions who weighs stripped 140 lbs. the head and neck together should weigh about 10 lbs., the hand 1 lb., the foot a little over 2 lbs. (2.3), the leg 6.7 lbs., etc. The area of the head and neck should be a little over 200 sq. in.; that of the hand 63 sq. in.; foot, 100 sq. in.; leg, nearly 200 sq. in., etc. If the volume of the individual be 4,000 cu. in. the volume of the head and neck should be something less than 300 cu. in., the hand 25, foot 50 and leg 180 cu. in. A knowledge of the areas of the segments of the body has a practical value in the case of extensive burns, for if more than a given total is injured the prognosis is unfavorable. In regard to weights of segments a butcher could perhaps make a much better estimate of the weight of a member in a human subject than could the amputating surgeon.

Biophysics.—Many interesting data are to be found under this head in works like Broca's "Physique Médicale" and Burns' "Biophysics." Some of the more recent developments not found in the older works have to do with electrophysics. It is possible with a diathermy high frequency circuit to add as many as 1,500 calories to the daily thermogenesis of the body, which amount alone nearly equals the basal metabolism of some individuals and suggests the query "could these calories act as food sparers in the same proportion?" We know, of course, that a definite amount of body covering, by preventing radiation, is equivalent to a definite number of food calories. Data in reference to ionic transport in which lithium ions can pass through the unbroken skin of the foot and shortly reappear in the urine are among the more impressive facts in electrophysics.

Chemistry of Body; Food and Nutrition.—The body is about 66 per cent. of water; the organic matter is nearly 30 per cent., and the balance is inorganic. Of the organic matter carbon makes up 18.4 per cent. and oxygen 6 per cent., the balance being about equally divided into hydrogen and nitrogen. The amount of sodium in the body is about 1,650 grams. Potassium (niter) can drive some of the sodium out of the body. An excess of sodium in the body means increased concentration of HCl in the gastric juice. The average amount of iron in the body is 3.2 gms., chiefly in the hemoglobin. Potassium occurs in every cell in the body.

Pure food has no flavor save in the case of sugar, which is not a natural food; fat, starch, and protein are all insoluble and hence tasteless. The mineral requirements of the body are readily supplied from the food with the possible exception of lime, which is sometimes lacking. Those who live on animal food do not eat or crave salt; the converse is true of vegetarians. Rice is the food that throws the least work on the kidneys; even potatoes contain fifty times as much saline matter. A man can exist barely four days without water.

The glycogen of the liver and muscles is used up far more promptly than the stored fat; it is the "quick assets" of the body. The liver, which weighs 3.5 lbs., may contain as much as 10 oz. of glycogen and the muscles of a very muscular man as much as 3 lbs., although such figures are extreme; usually the muscle glycogen is not much in excess of the hepatic. Muscle glycogen is utilized only in muscular action; hepatic for the body as a whole. The amount of blood sugar in health is not over 2 oz., while in diabetes it may go to 20 oz.

An adult may lose 2 5 of his weight in a fast and still recover. With plenty of water a man may fast for as long as thirty days and recover. In a protracted fast the brain and heart show practically no diminution. A child who has lost a fourth of its weight cannot recover. The basal metabolism of a faster does not go below 30 calories per kilo. Subjects have been nourished by rectal feeding for as long as five years.

*Every statement in this article and every fact in my collection is made on the very highest modern authority. To quote the references would, however, require far too much space. Nevertheless, the author disclaims any insistence on the correctness or finality of the statements and realizes that in some cases they may seem to conflict with every-day experience.

Thermogenesis and Effects of Temperature Change.—A subject with fever actually expands from the increase of temperature, and with fever of 104° F. he has expanded about 1/10 of 1 per cent. of his normal volume; or in other words has gained about 60 c.c. of volume. During sleep the thermogenesis has decreased to about 65 hourly calories, or less than half the production of a man engaged in light labor. In regard to the economy of diet possible through the fluctuations in wearing apparel, a nude man generates half as much again heat as a man who is fully clothed by reason of his increased radiation.

It requires a heat of 122° F. to coagulate the albumin of the body. In sunstroke the temperature may reach 118° F. and survival has occurred after having attained 115° F. Man can survive for a considerable time in an oven at 132° C. (265.6° F.) if the air is dry, but 50° C. (122° F.) is his limit if the air is moist. Application of cold to the surface increases the hemoglobin of the blood up to 14 per cent. Shuddering from the cold is a reflex defense reaction which tends to warm the chilled surface. Exposure of the nude body to 20° C. (68 F.) causes such an increase of blood pressure as to determine in some subjects cerebral apoplexy. When one hand is immersed in cold water the temperature of the other is lowered. Hot as well as cold water can cause gooseskin.

In polar regions colds in the head and pneumonia are unknown while the sterile character of the feces should render impossible autointoxication and its supposed consequences. In the tropics colds are readily contracted as cool nights follow hot days, evaporation is extreme, and winds are prevalent, all of which factors chill the surface. Atropine injections, by checking perspiration, tend to favor sunstroke, and monkeys supposedly immune to the latter may be fatally sunstruck under the influence of atropine. The degree of dampness in which it is unsafe to live may be measured by the increase in weight of 2 lbs. of chloride of lime, a gain of 12 grains being excessive.

Circulation and Respiration.—The heart does not get its growth at maturity but continues to augment in weight until middle life. During the period of general growth it increases in mass four times as much as the great vessels. The socalled apex beat is not due to the contact of the apex of the heart for the ventricle never leaves the chest wall; it is really due to the impact of the left auricle. If a subject with good chest expansion inflate to the utmost he may be able by compressing the subclavian artery to shut off his wrist pulse and thereby simulate heart disease. In the first two hours of sleep there is a notable fall of blood pressure. In the corpulent man a cramped sitting posture by compressing the femoral and popliteal vessel may cause extensive edema of the legs and simulate cardiac or renal disease; the edema, however, stops at the shoe line and does not involve the feet. The amount of blood in a given individual may be estimated by dividing the weight by 13—an adult of 150 lbs. should have about 11 lbs. of blood. The ratio in the newborn infant of blood weight to total weight is 1 to 19, and the young child has much less blood to lose than the adult. Menstrual blood is commonly said not to coagulate; it does, however, coagulate slowly but often does not appear to clot.

In a few individuals the heart may be stopped at will while others can voluntarily contract the diaphragm. An adult man inhales 7 lbs. of oxygen daily, of which 2 lbs. reach the blood. Carbonic acid is not a poison; man constantly rebreathes it; it is the normal stimulant of respiration and has been classed with the hormones. Man can develop tolerance to very large percentages, even ten fold the normal pressure.

Forced Respiration: Effects of Changes in Air Pressure.—Forced breathing by exhausting the carbon dioxide causes suspension of breathing or apnea. After increased respiration the subject can hold his breath for three or four minutes, although without this provision the usual duration is but thirty to forty seconds. If a subject cannot hold his breath for twenty seconds something is wrong and some anesthetizers would not give such a man ether or chloroform. Intense pain by causing forced breathing may lead to apnea, so that in some parts of the world a severely injured man is "smothered," which act enables him to retain his escaping CO_2. Apnea from forced respiration is the same as acapnia or absence of carbon dioxide. Cyanosis or livid discoloration is not due to accumulated CO_2 but to absence of oxygen (anoxemia). A man who has been completely winded from running regains his breath while counting sixty. A man, may, if he will try, make himself blue in the face by forced breathing.

A man can keep alive at a pressure of 5 atmospheres. The pressure in a caisson seldom exceeds 4 atmospheres. At 3 atmospheres speech is difficult. Compressed air by quickening the cerebral circulation increases mental and physical vigor (under ordinary conditions the term "compressed air" means a pressure of 2 atmospheres). In work in the caisson the air is forced into the body, especially the nitrogen; and the escape of the N under decompression causes caisson disease. The record for deep-sea diving up to 1917 was 360 feet with a special suit of heavy armor. Before this feat the record for working divers was 192 feet and experimental divers, 210 feet. The total safe duration under water is twenty-five or thirty minutes and a longer sojourn usually means decompression paralysis. A man loses one pound or so of weight on the higher mountains. In rarefied air the intestinal gases expand. Aviation statistics are changing so rapidly that not many figures can be quoted.

Alimentary Canal.—A coated tongue means a disused tongue; a man who has been up all night does not have a coated tongue in the morning. "Smacking the lips" is a misnomer; it is the tongue which makes the sound. In a general drying out of the body as in prolonged deprivation from water and in cholera the space under the tongue retains its moisture longer than any other locality. But for the presence of the frenum the tongue would be swallowed. It is difficult or impossible to swallow with the mouth open.

The stomach, like the skin, has a gas exchange; the blood gives up CO_2 to the organ and takes up oxygen from the same. The acidity of the stomach may be so marked that in pyrosis the pharynx may

be burned. That the stomach is essentially a motile organ which is very seldom at rest has long been known; in fasting stomachs the rhythmic contractions persist as hunger cramps. The average capacity of the adult stomach is about 2½ pints, its length is 10 inches, and its weight 4½ oz., while the average weight of its contents is 7½ oz. Swallowed sea water causes a contraction of the pylorus so that it cannot be absorbed; but sea water will quench thirst when freely infused into the colon. Finely powdered glass does not injure the stomach. Air swallowing may be prevented by holding a cork between the teeth. Drinking the two parts of a Seidlitz powder separately does not injure the stomach, but is in common use to aid in physical examination and *x*-ray work. About 6 or 7 gms. of pure chlorhydric acid are secreted in twenty-four hours. Hunger cramps recur about once in thirty seconds. These pains may be promptly stopped by running. There is enough muscular fiber in the small intestine to make a blacksmith's biceps. The first passage of intestinal gas after a meal means that the food has passed into the colon. Constipation is not necessarily a drawback; in some individuals the utilization of food is so complete that there is little fecal matter to come away. Fasters pass socalled fasting feces. Inflammable gas may escape by either mouth or rectum if there is sufficient cellulose in the food and may explode on exposure to flame with production of severe burns.

Osseous System.—The skeleton of a man of 150 lbs. weight should weigh 24 lbs. Bone will withstand twice the pressure of oak wood. Contrary to the general belief small muscles may be associated with large bones and vice versa. The age of a deceased subject may be told by a knowledge of the periods of ossification and consolidation, while in the living subject it may similarly be determined by the *x*-ray. The sternum of the male is longer than that of the female in the ratio of 8 to 7, this difference in length being in the gladiolus; it is of value in determining sex from the skeleton. In the male again the lower portion of the sternum is much better developed, and the costal cartilages are well separated. The contortionist can bend himself double because his lumbar spine is flexible; it retains the flexibility of the young child, which normally decreases after the sixth year. The humerus is twisted on its axis from 12 to 20 degrees in the white race; in the negro the angle of torsion is 35 degrees. But three people in five have three phalanges in the great toe; in the other two the two distal phalanges are fused. In true flatfoot the tendo Achillis is never straight and the lower end is deviated externally. The range of mobility of the joints is but little studied, but if this is ignored there is no way to determine the impairment of motion as a result of ankylosis, etc. Thus the knee should flex to 140 degrees, the elbow to 150, pronation is normally 180 degrees, and so on with other flexions, extensions, rotations, abductions, and adductions.

Muscular System.—Muscle tone is abolished during sleep and if a person can inhibit his muscle tone voluntarily he can put himself to sleep. Prolonged muscle tension means a great waste of energy while efforts limited to rapid contractions or twitches are highly efficient. Shuddering produced by cold or fear is a defense reaction to restore the peripheral circulation. The weight of muscle may be notably increased by injecting water into the bloodvessels; a fact known to some butchers. Muscle makes a resonant sound in contracting, with a pitch of 36 to 40; it may be heard in the contracting biceps with the stethoscope or perceived by contracting the jaw muscles with the ears stopped. Workers who use the flexor muscles extensively are apt to carry the arms in semiflexion. During any kind of mental excitement, as when watching a contest, the muscle tonus is increased perhaps to tonic contraction. In the latter there is no oxidation—no CO_2 is produced nor is there any increase in thermogenesis, but creatine is formed from protein waste. Voluntary movements can occur in 1/10 and even in 1/20 second. Trained muscles produce less fatigue-toxin than untrained, accounting for their superior endurance. Trained muscles react to electric stimulation with unusual vigor, and this test may be used in determining the condition of a pugilist, etc. One should never begin a strenuous effort of any kind without previous limbering up; there is a certain resemblance between untrained muscle and unlimbered trained muscle. A nervous subject may be betrayed by socalled static tremor which is seen when the edge of the forearm is rested on the edge of a table. There is a connection between intellectual vigor and the strength of the handclasp; the grip of the civilized man is much firmer than that of the savage. A man's clasp is one-third stronger than that of a woman.

Brain and Nervous System.—The brain comprises 80 per cent. of water and is practically the only organ in the body to contain no ordinary adipose tissue. The organ is never at rest despite the function of sleep and during a prolonged fast loses no weight. It is but 2 per cent. of the body weight in the adult, but 12 per cent. of the same in the newborn. The brain weight of the stillborn is heavier than that of the live born, which accounts to some extent for stillbirth. The brain rests on a water bed—the subarachnoid portion of the cerebrospinal fluid. Brain substance has a remarkable faculty of expansion and compression, despite the large content of incompressible water. Despite slow development of the mental powers every cell of the adult brain is present at birth and at seven years of age the organ has nearly attained its full weight. Ninety per cent. of brain substance is composed of neurons—about 12 thousand millions. The optic thalamus never undergoes atrophy.

While the mass of the brain shows great variability, that of the spinal cord is almost constant—27 to 28 gms. The normal tension of the cerebrospinal fluid is 150 mm. water.

Sleep.—A righthanded man sleeps better on his right side and a lefthanded one on the left side. During a night's rest the weight of the individual diminishes by one pound. During sleep the volume of the limbs increases. As one falls asleep the eyeballs turn up and a little out. During sleep the pupils contract to the maximum and dilate as the subject wakens. Day sleep is not normal sleep, but a special type, lighter than normal. Those who sleep amid noise are apt to waken when the noise ceases. Lost sleep may be made up by about one-half of the amount lost. One asleep is like a fur-

nace with fire banked; he consumes but half the waking requirement of oxygen; even in the young the joints are stiff on waking from immobilization of sleep.

Special Senses: Eye and Ear, Vision and Audition.—The distance between the eyes is from 55 to 65 mm. (2.2 to 2.6 inches). The realistic novelist who depicts the close-eyed villain may express himself quantitatively. The radius of curvature of the cornea is 7.8 mm. The eyeball is a shade less than an inch in diameter. The cornea occupies one-sixth of the total surface of the eyeball, and attains its full size at the age of three years. The average width of the pupil is 4 mm. Severe and agonal pain causes the pupil to dilate, which fact may expose a simulator. Blue eyes may appear in dark subjects, but when the blue-eyed intermarry they cannot produce dark-eyed children. An iris appears blue or gray because pigmented on one side only. The extent of retinal surface to be affected by light is 20 sq. cm. and the retina can perceive a flash which lasts only 1-8,000,000 of a second.

The skin of the upper eyelid is the thinnest in the body and the most lax. Its subcutaneous tissue is the only one to contain no adipose tissue, even in the most corpulent. A wink lasts one-tenth of a second, repeated about ten a minute. The eye muscles are the only voluntary muscles that never become fatigued. The eye itself has no expression, the latter being due to its motion.

The external ears show no atrophy in old age and in some individuals continue to enlarge slightly. A pull on the tragus may slow the action of the heart. The large ears of the consumptive are partly an illusion because of the wasting of the surrounding tissues. The drumhead is almost as large at birth as it ever becomes. It is of the same thickness as the cornea—1 mm. Acuteness of hearing increases up to the age of twelve years. A man may make himself heard in ordinary conversation in the open air at a distance of 200 feet. The whispering distance is from 65 to 80 feet and in forced whispering nearly 100 feet. There is no standardization of colored audition; certain individuals merely react to special sounds by special color images.

In congenital deaf-mutism there is a notable immunity to gyratory vertigo—at least one in three does not develop it on any provocation.

Special Senses: Smell, Taste and Touch.—The blindfold subject may be unable to tell the taste of foods. When the tongue is cocainized it can distinguish only salt, or in other words fails to perceive bitter, sweet, and acid. A very little bitter added to a sweet solution makes the taste sweeter. An unpleasant taste sets up a defense reaction, the facial expression mimicking that of antagonism. Mercaptan, the malodorous substance of intestinal gas, may be detected in the air in a percentage of 1 to 25 trillion and is therefore much stronger than musk. The sense of smell is quickly fatigued by smelling strong substances. One strong odor can suppress another when they are mingled. The odor of sweet fresh air incites nasal respiration, as shown by dilatation of the nostrils. The extremely acute touch perception of the tip of the tongue is wasted in nature, even by the blind. A leg fallen asleep feels heat but not cold. A cocainized conjunctiva still retains its sensitiveness to heat and cold. One does not smell the fumes of ammonia and the disagreeable sensation is one of general sensibility to pain.

Genito-Urinary Apparatus.—In about 5 per cent. of women the pubic hair is of the male pattern, a fact worth remembering in sex identification. Each kidney should supply to the bladder 1 oz. of urine for each hour. The bladder is at the peak of its expulsive power at the age of eight years. Clinicians have made the diagnosis of diabetes from the peculiar white spots on the shoes due to the presence of glucose. The testicle varies greatly in size and when but 1½ inches in length is within normal limits. The gravid uterus is sixty-four times as heavy as the unimpregnated organ, the former weighing 2 lbs. Beets eaten in large quantities may color the urine red and simulate hematuria; in such a case the feces are also red.

Skin, Pilous System.—The skin has a gas exchange like the lungs but only 1-100 as extensive; the weight of the skin, which is about 10 lbs. in the adult man of average dimensions, agrees roughly with that of the abdominal viscera; gooseflesh on a drowned body indicates that the subject was living when he entered the water. To demonstrate the fine down on the skin spray it with water from an atomizer and then examine with a magnifier. Two or three beads of water will be seen to cling to each downy hair. Thought lines appear in the forehead at the age of two or three years; many zealots and dreamers who do not think have smooth foreheads. The amount of perspiration for twenty-four hours agrees roughly with that of the urine and also with that of the aqueous vapor from the lungs. To make certain that a given area of skin cannot perspire it should be wrapped in rubber tissue. The scalp measures about 120 sq. in. and contains about 1000 hairs for each inch—hence about 120,000. The number of hairs in a beard is about 15,000 and in a moustache 1,200. The scalp hair may stand from anger as well as fear and under the influence of these emotions curly hair may become straight. Erection of scalp hairs is common in the insane, while baldness is rare among them. The life of a scalp hair is from 2 to 6 years and the life of an eyelash about 135 days. A scalp hair may sustain a weight of 6 or 7 lbs. and is so elastic that it stretches from one-fifth to one-third its own length. That gray hair is due to the entrance of air bubbles within the hairshaft is proved by the fact that the original color is restored when the cut hair is placed in a vacuum. The hair in all races of men contains the same proportion of sulphur—about 5 per cent. Polar races do not have heavy beards, while the latter are seen in white residents of the tropics. The lunula, or half moon, however absent on other fingers, is always present on the thumbs. The normal rate of nail growth is 1 mm. in ten days and there is no limit to its growth. A nitrate of silver stain on a protected finger nail will be absorbed in two weeks.

Attitude, Posture, etc.—The socalled hypererect attitude is the attitude for efficiency, the muscles being taut and the chest expanded; it is the attitude of courage. In the drooping attitude conditions are reversed, there being increase in the spinal curvature and most of the weight is on the heels. The head tends naturally to fall backward as does also the trunk, but this is corrected by muscular

tone. It requires 25 per cent. more energy to sit up than to lie down, and to sit up and talk requires 45 per cent. more. Men with poor sight have a bad posture, as they tend to bend forward. In standing at ease the subject constantly shifts his weight from one leg to the other. When man assumed the upright position he began to suffer from enteroptosis and hernias, while the soft tissues of the abdomen and groins became exposed to injury. The sacroiliac joints were inefficient. Constipation and dystocia became evils along with spinal curvature. The valves of some of the veins, adapted to the quadrupedal posture, are of no value to erect man.

Locomotion.—Man rises but little in walking—not over 15 mm. on an average. The stride of a man at a brisk walk is about 30 inches. In a true walk one foot is always on the ground and the knee joint is straight when the foot leaves the ground. In the walk the head sways from side to side. Vigorous walking exercises two-thirds of all the muscles. At a walking speed of two strides a second there begins a falling off in oxygen intake. A runner should be able to hold his breath for 130 yards, but if he inhales oxygen first he should run from 220 to 300 yards without breathing. A runner usually gets his second wind after three minutes of running. A runner while filling his chest should take about thirteen strides, but during expiration can take but five. Running and rapid walking cause the hands to swell.

Exercise, Effort, Fatigue.—In intense physical effort there is a tendency to close the eyes because owing to the engorgement of the orbital veins the eyes protrude and the lids instinctively seek to force them back. In intense effort the facial expression is that of rage. In strenuous effort the platysma muscle is tense and therefore termed the "muscle of emphasis." A sprinter can run 1,000 feet at the rate of 30 feet a second, 2,000 feet at 26 feet a second, and so on. A little girl who skips the rope 100 times in quick succession has raised her body the equivalent of nearly 400 feet. In violent sustained effort a subject may lose from 5 to 8 lbs. the first hour. In a six-day walk more nitrogen is destroyed than can be made good by any amount of eating. During sustained and strenuous exercise the red blood cells increase up to 25 per cent. of the original number. All kinds of exercise tend to employ unduly the flexors at the expense of the extensor muscles. The condition known as "muscle bound" is due to unnecessary contraction of the antagonist muscles of those actually in use. Errors in work begin to appear as efficiency falls off. The optimum indoor temperature for mental work is 68°-70° F.; the optimum outdoor temperature for the same is put at about 38° F. Disagreeable weather cuts efficiency in piece-work 10 per cent. Intervals of rest, short or long, greatly improve efficiency. School efficiency is best on Monday and Tuesday after the Saturday-Sunday intermission, and declines slowly from Tuesday to Saturday. In handling heavy material the greatest efficiency is seen if the laborer is "off the load" more than half the time. The modern typewriter is a highly inefficient machine because the keyboard is not scientifically arranged. Fatigue powerfully weakens attention and memory and in writing the subject omits letters, syllables, and words. Only voluntary muscles feel fatigue and not then when they act automatically. The socalled nervous subject tires rapidly.

Mental Processes and Faculties.—That which attracts attention inhibits activity; in extreme attention the body is bent forward and the lips compressed; attention is not a steady but an oscillating process; it becomes fatigued before interest is lost; close attention causes synergistic movements of various muscles; attention energizes motion. Profound attention leads to abstraction or absent mindedness, and, in the highest degree, ecstatic and hypnotic states. By fixing the attention on the hand—for example—it may become actively congested and thus when immersed in a basin just full of water may be made to overflow the latter. In close attention the breath is held. Suspense increases and maintains attention but perception is less accurate during suspense. In suspense the ability to appreciate the passage of time is weakened.

Memory may be visual or auditory. Memorizing cannot improve memory. The more rapid the memory the more accurate. Fatigue notably injures the memory. Artists and sculptors have good visual memories and some can even dispense with the model as the work advances. Women have better visual memories than men, while men of scientific attainment and training have poor visual memories.

Actions are motivated by mental pictures. The mind can learn to suppress from its consciousness anything which is useless to it, such as the tick of a clock. Monotony and boredom slow up work and make it a burden, but furnish powerful springs of action in other directions. The sense of danger intensifies the feeling of existence.

Cerebration is usually intensified just before death. Cerebral activity affects muscle tension so that the so-called mind-reader can, by feeling the muscles, divine the direction of thought. The mind may function better if the body is recumbent and in cerebral torpor may be revived by lying flat.

Articulation and Phonation.—In whispering the larynx is not required. Distinct articulation is such a strain on the voice that voice users tend to slur their words as much as is possible. There can be no speech without breath. Articulation is strongly individual and useful in identification. In pronouncing labial letters the soft palate is raised and the uvula shuts off the nasopharynx; hence in palate paralysis these letters cannot be pronounced. Nasal sounds are not the sounds made in nasal obstruction but the contrary—sounds made with nasal respiration. They are recognized by the cold mirror, bubble, and flame tests.

In whistling, the lips, held rigid, are made to vibrate in unison with the vocal cords. In the phenomenon known as mental singing the larynx rises with the high notes. Singing off the key need not be due to defective sense of melody; it may be the consequence of over-rigidity of the intrinsic muscles of the larynx, the so-called "tuners of the vocal cords." In trilling the vibration believed to occur in the larynx cannot be felt. The tremolo is not produced by the larynx, but is a phenomenon of breathing. The larynx determines the pitch of a vocal sound. In aphonia from vocal strain the voice may sometimes be made audible by pulling the larynx downward. Whispering, unlike speaking,

can be performed during inspiration. In the falsetto voice the soft palate is raised more than in the natural voice.

At least 3 per cent. of the people in the United States are sufficiently hard of hearing to profit by lip reading which may be learned in from three weeks to three months.

Ventriloquism must not be confounded with polyphony; the polyphonist imitates voices and sounds of all kinds. In ventriloquy proper the voice is not disguised. Ventriloquism does not fatigue the speaker. In ventriloquism the intranasal pressure is higher than in normal phonation; the singing tones are an octave higher; the larynx does not move but the cords approximate the falsetto position.

Emotional States.—The muscles of the face are the most affected by the emotions and next in order come the respiratory muscles. When emotions are suppressed the pupils dilate suddenly, the eyes becoming "black." Children begin to blush at three or four years of age and women blush throughout life, the tendency showing a special increase in both sexes at puberty. Vision is weakened by strong emotions. The feeling of shame affects the muscles of both the eyeball and lids. The feeling of pride causes the chest to swell and this reaction is seen in connection with praise and flattery. The feeling of physical superiority causes the subject to straighten up to his full height and to expand his chest, and that of moral superiority causes him to roll up his eyeballs and flicker his eyelids while he may also raise his hands.

Fear may blanch the surface and empty the blood-vessels of the skin so completely that the rings drop from the fingers. It parches the mouth so that the tongue cleaves to the palate—the brave man spits to show he is not afraid. While extreme fear paralyzes, a certain degree increases normal energy. Fear and terror cause a shuddering which is conservative because it stimulates the arrested peripheral circulation. In fear and also in anger the scalp hair may stand up. Anger causes turgescence of the veins of the head and neck which cannot be simulated; it causes a flow of saliva so that the subject in talking may emit a spray or froth at the mouth; the eyes may be reddened, including the fundus, and the subject may see red. When anger reaches a certain point the subject may destroy objects or injure himself. In irascible men the nostrils quiver, and in actual anger the respiratory muscles are disordered and the voice affected; the blood pressure may rise 25 per cent. and cause apoplexy. Some subjects choke from anger and attack the object of wrath instinctively to save themselves.

Female Sex.—The thigh bone of woman is shorter than that of man which in part accounts for the difference in stature. White women have a much greater tendency to prognathism than white men, for the latter very seldom exhibit it; hence in masculine disguise an orthognathous woman is more apt to escape detection. The feminine gait is chiefly psychical and not due to the formation of the hip-joint. The duration of the function of menstruation is thirty years. The normal duration is from two to five days; normal interval twenty-six to thirty-one days. The normal loss of blood is from 1 to 8 oz. Menstrual blood is commonly said not to coagulate but it does clot very slowly. The normal duration of pregnancy is 240 to 320 days. The umbilical cord shows extreme variability—from 3 to 75 inches. The amount of amniotic fluid is from 1 to 2 pints. The length of the normal fetus at term in the United States is 20 to 21 inches, weight 7 to 7½ lbs. The sex of a fetus can be made out at the end of the third month. A primipara is conventionally termed elderly at the age of twenty-eight. By the eighth day of the puerperium the womb should be reduced to half the size at term. The average total amount of lochial fluid is 3½ lbs. The average yield of breast milk for the first week is a pint and the maximum is in the eighth month of lactation when it averages a quart. A nursling, according to age, takes from 50 to 200 c.c. of milk at a feed. The appearance of the white lochia is at the beginning of the second week and it should persist for six weeks, these figures being of use in fixing the time of delivery. A woman, pound for pound, gives only about half the amount of milk as a cow. The menopause may vary in duration from zero to three years. The average age of appearance in American women is forty-nine years, and the extreme limits forty to fifty-five. Impregnation at the age period of fifty-fifty-five is not uncommon irrespective of the presence or absence of menstruation.

Breeding.—The normal ratio of male to female births is 106 to 100, but if the parents are near the same age the females may predominate, and if the wives are older the females considerably outnumber the males. When the husbands are much older the males may greatly exceed the females and this partly explains increased male births after wars. The first born child is more apt to be a male. The average period between date of marriage and first childbirth is seventeen months, and the normal space between labors, two years. The fertility of a woman under thirty is double that over thirty. The age of maximum fertility is twenty-two. The pelvis in woman is fully developed at the age of eighteen. Over-fertility and multiple gestation are always associated. A woman may bear as many as fifty children. After five years of sterile marriage the chance of offspring is about one in seventeen. Young adolescent males are fertile with older females and a boy of fifteen or sixteen is apt to impregnate a woman in the late twenties. Consanguine marriages occur in the ratio of about 2½ per cent. One-third of the offspring of consanguine marriages are normal. The older siblings of a family are the longer lived. The great majority of only children are deviates from normal, but this is not due to inheritance. The mortality of illegitimate children is double that of legitimate. The percentage of illegitimacy among white children in the United States is anywhere from 0.5 to 5 per cent., while in the negro population it may reach 22. Still births are twice as common among illegitimate births. The average age of the fathers of great men at the time of procreation is thirty-seven; of the mothers at conception, thirty. The average number of children in the families of great men is six.

Growth and Development.—During the first two months the infant merely vegetates and no pre-

cocious responses to tests should be included. About the eighth week it first blinks when startled. It has but three sensations at the outset—hunger, repletion, and pain. It reacts to all stimuli by suction movements. It expresses pleasure by wide open eyes, pain by tightly closed eyes.

A child is called newborn until the cord is shed, at the fourth or fifth day. Its weight at birth may be any weight up to twenty-five lbs. The anterior fontanelle increases in size up to the ninth month and closes at the eighteenth. The average placenta is seven inches in diameter and weighs a pound. The capacity of the stomach at birth is an ounce.

During the last month in utero the fetus gains 1,000 gms. The premature child has its eyes closed at birth. The mature child regains its initial loss of weight in a week, the premature's weight is not normal for a month. The cry of the newborn before birth is a displeasure reaction. Respiration is determined not from stimulation of the air but from the accumulated carbon dioxide of the blood. In the newborn the apex of the heart is outside the mamillary line.

Girls attain full stature at twenty, boys at twenty-one-twenty-two. During the nine months in utero the ovum increases its weight a million fold, but during the first twenty years of life the individual increases only sixteen fold. The infant doubles its weight at the twentieth week. The brain reaches its full development at the age of twelve. The boy from nine to twelve is more harmoniously developed than at any subsequent time.

The ages of normal puberty are ten to eighteen years, and only if earlier or later do we speak of precocious or retarded menstruation. Growing boys tend to strike the ankles together in walking and to develop high shoulder at clerical work, both being outgrown. The boy is best at climbing before puberty, although at the latter age the biceps enlarge. At the age of three weeks the infant shows for a time an unusual ability to hang by the arm.

Senescence and Death.—Senescence really begins at birth. The quantity of connective tissue in the body continues to increase from birth to old age and death. Senescence begins conventionally when a man is no longer able to support himself by his labor. The arcus senilis is a physiological phenomenon although it rejects for insurance. Age is shown by relaxation of the skin beneath the eyes, this being one of the most trustworthy evidences. Save in premature baldness grayness of hair precedes baldness. Senile kyphosis is emphasized by the weight of the heavy clothing necessary for cold weather. The senile man cannot rise on his toes because of the shrinking of the calf muscles and in consequence he shambles.

Death usually occurs with the eyes open. The dying are almost always unconscious. Those who have inhaled live steam apparently with impunity are apt to drop dead without warning. While rigor mortis is certain evidence of death it may sometimes occur before death (in some poisonings). It supervenes rapidly in death preceded by great exertion. The sooner it appears the longer it lasts and vice versa. In a very muscular subject it persists for a long time. It first appears in the muscles of the jaws and eyelids.

A blister on the foot in a holocaust shows that the subject was alive at the time of injury. The reaction of the tears changes after death from alkaline to neutral or acid. A few minims of ether or dionine solution instilled into the eye of the apparently dead may cause hyperemia, showing that life is still present. In death from suffocation the heart blood is fluid. In rare cases wounds inflicted after death may gape and bleed. In autopsy the brain must be opened before the thorax, otherwise the blood will escape into the latter. The death rate is high among widowers. The annual mortality of the whole world is 20 per 1,000 population. Nearly a third of all deaths occurs in those over sixty. Death in the first six days of life eliminates 36,000 unfit annually in the United States.

Identification.—Scars over the sacrum or heels point to past bedsores. All scars are useful for identification—vaccination, smallpox, hypodermic needle, and even chickenpox scars, which nearly everyone has. The duelling scars of German students made by the *schläger* are unmistakable. The scar of a superficial wound in the negro is darker than the surrounding skin, while if the wound is deep the scar is lighter. Bertillon measurements undergo no change after the age of twenty-one and hence are not usually taken before that age. Eye color practically never changes except in very young infants. Friction ridge patterns which serve for identification occur in the finger tips, palms, soles, and thenar eminences. Thin men have simulated fleshiness by puncturing the inside of the cheeks and forcing expired air into them, causing emphysema. A brogue or accent, usually useful in identification, may be outgrown with time. Peculiar phrases or oaths, as well as quick and slow speech, are of use in identification—also impediments in speech. The glance is difficult to change and hence of value—steady or fleeting, full or sidewise, etc. The finger prints of homologous twins are remarkably dissimilar (reversed) even when the Bertillon measurements correspond. In the palm of the white man there are forty-four different patterns, while in the negro palm there are but sixteen. Great toe prints present but two distinct patterns.

Physical Types of White Man.—Of many types described in the past but few have practical value. The "narrow-back" so called, or slender man (his stature is not essential), seldom increases his weight during life. His intestine is abnormally short, his spine long and flexible; in work he is in demand for his agility, in sport he excels in sprints and short efforts. The "narrow-back" woman bears children easily. The broad-back is the antithesis of the narrow-back in every way. The carnivorous type of man agrees in most respects with the narrow-back and the herbivorous with the broad-back—the herbivorous man, however, is not necessarily a vegetarian, but prefers starchy and fatty food.

Racial Types.—The negro is never prematurely gray, and gray or white wool means old age. The trunk of the negro is relatively shorter, as is the neck, and the extremities are long, the greater length of the upper extremities being in the forearm. The prominence of the negro heel distinguishes him from other dark peoples. The calf of the leg in the negro has no bulge, the lips are not thick but

everted, and the angles of the mouth are not as mobile as the white man's. The hair of the American Indian may attain a length of 36 inches. His nails are blueish and in the young the sclerotics are blue. The Indian child shows the Mongolian eyefold. The toes of the Indian are apt to be short and the bases of the second and third joined together. The hair has but slight tendency to gray.

Redundant and Defective Individuals.—Some apparent redundancies, like gigantism and twin birth, may be conceived also as defects; a defect like left-handedness or left-sidedness may be visualized as a redundancy as these subjects may readily become ambidextrous.

About 2 per cent. of mankind are left-handed and this peculiarity may run in families. There are also left-footed men who may be recognized by preferring the use of the left foot, as in spading. The left cerebral hemisphere is slightly heavier than the right and the viscera of the right half of the abdominal viscera are heavier than those of the left by nearly 1½ lbs., not counting the stomach contents.

Twins are born once in eighty or ninety labors; one-fourth of all twins and one-half of same sex twins are homologous. A giant is technically a man of 6 ft. 4½-in. stature—literally one man in a thousand. Exhibition giants must be at least 7 feet and several inches tall, while about twenty have measured over 8 feet.

Deafmutism.—The deafmute is not more irascible than the normal subject, whom he excels in courage and fortitude. His physique is in all other respects normal, but his breathing is peculiar from want of ear control; he is largely immune from spinning vertigo.

Stammerers.—The stammerer is usually a male, the ratio of male to female being seven to one; stammerers even stammer when whispering; the born deaf never stammer; stammering is a purely psychic defect and may run in families; the stammerer often has trouble in holding his breath; the vice seldom first appears after childhood; it is colloquial only, and often does not interfere with singing or speaking in the professional voice.

Color-Blind.—One man in twenty-five has some degree of red-green blindness; the latter is extremely rare in women. Quakers show more color blindness than the normal ratio. Color blindness may be acquired by those who habitually face a glare.

Albinos.—The albino is short lived; both pupil and fundal reflex are red; at night he sees without trouble; he may be recognized from afar by his peculiar carriage as he seeks to protect his eyes from the light.

Blind Subjects.—In total blindness the pupil does not contract on exposure to light; an eye long blind usually squints; there are more women than men who are blind in both eyes; the blind have no greater delicacy of touch than can be acquired by a seer, although they have a better faculty of interpretation; a blind person has an acquired instinct to protect his face; the second sight of old people is usually due to beginning cataract.

Bedfast Subjects.—The long bedridden become, by adaptation, a subvariety of mankind; they may develop corns on the ears from pressure on the pillow; with weight taken off the spine the latter increases in length, although not after the age of thirty; dropsy first appears over the sacrum; the bedfast may have much trouble in assuming the sitting posture which determines vertigo.

A BIOCHEMIC EXPLANATION OF THE SULPHUR MOLECULE.

By P. R. Vessie, M.D.,

Gowanda, N. Y.

Many attending physicians at health resorts, where "sulphur waters" are dispensed, concede that the sulphide contained therein shows definite reactionary powers in deep-seated diseases, whereas the popular remedy, *Calcium sulphide*, is regarded as decidedly antagonistic to pus-producing bacteria. No explanation, however, is advanced of its biochemic action in the human.* While sulphur is recognized as an ancient disinfectant and a traditional "blood-purifier" in the spring-time, it is destined to a great advance as soon as its action is known and understood by the coming school of biochemists. It is one of the chief elements used in the arts, industry, warfare, and medicinals, and is indeed a source of inspiration to creative chemistry. At any rate, the discussion of sulphur needs no profuse apology because it is one of the basic elements which constitute physical life.

The Destiny of Sulphur-Bearing Food.—In our diet sulphur is present as an inorganic sulphate and also as organic sulphur, found principally in protein and fatty food. After being acted upon by the gastrointestinal ferments this food is sulphurized into a definite amino-acid, "cystin." † While not in a free state in the organism it is distributed in the protein molecule in chemical combination, and when it is given experimentally a large amount of urea is excreted. This implies an increase of general metabolism and accounts for its value in hastening elimination of toxins. Sulphur is oxidized by the inspired oxygen to form nascent sulphuric acid which would upset the metabolism of the system if it did not combine with the carbonates of sodium and potassium,‡ resulting in a daily elimination of 15 to 45 grains of sulphates.

The Effect of Bacteria of the Sulphoprotein.—As to the chemistry and physiology of bacterial life, Wheeler[1] made the definite discovery of sulphur in the cellular substance of bacteria. Bacteria are stimulated to prolific growth on a culture containing colloidal sulphur. Jejunow[2] found that they digest the sulphur contained in organic bodies. This means that they oxidize the sulphur of the human cell which they then utilize for self-sustenance. In this process our sulphur is reduced to hydrogen sulphide. This sulphide is then oxidized to sulphuric acid, the vital source of bacterial energy.

*With the exception of the mention that it is altered in the stomach into hydrogen sulphide, entering the circulation to form sulphuric acid.

†This synthetic sulphur compound is oxidized and then excreted, principally in the urine; in part as an aromatic sulphate and in combination with sodium, potassium, and magnesium. Sulphur oxidation is decreased in carcinoma.

‡A large proportion of potassium is found in the blood corpuscles.

The carbonates of sodium and potassium in the body neutralize fractions of this sulphuric acid, causing a sulphate to be formed and eliminated as such. W. Smith[2] concludes that chemical reducing agents are common to all bacteria.

Oxidized Sulphur Neutralizes Bacterial Toxins.—Two of the well-known toxins of bacteria, indol and phenol, are acted upon by certain agents, causing less harmful products to be formed through neutralization. The following illustration shows the steps in the neutralization of indol:[3]

1.—Digestive ferments break down proteid food, producing amino-acids (simple compounds), many of which are synthesized into groups and rebuilt into protein, to replace wornout molecules of cells.

2.—The ferments of pathogenic bacteria attack these amino-acids, for example, tryptophane, and liberate:

3.—Indol (an aromatic toxic compound) which is oxidized to indoxyl. Fractions of this product are absorbed into the blood and are detoxicated by:

4.—Sulphuric acid, derived from the breaking down of "cystin" in the liver to form aromatic sulphates by the addition of potassium, constituting indoxyl potassium sulphate (indican*).

A BIOCHEMIC THEORY.

I.

Sulphur in the diet is sulphurized into an amino-acid, "cystin."

Cystin is a synthetic sulphur compound which constitutes one of the necessary molecules in the living body cell—protein sulphur.

Protein-sulphur serves the purpose of a life-giving force, and after it becomes oxidized it breaks down in the liver to form sulphuric acid.

In that organ sulphuric acid combines with the sodium and potassium of carbonates to form the end-products, sodium and potassium sulphate. Thus:

Food *Sulphur*
↑
Amino-acid, *"cystin"*
|
Protein sulphur molecule
↑
Sulphuric acid
↑
Sodium and potassium *sulphate*

II.

The ferments of bacteria split up the protein molecule in the living cell to form hydrogen sulphide.

The hydrogen sulphide is oxidized to sulphurous acid.

By the addition of more oxygen sulphuric acid is produced.

This sulphuric acid is the vital source of energy to the bacteria.

By the addition of the sodium and potassium of the body neutralization takes place to form the end product, sodium and potassium sulphate. Thus:

Protein *sulphur* molecule
↑
Hydrogen *sulphide*
↑
Sulphurous acid
↑
Sulphuric acid
↑
Sodium and potassium *sulphate*

III.

Fractions of the toxic compounds, liberated by the bacteria in the blood, are neutralized by combining with sulphuric acid produced by decomposition of the sulphur molecule of the body cell. Complete conjugation takes place with potassium to form an end-sulphate, which is eliminated. Thus certain bacteria attack "tryptophane," an amino-acid, to form a less poisonous compound, as follows:

*The same chemical conjugation takes place in the case of phenol potassium sulphate which is made from tyroxin, an amino acid.

Tryptophane
↑
Indol (toxic compound)
↑
Oxidized to indoxyl
↑
Indoxyl — Sulphuric acid + Potassium
↑
Indoxyl potassium sulphate (Indican)

IV.

The action of calcium sulphide, a popular remedy, which shows unquestionable results in systemic infections, may be explained by referring to the successive steps in the decomposition of poisonous products of bacteria into a less inert compound.

Hydrogen sulphide is liberated from calcium sulphide* in the stomach by hydrochloric acid, absorbed as such into the blood, then oxidized into *sulphurous acid*, then by the addition of more oxygen, into *sulphuric acid;* then fractions of this product combine in the liver with the basic poisons (indol, skatol, cresol, phenol, etc.) and by the addition of potassium forms the end sulphate which is eliminated. Thus:

Calcium sulphide
↑
Hydrosulphuric acid (hydrogen sulphide)
↑
Sulphurous acid
↑
Sulphuric acid
↑
Sulphuric acid — toxic compound (indoxyl) + potassium
↑
Indoxyl potassium sulphate

Conclusions.—A concentration of calcium sulphide heightens the chemical functions of the protein molecules so as to reduce the militant activity of bacteria.

Calcium sulphide also serves to neutralize toxins of bacteria by a stated chemical conjugation.

The so-called protective antibodies formed in the blood after the administration of sulphur are probably sulpho-protein bodies, since antibodies are admittedly complex chemicals.

A SUCCESSFUL SKIN GRAFT WITH A SLIGHT MODIFICATION OF THE REVERDIN METHOD.

BY FRANK WEHLE, M.D.,
BUFFALO, N. Y.

F. F., age twenty-four, an employee of the General Baking Company, while at work suffered a severe laceration of the left last digit, caused by cog wheels of a cracker machine. The damage was considerable, the skin was irregularly torn, muscles and tendons were lacerated, the nerves were torn, the bone crushed. The injury extended over two-thirds of the entire finger, involving the anterior, posterior, and external surfaces. Inflammatory phenomena supervened; however, in three weeks there was a fairly healthy granulation surface, but with a considerable amount of discharge. Notwithstanding this, a Reverdin was made with modifications in the following way at the Buffalo General Hospital.

Method.—The outer side of the patient's right thigh was shaved and rendered sterile, and an area of about ten square c.m. was anesthetized with ½ per cent. novocaine. A small portion of the cutaneous tissue was

*The calcium not only acts as a carrier for the sulphide, but aids blood-cell function. It also remineralizes the deficient calcium molecules which form the foundation for all cells.

picked up with a long darning needle and removed with a sharp thin-blade scalpel. It included the cuticle and a portion of the cutis vera. The grafts were then placed cutis downward on the granulations in rows transversely. They were then held in place by means of horse hair tied around the finger like a ring; where the horse hair came in contact with the graft on the cutaneous surface a minute drop of white shellac was put to insure greater immobility of the little pieces of skin. There were several grafts laid on the surface of the wound which were not held in place by horse hair, but were held in place with a drop of shellac placed partly on the edge of the graft and partly on the granulation. The dressing consisted of a bridge arrangement so that none of the bandages came into contact with the grafts.

Post-Operative Treatment.—The operation was done on December 19 and completed at 1 P. M. At 3.30 P. M. the surface of the wound was irrigated with 500 c.c. of saline solution. On December 20 the wound was again irrigated q. 4 h. with normal saline. On December 21 the wound was irrigated at 10.30 A. M. and at 8.30 P. M. with the same solution. The horse hair was removed on that date and all the grafts under the horse hair were found to be well anchored. On December 22 it was irrigated with saline again at 7 A. M. and 11 A M. After this hot applications were applied for two hours, and the patient was allowed to go to his home. On December 23 to 28 the only dressing was sterile vaseline and bandages.

Result.—On December 29 the wound was almost entirely covered with epithelium. Of thirty-five grafts thirty "took." All those held in place by the horse hair grew. It was found that the shellac on those not held in place with horse hair was of assistance in keeping the grafts in place. On January 6 the wound was entirely healed.

Conclusions—This report is published in order to stimulate interest in this procedure. Due to the nature of the writer's present work a series of these cases would be impossible. This, therefore, is in the nature of a suggestion for those who have a number of skin graft cases. It seems permissible though to conclude from this case that this method insures closer adhesion, obliterates dead space, and permits the removal of the discharge with irrigation. It is perhaps more applicable for grafts on the fingers, arms, legs, and feet than the other parts of the body where it would not be feasible to tie a ring of horse hair. There also seems to be some potentiality in the use of shellac for this purpose.

Medicolegal Notes.

Use of Text-Book on Cross-Examination Opens Door for Question on Redirect Examination.—In a prosecution for murder, the defendant assigned as error that, on redirect examination the trial court permitted a medical witness to answer the question of counsel for the state as to whether or not he agreed with the statement of the author of a text-book from which counsel for the state was reading. The question arose in this manner: The witness was the physician who performed the autopsy upon the body of the deceased. On direct examination he had merely described the condition of the body, the course of the bullet, the wound and its appearance. The defendant's counsel on cross-examination produced a medical text-book, read from it, and asked the witness if he agreed with the statement of the author upon the effect produced by hard-nosed bullets, and if a soft-nosed bullet would not mushroom as soon as it struck tissue. To this the witness answered that his understanding was that it might mushroom from a bullet shape into a mass, possibly the shape of a nickel or a quarter, but that he was not familiar enough with the subject to express an opinion. Upon redirect examination, counsel for the state read the rest of the statement upon the subject, and asked the witness if he agreed with the entire statement of the author. The Montana Supreme Court, citing the rule that medical books may be referred to on cross-examination to discredit the testimony of experts who refer to them as authority for, or in support of, their opinions, and for the purpose of testing their knowledge of the subject upon which they give opinions, holds that counsel, by inviting the doctor's opinion upon the effect of different bullets upon human flesh, and using a text-book for the purpose of discrediting him (as he had a right to do), opened the door for counsel for the state to fortify the doctor's opinion by calling his attention to the whole statement for the opposite purpose. The assignment was therefore held without merit.—State v. Ross (Mont.) 199 Pac. 426.

Question of Employment of Physician by Corporation.—Action was brought by a physician against an industrial company for recovery of reasonable compensation for operations performed on employees of the defendant under the following circumstances. The defendant maintained a medical staff for the treatment of its injured employees at various points of its activities, the plaintiff being the "company physician" at Vanderbilt, Alabama, one of these points, and another physician being physician at Dolomite. The employees in question were injured at Dolomite, and treated by the company physician at that point before they were transferred to Birmingham and came under the treatment of the plaintiff. The defendant's contention that Dr. Dabney, the plaintiff, was required by the terms of his employment to operate on or treat patients as the occasion required, whether they received injuries at Vanderbilt or elsewhere, was denied by the plaintiff, who insisted that his contract of employment with the defendant required that he give medical or surgical attention only to those employees working at Vanderbilt, and from whom the company collected a designated sum of money to pay for "medical services" required or desired by such employees.

The Alabama Supreme Court stated the law governing the case to be that, in the absence of an express contract, where valuable services are rendered by one person to another, which are knowingly accepted, the law assumes and implies an obligation to pay for such services what they are reasonably worth. This rule is applicable if the person for whom the work is done is informed that he is being looked to for payment and under such conditions and knowledge receives the benefit; but "in the absence of such knowledge or conditions, it cannot be said that a defendant knowingly accepted work done for him, and for which he must make a reasonable compensation." It was held that, in the present case, the question of whether the plaintiff's contract of employment required him to give medical attention only to employees working in the city in which the plaintiff was located, or whether it covered services in the treatment of employees injured in plants located at other points, was a question for the jury. The question of whether the corporation accepted such services knowing that the plaintiff looked to it for payment, so as to estop it from denying liability for services, was also held to be a question for the jury. Testimony as to the custom relating to the treatment of employees from plants located at other points was held competent and relevant.

Judgment for the plaintiff was affirmed.—Woodward Iron Co. v. Dabney, Alabama Supreme Court, 88 So. 873.

Compulsory Vaccination of Scholars.—The Pennsylvania Superior Court holds that a school district is reasonably embraced within the term "municipality," and as such is within the Act of June 18, 1895, P. L. 203, requiring compulsory vaccination for the public health "in the several municipalities" of the Commonwealth. It is also held that a conviction of a viola of section 1414 of the Act of May 18, 1911 (School Code), P. L. 383, providing for compulsory attendance at school, will be sustained where it appeared that the defendant had refused to allow his son to be vaccinated, and, in consequence, had rendered him ineligible for attendance at schools. In such a case, it was irrelevant to inquire into the effect upon the defendant himself of a particular vaccination or on the effect of vaccinations on other persons.—Commonwealth v. Butler, 76 Pa. Superior Ct., 113.

RECENT DEVELOPMENTS IN OUR KNOWLEDGE OF ECLAMPSIA.

SYNTHETIC reviews of this subject, from time to time, do not appear to show that any undoubted progress is being made in our knowledge of the nature and treatment of eclampsia. The experience of the last war had been expected to teach something and the earliest reports seemed to show that the reduced rations of the Germans greatly diminished the incidence of eclampsia and pointed to dietetic causes and control. Later information showed that this diminished incidence was in spots only. Today it is said that the combination of physical fatigue and mental anguish caused a decided increase in the number of cases among women employed in the factories. In great cities like Berlin and Munich the notable increase was attributed in part to psychophysical overstrain and in part to insufficient diet, factors which are seldom thought of in peace times. In the rural districts where the robust and hardy women were not overworked and where food was more abundant eclampsia showed no increase over peace times. In 1919 the statistics of Germany show a figure which approximates that of 1914, although in 1919 food was still scarce. In other words, to quote Gessner in the *Zentralblatt für Gynecologie* for December, 1921, xlv, 50, intensive physical toil of the munition factories and moral anguish are the most salient contributory factors in the increase in the number of cases.

In the same journal Hofbauer offers a theory of the nature of the disease which differs from those of other recent writers. For while both views accuse anemia of the brain as the motive of the convulsions, Hofbauer does not impute this to increased intracranial tension and edema but simply to angiospasm due in turn to excessive production of pituitin and adrenalin in the organism. We know that the hypophysis is enlarged during gestation but this overproduction of the two hormones is imputed to the entrance of toxic products from the fetal into the maternal circulation. This blood state might be antagonized by the detoxicating action of the hormone of the lutein cells, which lower the increased blood pressure caused by the adrenalin-pituitrin excess in the blood, were not the function of the ovary more or less suspended during gravidity. Hofbauer would therefore give lutein extract as a prophylactic of eclampsia, combined with thyroidin. Venesection at an early date is another indicated resource. Liepmann in the same journal gives the results of 19 years study of eclampsia along a certain line. He accuses the placenta instead of the fetus and asserts that it secretes a hormone resembling pancreatin. It resides and acts within the placental cells and the products of its digestive action are toxic to the mother. Hence there can be but a single grand indication, to remove the placenta as quickly as possible by emptying the uterus, at the same time practising venesection and if necessary transfusion.

Lichtenstein, writing from the merely practical aspect, still advocates a copious venesection repeated once or twice if necessary and taking a pint of blood at a time. This will lower the blood pressure, aid in detoxication, and allow a freer circulation with more oxygen in the blood. Such treatment must be begun with the first convulsion. The balance of the management is sedative—opiates, chloral, etc. The author has been using this management since 1911, and his figures surpass those of the ordinary method of emptying the uterus. This idea was first carried out on a large scale in Russia and with marked success.

THE CLINICAL ASPECTS OF CANCER OF THE HEPATIC DUCT.

PRIMARY cancer of the hepatic duct is essentially characterized by chronic jaundice with slow development, to which symptoms of cachexia and progressive weakness become added, ending in death within a few months, the average being about nine months. The onset of the process is frequently marked by icterus, but previous to its occurrence the patient will have complained of loss of strength. Or the patient may suffer from anorexia, headache, slight abdominal pain, and some diarrhea before the jaundice appears. The jaundice is intensely dark and remains so throughout. The skin and mucosæ are alike involved. In some few cases the icterus may decrease towards the end, or remissions and successive exacerbations in the intensity of the jaundice may occur. Pruritus occurring with the jaundice is considerable and may acquire an extreme acuity, almost intolerable. In most recorded cases the stools were decolorized, an important sign of occlusion of the hepatic duct. The urine usually contains large quantities of bile pigments, but Houssin has met with a case in which the urine was very dark but without any trace of foreign coloring matter, sugar, or albumin, and very poor in urea. The percentage of urea may drop to a low point and in some cases an alimentary glycosuria, absent at the outset of the affection, may develop toward the end. Oliguria or even anuria may occur at the end.

Spontaneous pain in cancer of the hepatic duct is apt to be absent. On the other hand, sensitiveness to pressure over the liver is usually distinct. The continual pruritus is, however, a cause of in-

somnia and intolerable distress. Anorexia is a common symptom; disgust for fats is much more marked than for other articles of diet, although, strange to say, the appetite is preserved. Vomiting, nausea, and gastralgic pains have been observed in some cases. The blood contains bile pigment which is eliminated by the kidneys, and toward the end of the process the hemoglobin may be as low as 15 per cent. with one leucocyte for every one hundred red blood corpuscles in the count. There may be a slight poikilocytosis, but leucocytosis, as in other cases of cancer, is the rule and when infection is added there is a polynuclear leucocytosis. Examination of the liver during life will give some important data. Usually there is some hypertrophy, occasionally so considerable that it is evident by inspection. In other cases the liver extends below the costal margin to the extent of one to several fingers' breadth, but its surface is always smooth and frequently hard. Sometimes it is completely painless on pressure, at others slightly so, but it can be very sensitive. The liver rarely decreases in size during the evolution of the process, but this has been known to occur. The gall bladder cannot usually be palpated, but occasionally is distended when it can be felt under the edge of the liver like a tumor. The spleen is sometimes enlarged but ascites is most uncommon, although in certain cases there may be more or less fluid in the peritoneal cavity with edema of the lower limbs.

As in malignant disease of other viscera, cachexia is the essential cause of death. The cachexia opens the door to secondary infections or an inflammatory process may develop behind the site of the occlusion in the duct. Infection is almost always a principal factor in the genesis of the terminal accidents of the process. This infection may involve other organs than the liver and cause death before this organ has become seriously involved by the malignant process. Thus, these patients may die of pneumonia. The final picture is ordinarily that of hepatic insufficiency, the icterus with or without the elevation of temperature, brings about the fatal issue. Gastrointestinal, pericardial, cerebral, or retinal hemorrhages not infrequently occur, denoting a profound change of the blood and vessels. Death may take place in coma.

IMPERFECTIONS OF THE HUMAN BODY.

It may be remembered by some of our readers that many years ago a clergyman wrote an article under a nom de plume in which he pretended to criticise the Deity for faulty construction of the body. The article was really a satire on certain sporadic efforts by anatomists at pointing out faulty mechanisms in the animal organisms. One, perhaps Helmholtz, had criticised the eye as a defective piece of optical apparatus. The joke lay in the fact that the would-be satirist was understood literally by many of his readers and soundly rated for impiety. Hence one must be a little cautious when confronted by an article of this scope. This perhaps should be true particularly of an article in a Spanish source, for in Spain there has been no struggle worth mentioning between religious authority and science. Nevertheless in *El Siglo Médico* for February 18, 1922, lxix., 3558, we find an article by Dr. D. Amalio Gimeno y Cabanas with the title above mentioned. This gentleman is also spoken of as Professor Gimeno and the Count de Gimeno. The address was delivered January 29, 1922, before the Royal Academy of Exact, Physical, and Natural Sciences.

Dr. Marco, who reports this lecture for the readers of *El Siglo*, speaks of it, as well as of the orator, in the highest terms. He recalls an alleged saying of King Alfonso the Wise (Alfonso X) of Castile, made before a joint body of Christions, Jews, and Musselmans, that if the Deity had consulted him before having created the Universe he would have made suggestions which would have led to a better piece of work. Much more modest was a certain American physician, whose name unfortunately is not supplied, who, had he been consulted, would have left out the tonsils from the human body. It is evident that statements of this sort intend no irreverence, but only express in a whimsical manner our ignorance of the purpose of certain organs.

The orator is said to have enumerated many examples of imperfections from the somatic angle but such imperfection does not extend to the psychic functions. One might say that the superiority of the latter is necessary to offset these new physical defects, which statement is in harmony with the dogmas of evolution. He criticizes the diaphragm, the ureter, the cystic duct, the entire anterior abdominal wall, the too-easy communication between the vessels without and those within the cranium, the teeth, so fragile in respect to caries, the tonsils and Waldeyer's ring in general, the functional disharmonies of the gastroenteric tract, the poor drainage which attaches to the emptied gravid uterus, and so on through the whole domain of pathology, whenever some apparent anatomical shortcoming makes possible the development of some disease. Apparently he denies the supposed benefits and conservative functions of pain. Nevertheless all of the shortcomings which can be enumerated have a definite role in creation; for in seeking to overcome them, man has been forced to develop his brain and if he is to become a superman, it will be because he will continue to develop his brain in the same manner.

It seems a strange contradiction that in orthodox and religious Spain a representative scientist can thus address a representative body of his learned countrymen while in the wicked United States, Mr. Bryan is working in the exactly opposite direction, endeavoring to place medieval fetters on scientific men who harbor any doubts regarding the mosaic account of creation, and to compel them to silence on all subjects which have even the remotest suggestion of agnosticism.

SURGICAL OBLITERATION OF THE LACRYMAL TRACT IN CERTAIN OCULAR AFFECTIONS.

Destruction of the lacrymal sac has been practised in all ages, but usually quite unintentionally. To Angelo Nannoni, in the XVIII century, the credit is due for having deliberately resorted to obliteration of the lacrymal tract for therapeutic purposes. After having been greatly in favor toward the middle of the last century it is now being replaced by methodical removal of the lacrymal sac. The latter operation was first performed by Berlin, in 1868, and is at present generally accepted in Europe. Of the various methods employed for obtaining surgical obliteration of the lacrymal tract, destruction and extirpation of the sac are the only operations of use because they alone permit the complete obliteration of the diseased structures. In performing extirpation the skin incision should be curved and from two to three centimeters long, the convexity being internal to and distant from the inner canthus of the eye for at least five millimeters. The incision should include the internal palpebral ligament and beginning a little above it; the sac is carefully dissected out and removed entire. The upper part of the lacrymonasal duct should be cauterized with the thermocautery and a compressive dressing applied which is left in place for several days. Destruction of the lacrymal sac does not differ from extirpation other than that the greater part of the sac is destroyed *in situ* with the thermocautery, an acorn point being used. The wound is merely covered with sterile gauze and allowed to granulate. The dressings are an important factor in the successful result of the treatment and a great deal of care and attention must be given them.

Recurrences of the affection are ordinarily due to an incomplete operation, but they may be caused by ascending infection along the lacrymal duct in cases where some nasal affection coexists; or they may result from filtration of the tears into the wound, hence the necessity of cauterizing the nasal duct and obliterating the lacrymal canaliculus. A cure of lacrymal affections treated by the method of obliteration is rapidly procured. Lacrymation always ceases as numerous cases prove. Ablation of the lacrymal tract would seem to bring about by reflex action histological changes which have as a result the drying up of the glandular secretion.

Generally speaking, the majority of cases of chronic dacryocystitis, with or without fistula, should be dealt with by extirpation of the sac, and the same may be said of mucocele, ectasis of the sac, dacryocystitis complicated by serpiginous ulcer of the cornea, dacryocystitis involving eyes which are to be operated on for cataract or iridectomy, and simply epiphora without lesions of the lacrymal tract. The chronic dacryocystitides which assume the form of chronic pericystitis, and those which frequently show acute inflammatory phenomena or which are accompanied by osteoperiostitis of the unguis or ethmoid should be treated by destruction of the lacrymal sac, and this procedure is the only proper way of dealing with tuberculosis of the lacrymal tract.

Autooxidation and Antioxidation.

While oxidases and reductases are familiarly spoken of in biochemistry, such enzymes seldom figure in any kind of practical effort, and in connection with a certain new field of experiment are not mentioned by name at all. Instead of this, Moureu and Dufraisse speak of processes such as autooxidation, which may be arrested by very minute quantities of certain chemicals. The authors read their announcement at a recent session of the Société de Biologie (*La Presse Médicale*, February 8, 1922, xxx, 11), and suggest as a name for the inhibiting substances "antioxygens." The most active in this direction are certain phenols as pyrocatechine, hydroquinone, and pyrogallol. Ordinary phenol and resorcin possess this power only to a slight extent. Among autooxidizable substances are acetic aldehyde, benzoic aldehyde, furfurol, etc. To take one of these at random, acrylic aldehyde (acrolein) may be prevented from self-oxidation by 1-20,000 part of hydroquinone. Otherwise stated one molecule of the latter can protect 40,000 molecules of acrolein. A single gram of hydroquinone can retard the oxidation of a metric ton of ordinary aldehyde. With addition of this sort, furfurol no longer turns black, acrolein does not become turbid, and styrolin no longer thickens. Fats do not become rancid. This discovery may be of no benefit in medicine because we do not as a rule wish to prevent oxidations in the body but rather to stimulate them. However there may be conditions of hyperthermia in which some of these phenols may exert a salutary action. One wonders whether the value of the Baccelli carbolic acid treatment of tetanus could be in any way due to antagonizing the hyperoxidation. The power of phenol derivatives of various kinds to depress the temperature may also be thought of in this connection.

Hepatic Insufficiency and Puerperal Infection.

A score of years ago, when the new doctrine of an all-comprehending toxemia of pregnancy was making its first converts, the opinion was ventured that this same basic state might be made to account for much of the incidence of puerperal sepsis, especially in the absence of definite exogenous factors. In the *Schweizerische medizinische Wochenschrift* for February 16, 1922, lii, 7, Bourcart of Geneva advances a view which is coterminous with the preceding. He starts with the assumption that the hepatic cell is a sort of fixed leucocyte, the prime duty of which is organic defense. When the latter becomes insufficient for its daily functions a protein meal is enough to cause a slight hemoclastic shock, which therefore becomes the most sensitive test for hepatic insufficiency. Yet in a way hepatic insufficiency can only mean an insufficiency of the entire organism, with especial emphasis on circulatory insufficiency. Defect in the general circulation means defect in the hepatic circulation. In passing, the author dwells on the effects of massage of the liver in reestablishing its partly suppressed function. This resource, including the use of the electric vibrator, he regards

as more simple and safer than the injection of colloidal metals and nonspecific protein. In connection with puerperal sepsis, which he regards as determined largely by hepatic insufficiency, of which acidosis is a leading manifestation, he announces that his hepatic massage can actually bring down to normal a temperature of 104° F., and can cause the disappearance of the various symptoms comprised under acidosis. The author has been at work along these lines for many years and it might be well if more members of the profession made the same kind of effort in the direction of the simple and obvious, instead of rushing into novel and possibly dangerous forms of medication on all occasions.

News of the Week.

State Charities to Observe Semicentennial.—The secretary of the Charities' Aid Association of New York State announces that the association will observe its fiftieth anniversary with events distributed over several months and over many parts of the State during the current year. A meeting will be held in the Town Hall on May 11, the fiftieth anniversary of the day when Miss Louise A. Le Schuyler, great-granddaughter of Alexander Hamilton, founded the organization to ameloriate the evils of the county almshouses of those days. The association was instrumental in having the State take over the care of the insane in 1890, and in 1907 the association began a campaign against tuberculosis in the State outside of New York City. The association is an unofficial body. It has 1,200 members in the State, seventy-six visitors to institutions, and several hundred visitors to almshouses and public hospitals.

Annual Meeting of Board of Trustees of Mt. Sinai Hospital.—At this meeting, held on March 19, gifts totalling $150,000, in addition to one previously announced of $150,000 from Adolph Lewisohn, were announced. The meeting was held in the new auditorium of the hospital. The chief address was made by Dr. Lewellys F. Barker of Johns Hopkins Hospital, who urged making New York the leading center of graduate medical instruction. The annual report showed that more than 187,000 persons were treated in Mt. Sinai dispensaries during the past year, while 9,667 persons were cared for in the general hospital. The daily per capita cost of patients in 1921 was $6.53 to the hospital.

Armenia Threatened With Blindness.—According to a despatch from Dr. R. T. Uhls of Kansas City, who is head of the medical department of the Near East Relief, there is an epidemic of trachoma raging throughout Armenia. Examination of 30,000 refugees revealed the fact that 27,000, or 90 per cent., were in the first stages of the disease. If the proportion holds good in all parts of Armenia, Dr. Uhls says, the situation is one of the most serious with which any nation was ever confronted. Only an extensive medical campaign can save the country from becoming a nation of blind.

Red Cross Will Move From Geneva to Paris.—The League of Red Cross Societies has decided to move its headquarters from Geneva to Paris. This step is taken in order to reduce expenses $15,000 yearly. At the time this decision was made, the League unanimously adopted the principle that all nations be allowed to join, after the French delegate had declared France no longer opposed the entrance of Germany.

Genoa Conference to Consider Prevention of Disease.—The Genoa conference will be asked to take up the task of preventing the spread of contagion from Russia into central and western Europe, in pursuance of a resolution adopted by the Council of the League of Nations. A partial report received by the Council from the hygienic conference in session at Warsaw depicts the situation as of the gravest character. The report states that 20,000,000 cases of typhus, cholera, and other contagious diseases have occurred in Russia during the past two years.

New Regulations to Restrict Liquor Blanks.—New regulations further limiting the use of liquor prescriptions by physicians are said to be in preparation by the Treasury. It is said they will accord with the Willis-Campbell bill prohibiting beer as a medicine and limiting the alcohol which may be prescribed to one-half pint in ten days and the number of prescriptions allowed to a physician to 100 in three months. The Treasury is understood to be considering a change in the definition of a liquor prescription to extend that classification to cover prescriptions issued for medical compounds of which alcohol is an ingredient as well as a prescription for a regular alcoholic liquor.

Supreme Court Ruling on Narcotic Dosage.—Two decisions bearing on the enforcement of the Harrison antinarcotic act were handed down by the Supreme Court on March 27. In one the court held in effect that a physician is prohibited under the act from prescribing narcotics to drug addicts in exceptionally large doses. The ruling in the second case declared that in prosecutions under the act it is not necessary for the Government to charge in the indictment that those selling the drugs "knowingly" violated the law. Both cases reached the court from New York. In the second case the District Court in New York had quashed the indictment because the word "knowingly" had not been used.

Additional Appropriations for Soldier Hospitals.—An appropriation of $17,000,000 to give additional hospital facilities for war veterans was authorized by a bill passed by the House of Representatives on March 31. The bill would put the Director of the Veterans' Bureau in charge of all activities resulting from passage of the measure, including the selection of sites and plans for new buildings and for remodeling existing structures.

Numerous Hiccough Cases Puzzle Doctors.—Physicians of Williamsport, Pa., are said to be puzzled over the large number of severe cases of hiccoughs existing at the present time and occurring since the first of the year in and about Williamsport, Pa. No cause has been assigned for the prevalence of this affection and no other city in the State is troubled to the extent observed in this locality.

City-Wide Clinics for Industrial Workers.—A movement has been started in Philadelphia to secure good medical clinics for all workers in the city of Philadelphia. Representatives of four leading or-

ganizations interested in industrial, medical and surgical conditions recently met with a sub-committee of the Industrial Relations Committee of the Philadelphia Chamber of Commerce to work out the practical details of a plan whereby all employees of the industries in that city shall have the same attention in case of injury or illness which is now possible in some establishments where they maintain first class clinics. It is planned to work out a model clinic to handle 10,000 workers, which would be situated in one of the closely built industrial zones of the city. It is believed that with the city properly zoned and with model medical and surgical clinics great sums now spent for compensation would be saved, and, what is more important, many lives will be saved and much invalidism avoided.

Pay Clinic Scored By Doctors.—On the evening of March 29, a joint meeting of the Eastern Medical Society, the New York Physicians Association, the Yorkville Medical Society, and the Harlem Medical Society was held under the Auspices of the Medical Society of the County of New York, for the purpose of discussing "The Pay Clinic from the Medical, the Public and the Economic Standpoints." A report of the combined committees of these societies was presented. The meeting was the result of the establishment of the Cornell Pay Clinic opened November 1, 1921, under the auspices of Cornell University Medical College. Dr. Walter L. Niles and Dr. Michael M. Davis defended the clinic, while Dr. Louis I. Harris and Dr. Henry W. Berg condemned the pay clinic as a socialistic scheme which pauperized both the patient and the doctor. The Attorney-General of the State has given the opinion that the Cornell University Medical College Dispensary is a dispensary within the meaning of Section 290 of the State Charities Law and is properly licensed by that Board.

Hay Fever Pay Clinic.—A special pay clinic for hay fever and asthma was opened at the New York Hospital on March 27. The clinic will be open on Tuesday and Thursday afternoons between 5 and 7 o'clock. It is said the charge will be $20 for from twelve to fifteen treatments.

Medicines to Help Russia.—Surplus medicines, medical, surgical and hospital supplies held by the War, Navy and Treasury departments and the Shipping Board will be made available for the Russian relief under an executive order issued by President Harding. The order is in accordance with the resolution recently adopted by Congress. The supplies will be delivered to the American Relief Administration within four months from the date Congress passed its resolution, January 20, 1922, and will not exceed $4,000,000 in original cost to the Government. The Relief Association is authorized to make the distribution of the materials.

Rabies Appears in New Jersey.—A rabid dog recently bit two children in Lyndhurst, N. J., one of whom died of hydrophobia and the other is taking the Pasteur treatment. A posse has been organized which is killing all stray dogs in that locality.

Damage Suit for Failure to Use "Dr."—Dr. J. J. Durrett, superintendent of health for the city of Memphis and a member of the medical faculty of the University of Tennessee is reported to have a suit in the circuit court, asking $100,000 damages from the president of a nationally known chain of grocery stores. The plaintiff alleges that in a series of political advertisements he was referred to as "Mr." Durrett, and that such reference was a studied effort on the part of the defendant to convey the meaning that the plaintiff was not skilled or learned in his profession and not entitled to hold a position requiring a reasonable amount of knowledge and skill.

Hospital Notes.—The Volunteer Hospital of New York has been saved from closing its doors by a group of business men who have prevented its sale to satisfy a judgment of $65,000 authorized by the Supreme Court. The hospital also has debts amounting to between $300,000 and $400,000, but with reorganization and new capital it is thought these can be readjusted. The Volunteers of America will sever all connection with the institution, and with the reorganization of the hospital its name will probably be changed to the Beekman Street Hospital.

Purchase of a site of nine acres at Walkerville, Mich., for a general hospital to serve all the Canadian border municipalities was recently recommended by the Essex Border Utilities Commission. It is proposed to first build an isolation hospital.

Ground was broken for the new Reconstruction Hospital to be built at the southwest corner of Central Park and 100th Street, New York City, on April 1. The first spadeful of earth was turned by Dr. W. Gilman Thompson, who has been largely instrumental in fostering the work of the Reconstruction Hospital. The new building will cost approximately $1,500,000 and will provide space for 175 beds. It will be supplied with every equipment embodying the latest principles of rehabilitation.

Sims Operating Theater of the Woman's Hospital.—A handsome bronze memorial tablet dedicated to J. Marion Sims has been erected in the newly remodeled operating theater of the Woman's Hospital. The inscription on the tablet reads: "Sims Operating Theater dedicated to the memory of James Marion Sims, M.D., LLD., 1813-1883. The Founder of the Woman's Hospital and of Modern Gynecology." The remodeling of the operating theater and the placing of the memorial tablet were made possible through the generosity of Mrs. Frederick Ferris Thompson.

Dr. Albert M. Wehenkel has been appointed medical superintendent of the American Legion Hospital at Battle Creek, Mich. He has named Dr. Wilfred Haughey as chief of the Advisory staff. Other members of the staff are Dr. R. C. Stone, Dr. R. D. Sleight and Dr. George F. Inch.

Charitable Gifts and Bequests.—The will of Mrs. Julia Seligman of New York makes the following bequests: Mount Sinai Hospital, $25,000; New York Post-Graduate Hospital, $25,000; $5,000 each to the Hebrew Orphan Asylum, United Hebrew Charities, Hebrew Sheltering Guardian Society, Tribune Fresh Air Fund; $3,000 to St. John's Guild, $2,500 each to the Hospital for Deformities and Joint Diseases, New York Society for the Relief of Ruptured and Crippled, Manhattan Eye, Ear and Throat Hospital, New York City Home for Destitute Blind, Bellevue Hospital and Montefiore Home; $2,000 each to the Henry Street Settlement and the Monmouth Hospital at Long Branch, N. J.

The will of the late Mrs. Rosina E. Hoyt makes a bequest of $15,000 to the Woman's Hospital, New York.

Obituary Notes.—Dr. Charles Theodore Sauer of Brooklyn, N. Y., attending laryngologist to the Methodist Episcopal Hospital, died there from septicemia and pneumonia, on March 28, at the age of fifty-seven years. He was graduated from the Long Island College Hospital in 1885.

Dr. Porter F. Chambers died of heart disease at his home in New York City on March 19, at the age of sixty-nine years. He was born in Russel County, Ga., was graduated from Emory College in 1873, and from Bellevue Medical College, New York, in 1876. He was a Fellow of the American College of Surgeons and the American Medical Association, a member of the New York Pathological Society, the New York Academy of Medicine, the New York Obstetrical Society and of many lay organizations. He was senior consultant of the staff of the Woman's Hospital and a professor of clinical gynecology at Columbia University. He was consulting surgeon to the French Hospital and a member of the staff of the Southampton, L. I., Hospital.

Dr. David G. Willets, assistant epidemiologist of the United States Public Health Service, died in Atlantic City on March 26, at the age of forty-eight years. He was graduated from the Georgetown University in 1907. Since that time he has been an assistant in the biological laboratory of the Bureau of Science at Manila, assistant professor of medical zoology at the College of Medicine and Surgery, University of the Philippines, and in various branches of the Public Health Service. He was a member of the American Medical Association and the Helmintal Society of Washington. He was an author of bulletins and pamphlets on pellagra and conditions affecting health in the Philippines.

Dr. McWalter Bernard Sutton of New Rochelle, N. Y., a graduate of New York University and Bellevue Hospital Medical College in 1905, died in Hamburg, Germany, on March 30, at the age of forty-nine years.

Dr. Charles Clinton Agin of Cincinnati, a graduate of Miami Medical College in 1875, died on March 22, at the age of seventy years. He was a Fellow of the American Medical Association. He was instrumental in founding the West End Medical Society and served as its president for more than twenty years.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, March 17, 1922.

Lunatic Asylums in Great Britain.—Mention has been made in previous letters of severe criticisms made on the conduct of lunatic asylums in this country. A Dr. Lomax, who has held positions in asylums, some few weeks ago severely arraigned the whole system. A committee was chosen to investigate his charges, but inasmuch as two of the committee have been superintendents of mental hospitals and therefore presumably not devoid of bias, Dr. Lomax has refused to give evidence before the committee. This attitude has been characterized by some as evidence that he was unable to support his charges and therefore unwilling to be cross-examined. On the other hand, there are those who, like an editorial writer in the Medical Press and Circular, believe that he was quite justified in making such a decision. The writer in question who heard Dr. Lomax speak on the subject, holds that no one who has heard him can fail to have confidence in him or doubt his good faith. His sincerity is obvious and it must be borne in mind that he does not impeach the officers of the institutions, but lays all the blame on the system itself. An interesting point was brought up in the speech of Dr. Lomax, namely, the value of a lunatic's evidence in a court of law. The speaker contends that in certain cases evidence of this nature may be relied on. While a lunatic may suffer from delusions regarding self-persecution, it seems that he seldom, if ever, entertains delusions concerning the persecution of others. Consequently, if an individual who has been an inmate of a mental hospital makes a charge of ill-treatment of another inmate, there is some probability of its being true. It does appear that a committee appointed to investigate the methods in which mental hospitals are conducted, should consist of absolutely impartial persons. It may be said that ex-superintendents of such institutions are well qualified from the standpoint of expert knowledge, to investigate charges brought against their management. But by reason of having been themselves responsible for or concerned in the conduct of these hospitals cannot but render them biased and thus not well fitted to act as judges. Mental cases should be treated with the greatest humanity, although it cannot be denied that the habits and behavior of those suffering from certain forms of mental disease are trying in the extreme.

Accident to Sir Thomas Barlow.—Sir Thomas Barlow, one of the best known and most respected of British surgeons, met with a somewhat serious accident a few days ago. On March 2 last in the early evening, he was crossing Southampton Row, a generally crowded thoroughfare with a good deal of swift motor traffic, when he was knocked down by a motor car. When he was picked up he was found to be unconscious and was taken in an ambulance to the Royal Free Hospital, where he was discovered to be suffering from cerebral concussion, and to have sustained a large scalp

wound on the back of his head. After having been treated he was taken to his own house in Wimpole Street. On account of his age much anxiety is felt by his numerous friends as to his progress, although it is satisfactory to learn that at the time of writing he was progressing as favorably as could be expected in the circumstances. This accident follows somewhat closely on the death by similar means of another distinguished London physician, and once again draws attention to the dangers to the pedestrian of the streets. In spite of the fact that in the control of street traffic London policemen deservedly have a world-wide reputation, traffic is not regulated in this immense city with the highest regard for the safety of those on foot. Swift vehicles, slow vehicles, and bicycles all run on the same streets, and even if one be young and agile, one must look out very carefully and sometimes exercise one's agility to the utmost extent in order to avoid injury. To the old, feeble, or crippled the crossing of a crowded street is a veritable menace.

National Health Insurance.—Sir Alfred Mond, the Minister of Health, has now decided not to introduce a bill for increasing National Health Insurance contribution, despite the fact that he gave notice of it at the opening of the session. He has now prepared and will continue another bill to bring about by different means the economies in Health insurance which the Geddes Committee recommended. He has made a deal with the approved societies, by virtue of which there will be no increase in contributions, but they will have to draw on their reserves to tide over the present difficulties of insurance.

Third International Congress of the History of Medicine.—The International Society of the History of Medicine was founded in Paris on October 8, 1921. It has for its object the study of the history of medicine in all its branches and the coordination of research work in these subjects. The society meets in congress every three years and it has been decided to hold the next meeting from July 17 to 22, 1922, in London. Meetings will be held in the buildings of the Royal Society of Medicine, of the Royal College of Physicians, the Royal College of Surgeons, the Wellcome Historical Museum, and elsewhere. In passing it may be said that the Wellcome Historical Museum comprises a wonderful collection of articles connected with medicine and surgery. It is almost unique of its kind and is housed in a fine building in the midst of the doctors' quarter of London. The following subjects have been suggested for consideration and discussion at the Congress in question: (1) The principal seats of epidemic and endemic diseases in the Occident and Orient in the Middle Ages, including Plague, Gangrenous Ergotism, Leprosy, and Malaria. (2) The History of Anatomy. (3) The revival of medical knowledge during the sixteenth century.

Ray Treatment of Malignant Growths of Nasal Accessory Sinuses.—At a meeting of the Section of Laryngology held at the Royal Society of Medicine on March 3 last, Dr. Finzi discussed the question from the radiological aspect. He said that the whole matter of the efficacy of ray treatment in malignant conditions depended on giving to every cell in that growth a lethal dose of the rays being used; and that lethal dose varied in different classes of growth. That for sarcoma was much less than for carcinoma, that for round-celled sarcoma was less than for spindle-celled sarcoma or myxosarcoma. For sarcoma he thought ray treatment might well replace surgery. The worst results from the rays were in epitheliomata because it was so difficult to get a lethal dose to the whole growth. By the Ehrlanger method, however, the aim was to get a sufficient dose of highly penetrating rays to every cell in the growth. Treatment of recurrences by irradiating methods was not so satisfying as the treatment of a primary growth untouched by surgery. He advocated intensive *x*-radiation preceded by a sterilizing method such as that of copper ionization, especially in epitheliomata. Operation should not be attempted sooner than a month after radiation had been carried out.

French Edition of Dr. Bainbridge's Cancer Problem.—This well known work on cancer by Dr. W. S. Bainbridge has been translated into French by Dr. Hertoghe of Antwerp, Belgium. A point of considerable interest in the publication of this book is the fact that it is the first work issued from the press of Louvain University, since the stately and ancient buildings of that university were razed to the ground by the Germans. The book is a good example of the printer's and binder's craft and augurs excellently for the future of the Press of Louvain University, which has risen Phoenix like from the flames.

Progress of Medical Science.

Boston Medical and Surgical Journal.

March 23, 1922, clxxxvi, 12.

1. Clinical Diagnosis of Cardiac Conditions. William E. Preble.
2. Ankylosis of the Jaw. R. H. Gilpatrick.
3. The Public Health Status of Amebic Dysentery in the United States as Potentially Influenced by the World War. C. W. Stiles.
4. Relative Fertility. Edward Reynolds.
5. Pathology of Tuberculosis. Lawrence Weld Smith.
6. Serum Treatment of Lobar Pneumonia. L. W. McGuire.
7. A Case of Mesenteric Thrombosis. John C. Henry.

1. Clinical Diagnosis of Heart Disease.—William E. Preble points to a death rate from cardiac disease in Massachusetts of 198.4 per 100,000 population, of which 7.7 were due to acute heart infections and 190.7 were due to chronic organic heart disease. He sums up the more important points in the clinical diagnosis of chronic heart disease and reviews White's so-called triple diagnosis of cardiac disorders. In discussing myocardial disorders he states that most authorities attach very little significance to premature contractions, or "extrasystoles." However, as they are practically all agreed that auricular fibrillation, auricular flutter, paroxysmal tachycardia, and extrasystoles are related conditions, there would seem to be reasonable ground for assuming that the extrasystole may be a sign of beginning myocardial disease. Commenting on cardiac disorders of the obese, he emphasizes the fact that the very obese are prone to have heart and arterial disease, and to die before their time. Of 600 cases of obesity seen in his private practice, 388, or approximately 65 per cent., had mitral regurgitation, functional or organic. Of these 600 cases, 496 were treated dietetically to reduce their weight. In 58 the murmur disappeared altogether with all signs of cardiac distress and usually with a marked drop in blood pressure. Most of these obese patients have a more or less elevated blood pressure which promptly drops to approximately normal, under treatment, provided there

is no other cause for the hypertension. Insurance companies do not reject fat people because of sentiment, but because they are poor insurance risks, on account of their proneness to develop disease of the heart and arteries. In the writer's opinion, these patients are all *potential* cases of myocardial disease, unless appropriate treatment is instituted.

3. **The Public Health Status of Amebic Dysentery in the United States as Potentially Influenced by the World War.**—C. W. Stiles reviews the question of infection with *Endameba histolytica* and other protozoa in this country. The replies to a questionnaire sent out to hospitals and medical schools show that in at least 31 states clinical amebic dysentery has not increased since the armistice to an extent that it attracted the attention of hospitals and medical schools. The public health service has examined 13,043 specimens from 8,029 persons, in 48 institutions, located in 22 states and the District of Columbia. Of these, 44 per cent. showed either protozoan or worm infection of one kind or another; 39.9 per cent. showed protozoa. There were 333 persons (4.1 per cent.) who showed infection with *Endameba histolytica*, and these cases were scattered in every state which sent in a fair number of specimens. The conclusions seem justified that on an average the soldiers who served in Europe were not infected with amebic dysentery any more than are certain other elements of our population, namely, the soldiers who saw only home service, certain groups of civilians and certain training schools. Therefore it would not be justifiable to go to the trouble and expense involved in trying to search out and treat the numerous carriers of amebic dysentery presented by the veterans of the late war. So far as the rates of infection are concerned, it is safe to concede the point that these are higher than were preconceived before the war, but so far as the significance of these rates are concerned, it seems that we must revise our former conceptions and must conclude that the carrier of amebic dysentery in this country is not such a menace to his neighbors as has often been taken for granted. Dr. Stiles points out that the fly is the most potent mechanical vector of the infection.

6. **Serum Treatment of Lobar Pneumonia.**—L. W. McGuire reports a series of 35 cases including all the Type I pneumonia which occurred in his service at the Naval Hospital at Chelsea, Mass., as well as those treated in private practice since leaving the service. In these cases the leucocyte count averaged 26,000. The amount of serum given averaged 205 c.c. The mortality was 5.7 per cent. Complicating empyema occurred in two cases. The average duration of the pneumonia in this series of 35 cases as determined by the temperature and symptoms was 66 hours; in other words, the time from the initial chill and fever until the temperature was again normal was less than three days. The course of the disease was thus decidedly shortened. The cases were practically all treated during the second day of the disease. The results in this series of cases compares favorably with an average mortality of 10.5 per cent. in 495 reported cases, many of which were treated late in the disease, and with the normal mortality of Type I pneumonia (25 to 30 per cent.)

2. **Benign Lesions of the Female Breast for which Operation is Not Indicated.**—Joseph Colt Bloodgood states that it seems almost incredible yet is true that in the last 100 women whom he has seen because of some complaint referred to one or both breasts, in more than one-half, after a history and careful examination, operation has been advised against. A total of 267 cases, the majority observed during the last five years, which were designated as benign conditions in which no operation was indicated, are considered in eleven groups as follows: (1) pain, 64 cases; (2) painful scar, 22 cases; (3) discharge from the nipple, 36 cases; (4) retraction of the nipple, 3 cases; (5) lesions of the nipple suggesting Paget's disease, 3 cases; (6) history of disappearing tumor, 24 cases; (7) definite and indefinite, single and multiple tumors in women under the age of 25, 23 cases; (8) definite and indefinite tumors in women over 25, 64 cases; (9) tumors in the axilla-aberrant breast tissue, lipoma, lymph glands, tumors of the sebaceous and sweat glands, 17 cases; (10) unilateral hypertrophy at puberty, 12 cases; (11) diffuse virginal hypertrophy, 3 cases. Bloodgood asserts that pain and discharge from the nipple are not conditions for which operation is indicated; retraction of the nipple as a symptom of onset of cancer is rare, but when retraction is of recent origin and not associated with a history of lactation, it should be looked upon as a sign of cancer and the complete operation performed. Any warty condition of the nipple associated with scaling, discharge or ulceration; any irritation of the nipple with redness or weeping; anything suggesting eczema or ulceration, which does not heal within a few weeks after simple measures of cleanliness, should be looked upon as Paget's disease, and be treated by complete excision of the breast. There is some evidence that benign adenoma in young girls, if left alone, ultimately disappear. The indication for operation on a single tumor or multiple definite tumors in one or both breasts in a girl 20 years or less of age is: size, recent rapid growth, extreme pain, and prospect of early marriage. Multiplicity of multiple tumors is suggestive of benignity. Therefore, there should always be a careful examination of both breasts. The differential diagnosis of breast lesions depends more on palpation than on any other factor in the history or examination. The writer's method is to palpate both breasts at the same time, the right breast with the left hand, the left breast with the right hand, palpating corresponding areas, never touching the nipple until palpation is completed.

3. **The Function of Colostrum.**—Julian H Lewis and H. Gideon Wells review the literature and record studies on the protein content of the human blood and human colostrum which they summarize as follows: The blood of newborn infants, and probably of all other mammals, contains little or none of the serum protein fraction known as euglobulin. This seems to be supplied chiefly by the colostrum which differs from milk in containing a large amount of this protein secreted directly from the blood. The euglobulin is the only blood protein that appears in the colostrum, and it is the only protein fraction in which the newborn infant's blood is deficient. Evidently the colostrum is formed to provide the fetus with a supply of euglobulin for its blood, during the short period immediately after birth when proteins may be best absorbed without disintegration by digestive proteolysis. The importance of this lies in the fact that the protective antibodies of the blood are found associated with the euglobulin fraction, and that the quantity of protective antibodies found in the colostrum, the milk, and infants' blood varies directly with the euglobulin content of these fluids. Evidently the colostrum furnishes to the newborn mammal protective antibodies, which probably add must to its capacity to resist infection in early life. If the infant does not receive colostrum it acquires euglobulin in its blood much more slowly, and presumably is in corresponding degree less resistant to infection. It is not probable that there is any equivalent substitute for human colostrum for newborn infants. The findings of numerous recent workers add force to the statement made by Famulener, ten years ago, that it is most

highly desirable that every newborn infant should receive its full ration of human colostrum.

5. The Treatment of Multiple Sclerosis.—Charles Metcalfe Byrnes cites five cases of multiple sclerosis in which antisyphilitic treatment was used and draws the following conclusions: No organic disease of the central nervous system so closely resembles syphilis in its symptomatology and pathology as does multiple sclerosis. In all probability the lesion in insular sclerosis is of an inflammatory nature. The cellular reactions are quite similar to those of syphilis; and, with the exception of the Wassermann test, the spinal fluid exhibits changes comparable to those in the vascular and gummatous types of cerebrospinal syphilis. Failure to demonstrate *Spirochæta pallida*, or secure a positive Wassermann reaction in all cases, is no proof that syphilis may not be an etiological factor. On the other hand a positive Wassermann reaction in multiple sclerosis does not establish its specific nature, since the two affections may exist simultaneously. The therapeutic test is of no value as a diagnostic measure, since ineffectual treatment does not disprove a syphilitic factor, nor does effective therapy establish its presence. Although syphilis may not be an etiological factor, there are undoubtedly clinical types of disseminated syphilis that are indistinguishable from insular sclerosis; and until the etiology of the latter disease is established, or a more acceptable form of therapy devised, the adoption of antisyphilitic treatment is worthy of consideration. Treatment is more likely to be effective if begun early, and both intravenous and intradural medication are recommended. Mercury and the iodides may also be prescribed to advantage.

7. Quinidine in the Treatment of Cardiac Irregularities.—Fred M. Smith reports that he has treated 12 patients with permanently established auricular fibrillation with quinidine sulphate. In 6 the sinus rhythm was restored. In 3 the duration of the normal mechanism was transient. Two have maintained a sinus rhythm two and one-half months and eight months, respectively. Three patients with paroxysmal auricular fibrillation were treated with quinidine. Two of these have had no further attacks. The remaining one took 0.2 gm. of quinidine after meals over a period of several weeks without apparently influencing the frequency of the condition. The treatment was most successful in those in whom the auricular fibrillation was of short duration and associated with a good cardiac muscular. In this group, however, the results could not always be predicted. The results of the quinidine treatment of auricular fibrillation from the standpoint of improving the general condition of the patient have on the whole, in the opinion of the writer, been unsatisfactory. It would seem that results might further be improved by the employment of drugs that have a favorable action on the cardiac musculature, provided the former does not counteract the action of the latter in maintaining a sinus rhythm. Twenty patients with premature contractions were treated with quinidine. Seventeen reported that they were markedly improved by the treatment; in 10 the irregularity was apparently eliminated. Of two patients with paroxysmal tachycardia, treated with quinidine, one was definitely improved.

2. Duodenal Regurgitation into the Stomach during Gastric Digestion.—Charles Bolton and Gordon W. Goodhart record the results of observations made to determine when, and to what degree, the contents of the digesting stomach are neutralized by the regurgitation of pancreatic juice, and how the curve of gastric acidity is modified by such regurgitation. They conclude as follows: (1) Duodenal regurgitation occurs at a definite period, but not always at the same time, during gastric digestion, and must be considered as a definite link in the chain of events occurring in the digesting stomach. (2) It determines the shape of the curves of hydrochloric acid and of inorganic chlorides, the former rapidly falling and the latter rising. (3) This regurgitation depends upon relaxation of the pyloric sphincter; and its presence or absence as determined by the shape of the curves above mentioned is a measure of the degree of tone or spasm of this sphincter, or of the obstruction of the pyloric orifice. (4) The curve of gastric secretion follows closely that of the total chlorides, but at a somewhat lower level. (5) The absence of free hydrochloric acid or the presence of a low active hydrochloric acid curve are no indications, when taken alone, that the gastric secretion is correspondingly diminished, for the total chlorides may still be at the normal height; these cases are due to free duodenal regurgitation and are similar to those of successful gastroenterostomy cases. (6) A curve of the "climbing type" does not necessarily indicate hypersecretion, but rather a delayed and deficient pyloric relaxation. Hypersecretion during the digestive phase is indicated by a rapid and high rise in the total chloride curve in the early part of the period; and during the interdigestive phase by the presence of an excessive amount of residual fluid containing a high percentage of total chlorides. (7) The two great factors contributing to the form of these curves are: (a) varying degrees of pyloric relaxation occurring at varying times, and (b) hypersecretion. The part played by deficient or excessive pancreatic secretion remains an open question. (8) The curves of free hydrochloric acid and total acidity at present in use show, in most cases, the general shape of the curves described in this paper, more particularly when the acidity is high; but they fail in this respect when free hydrochloric acid is absent.

5. Twilight Sleep: Notes on 75 Cases.—H. M. Gerson gives a résumé of his experience with twilight sleep from May to December, 1920. When the patient was of a nervous temperament, he relied upon the regularitv of intervals of pain (7 minutes) rather than dilatation of the os, and commenced treatment without any vaginal examination. In the case of the multiparæ treatment was commenced as soon as labor definitely set in, always making quite sure that the pains were those of labor and never relying upon the nurse or patient for such information. Before giving the first injection, that is, 1/150 gr. scopolamine and 1/3 gr. morphine, the room was darkened and instruments, dressings, etc., removed. A second injection of 1/150 gr. scopolamine was given alone in one hour's time. After this true amnesia is not obtained until three-quarters of an hour has elapsed. The percentage of complete amnesia in primiparæ is very high in comparison with multiparæ, owing to the fact that the latter were seen too late in labor for the action of the drug to be effective. Of the 75 cases forming the basis of this report, 48 were primiparæ and 27 multiparæ. There was no maternal mortality, but three of the infants did not survive. The average number of injection was 6 in the primiparae and 4.2 in the multiparæ. The maximum number of injections was 12. Gerson is of the opinion that oligopnea occurs more frequently in labor in which twilight sleep has been employed than in unaided labor, although in none of his cases could the infant mortality be attributed to this cause. In every case it is advisable to exercise a certain amount of vigilance until the child gives a healthy, prolonged cry. In this series oligopnea occurred more frequently in labors of short duration when delivery took place shortly after an early injection. In regard to the after effect of twilight sleep upon the children, in following up his cases the writer found the mortality during the first year nil, and the mentality, as far as could be judged, normal.

3. The "Buffering" of Blood.—A. V. Hill refers to the work of Barcroft and his collaborators which has shown that in the average normal man, if the volume of carbon dioxide taken up by the blood be plotted against the hydrogen-ion concentration of the plasma, then over the range of importance in the living body, the relation is a straight line. The slope of this line is a measure of the efficiency with which the blood is buffered. There are certain small variations in normal persons from the average curve, and the factors causing these variations may be of importance clinically. Hill pursues the following line of argument: Carbon dioxide is present in blood almost entirely in the combined form, as bicarbonate; a little is dissolved. The hydrogen-ion concentration is proportional to the ratio of dissolved carbon dioxide to combined carbon dioxide. Since the dissolved carbon dioxide is proportional to the carbon dioxide pressure, one may say alternatively that the hydrogen-ion concentration is proportional to the ratio of carbon dioxide pressure to combined carbon dioxide. If we add bicarbonate to the blood, keeping the hydrogen-ion concentration constant, while we do so by increasing the carbon dioxide pressure in the same proportions as we increase the total bicarbonates, that is the combined carbon dioxide; then the total carbon dioxide held by the blood is increased by the amount combined in the bicarbonate added, plus the extra amount dissolved, owing to the increased carbon dioxide pressure. The second amount is very small, so that the only important increase is that due to the added bicarbonate. The same is true of adding bicarbonate at any fixed hydrogen-ion concentration, so that by adding bicarbonate to blood we merely raise the volume carbon dioxide hydrogen concentration line by a uniform amount all along; in other words, the degree to which is blood is buffered is unaffected by the addition of bicarbonate as such. The volume carbon dioxide hydrogen-ion concentration line is much less steep for plasma than for blood, which is natural since the red cells contain the major portion of the phosphates, and all the hemoglobin which provide the greater part of the base required to combine with, and to absorb, the carbon dioxide. The more red blood corpuscles in the blood, the steeper will be the line; hence the differences in the blood of normal individuals in this respect may be attributed to differences in the number and contents of the red cells. A steep volume carbon dioxide hydrogen-ion concentration line, implying a well buffered blood, will be a characteristic of an individual in whom exercise produces little respiratory distress; a line of little slope one would expect to find associated with dyspnea. Hill points out that it will be very interesting to study the physiological and the clinical aspects of variations in the slope and position of this line.

4. The End-Results of Removal of Tonsils and Adenoids.—Harold S. Sington gives a summary of 52 cases which have been under his care during the last few years. He has included all children under 10 years of age who have had their tonsils completely removed by dissection, and their adenoids removed at the same time. The striking fact brought out by the summary is that once convalescent after the operation is complete, the child's health is so greatly improved that one has hardly ever had to attend him or her again; and that the child is not so liable to other and fresh illnesses as one who retains this lymphatic tissue.

5. The After-Results of 21 Cases of Iliocolostomy Performed for Tuberculous Bones and Joint Disease.—Hamilton Drummond recalls that a few years ago the condition known as intestinal stasis was held responsible for many lesions, and among them tuberculous bones and joints. Arising out of this the operation known as iliocolostomy was introduced by Sir William Arbuthnot Lane. The cases selected for this operation were those which had defied all methods of treatment and were gradually losing ground. Of 21 patients operated upon in 1911, 1912 and 1913, three are alive at the present time; one, a case of hip disease, is cured, while the remaining two are greatly improved. Five cases cannot be traced to date; two of these were known to be well and healed two years after operation. X-ray evidence indicated that the short-circuited colon is still functioning in two cases. The third patient was not any better after iliocolostomy but complete colectomy was followed by improvement.

6. The Function of the Chromophil Tissues in Relation to Splanchnic Stimulation.—A. W. Sheen and Swale Vincent described observations carried out in cats, which show that peripheral splanchnic stimulation in cats produces a characteristic curve in which an initial rise is followed by a marked "dip" and a prolonged secondary rise. Elimination of the adrenals from the circulation abolishes or reduces the "dip," the more usual effect of splanchnic stimulation being a simple prolonged rise. While the adrenal elimination is probably an important factor in altering the curve, further experiments are required to determine completely the origin of the "dip." Since some "dip" may occur after adrenal elimination, a part of the effect must be normally due to influences other than chromophil secretion.

4. The Re-Education of the Incapacitated Soldier (continued). G. C. Graves.

2. Appendicitis Complicating Pregnancy.—M. C. Sexton lays down the following rules: (1) The time to operate a chronic appendicitis is before pregnancy occurs. (2) Very mild primary appendicitis, or such cases as those in which the diagnosis is a matter of uncertainty, may be taken through the pregnant period with comparative safety. (3) Cases of recurrent appendicitis which constantly threaten the pregnancy with danger should be operated on as early in the period as possible. This also applies to severe primary attacks. (4) Perforative or gangrenous cases must be operated at once, no matter at what period. In a series of nine cases coming under the writer's observation the above statements and conclusions have all been borne out. These few cases have served to show that appendicitis in pregnancy will bear more watching and care than is ordinarily given to it. They have served to emphasize that which is now almost universally accepted in appendicitis of the non-pregnant, namely, early operation in all cases.

3. An Analysis, Clinical and Otherwise, of Four Hundred Nonsurgical Drainages of Pathological Gall-Bladders.—George M. Niles finds the Lyon-Meltzer method of gall-bladder drainage a worth while one and believes it has come to stay. It cannot, however, supplant surgery where there are gross pathological

lesions of the gall-bladder, as empyema, dense pericholecystic adhesions, or where gallstones are present. In some instances by early and adequate drainage this method may clear up certain cases that without it would have developed into surgical states. Its employment is indicated in jaundice, cholecystitis, choledochitis, migraine, and those indeterminate "bilious" conditions that have resisted other treatment. None of the patients in this series have suffered marked depression or illness as a result of this treatment.

13. Dilatation of the Pharynx as a Means of Relieving Dysphasia in Tonsillitis, Peritonsillar Abscess, and Postoperative Tonsillectomies.—F. E. Hasty states that to assist nature in combatting and eliminating systemic toxemia following operation we must make it possible for the patient to swallow with a reasonable degree of comfort. Sanger's method makes full fluid intake not only possible but comparatively comfortable. It consists in standing behind the patient, grasping each side of the head with the two hands encircling the ears, taking care not to press upon the neck behind the angle of the jaw, then raising the patient up, directing him to drink at the same time that he is being raised. While Sanger suggested pressure both before and behind the ears, the writer has found that pressure in front of the ears only is necessary. He has devised a mechanical appliance which is attached to a chair or the bed and by which the proper degree of suspension can be secured. This device solves most, if not all, of the swallowing problems of tonsillar infections and postoperative tonsillectomies.

2. Clinical Studies in Functional Disturbances. Functional Thyroid Tests As an Aid to Differential Diagnosis.—Nelson G. Russell, John A. F. Millet, and Byron D. Bowen have endeavored to correlate the basal metabolism, glucose tolerance and adrenalin sensitivity tests in disturbances of the thyroid and to note the results of their use in other endocrinopathies and various conditions of chronic disease in 85 cases. These cases were divided into four groups: Hyperthyroid, hypothyroid, fatigue and a large miscellaneous group. Clinical methods were found satisfactory in the diagnosis of frank hyperthyroidism, myxedema, and to a lesser extent in the third and fourth groups. In apparent hypothyroidism—not myxodematous in type—the ordinary clinical methods usually failed to suggest the probable diagnosis. In such cases the diagnosis was made entirely on the basis of a decreased metabolic rate, together with a definite improvement after the administration of thyroid extract. Of the functional tests used the basal metabolism was the only one to yield uniform results, which could be reasonably interpreted in association with the clinical findings and subsequent progress of the cases studied. Both of the other tests yielded positive results in almost all cases of hyperthyroidism, but the frequency of similar responses in a variety of other conditions, in some of which the diagnosis of hyperthyroidism was not even a remote possibility, necessarily detracts from their value as specific tests of thyroid function. Three points of special interest are brought out by the data presented. These are: (1) That there are some patients showing definite hypersensitiveness to adrenalin and intolerance to glucose, who tolerate thyroid extract well and improve under its administration; (2) that it is dangerous to attribute much importance to a positive adrenalin response in the diagnosis of suspected hyperthyroidism, and (3) that an occasional case of classical exophthalmic goiter showing marked increase of basal metabolic rate may exhibit no hypersensitiveness to adrenalin.

4. Observations on the Treatment of Auricular Fibrillation by Quinidin Sulphate.—C. C. Wolferth presents observations made on twelve cases of auricular fibrillation treated with quinidine, in seven of which the normal rhythm was restored, the fibrillation was converted to flutter in one, while in four there was failure to abolish the rhythm. During the periods that attempts were being made to abolish fibrillation the subjective effects were various. Four patients, including two in which the treatment was unsuccessful, said they felt better, but in the remainder there was no improvement. In no case did alarming symptoms develop. There was no significant effect noted on urinary excretion. In three patients there was rather sudden marked increase in the ventricular rate; in one of these the symptoms of cardiac embarrassment began to develop and the drug was discontinued. From the electrocardiographic evidence it would seem that quinidine must exert a profound effect on the transmission of the excitation wave through its abnormal path in non-specialized auricular muscle. It seems not unlikely that such an effect of the drug may play an important part in the abolition of fibrillation and flutter. In these cases after the restoration of normal rhythm the auriculo-ventricular conduction time appeared to be increased above the average, but it is scarcely justifiable to assume that the alterations in conduction were necessarily due to quinidine. The presence or absence of valvular disease did not seem to affect the efficacy of the treatment. Likewise the age of the patient did not seem to make any particular difference. The most favorable cases for treatment are those with relatively good heart muscle and at least fair compensation, and those in whom the flutter or fibrillation has been of relatively short duration.

5. Nonspecific Wassermann Reactions in Diabetes Mellitus.—Edward H. Mason reports two cases of diabetes mellitus, which gave strongly positive Wassermann reactions. He points out that such reactions in cases of diabetes mellitus, which give no evidence of past infection, must be considered conservatively. It is probably due to some disturbed physico-chemical relationship. The facts indicate that material damage was done to the patients by the arsenic treatment. Probably the arsenic acted as a toxic agent upon the weakened pancreatic cells.

6. Lead Poisoning, With Special Reference to Poisoning With Lead Cosmetics.—Moses Barron and Harold C. Habein hold that the importance of lead and its compounds in producing disease is known to very few doctors, as well as laymen. He reports four fatal cases of encephalopathia saturnina, due to the use of a cosmetic containing lead occurring in one family. He points out that basophilic granulation of the erythrocytes is a striking and characteristic feature of most cases of lead poisoning. With proper straining technique this finding is of inestimable value for diagnosis and careful routine blood studies should be made as a prophylactic measure among workers in industries using lead. Besides being an industrial poison, lead is also the source of many miscellaneous forms of poisoning, chief among which is probably that resulting from the use of lead-containing cosmetics. Mild degrees of poisoning from one form of face powder containing lead is probably widespread, but because the symptoms are indefinite the true etiology remains undetected.

Wiener klinische Wochenschrift.

January 12, 1922, xxxv, 2.

Cancer of the Rectum.—Hochenegg has operated for this affection considerably more than 1,000 times, but for some reason he analyzes only the material of the past fourteen years, which amounts to 779 cases. The

ratio of male to female is nearly two to one. Twenty-nine patients were under thirty years of age, with the youngest a girl of twelve. The majority were in the sixth decade. Attempts to isolate special causal factors proved futile, for only about 3 per cent. suffered from obstipation, and but 7 per cent. had hemorrhoids. The attempt to form groups by symptoms was also unfruitful. In about one patient out of three the first symptom was some irregularity of stool. In sixty-six cases, or about once in eleven or twelve patients, some one had made a diagnosis of piles or intestinal catarrh before the admission to the author's clinic. The full clinical picture of the disease was presented but a limited number of times, while there were forty-one so-called "few-symptom" patients in which the disease was almost silent. In 138 cases the patients must have had the disease at least a year before they reached the author. The latter uses the term "drastic course" when the entire disease picture is evolved within four weeks, while by protracted course he means a duration of more than eighteen months. Anything from two to eighteen months in developing he terms of normal evolution. About 4 per cent. were admitted to the clinic with ileus and thirty-four patients were at once colostomized on this indication alone. The death rate in this class of case is shockingly high—44 per cent.—because the colon is enormously distended and secondary peritonitis from migrated bacteria is usually added. In about 32 per cent. the neoplasm was fixed to the surrounding tissues. In about 45 per cent. the growth was seated in the ampulla and in 26 per cent. within 10 cm. of the sphincter. The radical operability was 72.3 per cent., and the number actually thus operated on was 66.7 per cent. The number of patients colostomized was 184, including temporary, permanent and emergency. While there were a few individual survivals up to twelve years, 72.5 of these colostomized subjects survived less than a year. Of the considerable number who lived from one to three years, some showed good continence by reason of the warning sensation, but were in the minority. The author performed his radical sacral operation on 461 patients with an operative mortality of 11.1 per cent. and 33.6 per cent. of permanent cures (three year). The mortality of sacral anus operations was higher (14.1 per cent.), while that of resection was but 8.9 per cent. The three-year cures following resection numbered 37.1 per cent. The five-year survivals by all methods averaged about 25 per cent. The operation figures of the author so greatly outnumber the patients analyzed in the early portion of the paper that he is evidently quoting from his total operative material.

Wiener klinische Wochenschrift.

January 19, 1922, xxxv, 3.

Direct Heart Massage.—Amreich states that 48 cases of direct cardiac massage are now on record and that the percentage of reanimation as a result of this resource is 37.5, although in some of the cases the result was only temporary. The author has analyzed the material from the standpoint of certain criteria. Thus direct massage must have been undertaken only after the total failure of all of the more conservative measures. Again the first response to massage must have been at least five minutes after beginning the latter. Only 5 cases measure up to this standard. To this number the author adds a new observation. The patient was to be subjected to total hysterectomy under sacral analgesia and twilight sleep. The laparotomy incision had been made and 8 minutes had expired since the spinal injection. At this juncture patient became cyanotic and pulseless. She was brought up out of the Trendelenburg position and put under artificial respiration and oxygen inhalation, with an injection of camphor. Cardiac massage by the indirect König-Maas technique was added, with 5 cm. adrenalin solution thrown directly into the ventricle. As these measures provoked no response the author resorted to extrapleural exposure of the heart by the method of Kocher. The organ was found relaxed and motionless, and was now directly squeezed by four fingers of the right hand at its posterior surface against the back of the sternum. The effort was to press rhythmically 60 times a minute and this was maintained for 6 minutes with a second intraventricular injection of adrenaline before a few feeble contractions were felt followed at once by strong pulsations of 120 to the minute. All of the accessory measures were kept up but after three-quarters of an hour the organ began to flag and was massaged a second time with only temporary advantage. A third application of massage had a negative result and patient was pronounced dead.

Journal de Médecine de Bordeaux.

February 10, 1922, xciv, 3.

Study of Cancer in Holland.—Hammer, a physician of Amsterdam, calls attention to the high cancer death-rates of both France and Holland and mentions the activities of the Netherlandish Institute for the Study of Cancer. An old mansion has been transformed into a joint clinic, laboratory and radiologic temporary headquarters. Despite the outbreak of the war just as the Institute was beginning to function a notable amount of work has already been accomplished. Leeuwenhoeck, the first clinical microscopist, is a sort of patron saint and source of inspiration. Numerous statistics have been compiled and graphics teach us that the incidence of the disease throughout the country is very unequal, as is also the rate of increase. These inequalities cannot be accounted for by the prevalence of different types of cancer in different regions, although it is conceivable that occupation types especially would be present in special localities. In Limbourg the incidence is a fourth less than in Frise, these regions representing the lowest and highest death rates respectively. Since the Frisians are notably hardy and long lived it might be imagined that more people reach the cancer age, but this fact if proved would not explain the discrepancy. The problem is really of the most baffling nature. In Rotterdam it was noted among the record of curiosities that a very wide difference of incidence was found among the members of the two leading Protestant denominations. This difference was more marked than that between the Christians and Jews. Another fact brought out is that sarcoma is not especially a menace to the young as compared with the old, for it increases with age just as does cancer itself. Certain private practitioners submit their entire cancer figures. One in Hague finds one death in five among his patients due to cancer. A rural practitioner finds the distribution suggestive of an infectious disease and he has been struck by the frequency of familial cancer. At the same time it seems possible to eliminate heredity as a factor. Statistics from Tropical Holland are also instructive. In the Dutch East Indies cancer has but one-tenth the incidence of Holland proper. In the latter cancer of the digestive tube is fearfully common, while in Java it is unknown, although there they have primary cancer of the liver, which is extremely rare in Holland. But in Curacao cancer is said to be about as common as at home. Cancer of the breast in Holland seems to bear a distinct relationship to maternity and lactation, although in all other locations, aside from the uterus, the married woman has advantage over the single. In regard to treatment, a follow up to the limit of 300 cases submitted to operation, cases limited wholly to cancer of the breast, it was found that 10 out of 15 women were dead at the end of four years, while three others died sooner or later of the disease. Two out of 15 seem to have been cured by the knife, less than 14 per cent. Probably the salvage is a little higher at the present day.

In Honor of Theophile de Bordeu.—The second centenary of the birth of this pioneer in hydrology was celebrated at Pau on February 19, 1921. He anticipated to some extent the work of Bichat in anatomy, and Bernard and Broca in physiology, and was one of the medical philosophers of his day. Among those who took part in the exercises were some of the leading physicians of France, as Doleris, Cornet and Champetier de Ribes. Upon the house of his birth was affixed a marble tablet bearing the inscription "Theophile de Bordeu (1722-1776), Illustrious Physician Who Introduced the Use of the Pyrennean Mineral Waters, Was Born in this House February 22, 1722."—*Journal de Médecine de Bordeaux.*

Book Reviews.

FOOD PRODUCTS. Their Source, Chemistry, and Use. By E. H. S. BAILEY, Ph.D., Professor of Chemistry and Director, Chemical Laboratories, University of Kansas; Author of "A System of Qualitative Analysis;" "Sanitary and Applied Chemistry," etc. Second Revised Edition, with 92 Illustrations. Price, $2.50. Philadelphia: P. Blakiston's Sons & Co.

IN this work the author discusses the chief foods found in the different markets; he describes their source, methods of preparation for the market, how they are packed, preserved and shipped, their composition and food value. The book is of distinct value for, while there is little or nothing in it that is new, the facts here presented are only to be found in a large variety of books, pamphlets, and scientific reports, which are not always available when one is searching for information of this kind. In this new edition the sections dealing with alcohol and alcoholic liquors have been considerably condensed, since their manufacture is "of much less importance than formerly." The volume should find a place in all households where the family follows the oldfashioned habit of taking meals at home rather than in restaurants and hotels.

MIKROMETHODIK. Quantitative Bestimmung der Harn- und Blutbestandteile in kleinen Mengen für klinische und experimentelle Zwecke. Von Dr. med. et phil. LUDWIG PINCUSSEN, wissenschaftlichem Assistenten der II. Medizinischen Universitätsklinik zu Berlin. Price, M. 28. Leipzig: Georg Thieme, 1921.

THE author here presents the technique of socalled micromethods for the estimation of the principal chemical constituents in the blood and urine. He makes no claim for completeness in this field presenting only those methods with which he is familiar and attempting to choose the simpler ones with a view having them more generally applicable. He has collected these methods from many sources and for the most part has presented them as originally described. In some places he has introduced modifications that have appealed to him as effecting improvements. He has, perhaps naturally, not drawn heavily upon American sources for his technique and has followed Bang closely in many estimations. We believe that one who has not been familiar with the development of this branch of biochemistry will be surprised and interested to find how many estimations are included in this manual. There are sufficient illustrations of apparatus to make the text clear. It is a very satisfactory little book.

SURGICAL AND GYNÆCOLOGICAL NURSING. By EDWARD MASON PARKER, M.D., F.A.C.S., Surgeon to Providence Hospital, Washington, D. C.; and SCOTT DUDLEY BRECKINRIDGE, M.D., F.A.C.S., Gynæcologist to St. Joseph's Hospital, Lexington, Kentucky. With 134 Illustrations in Text. Second Edition, Revised. Price, $3.00. Philadelphia and London: J. B. Lippincott Company.

THE second edition of this book differs but little from its predecessor. Besides minor changes, there is some new matter, and some condensation and elimination of old matter, so that the volume is but little (if any) larger than before. The chief addition is the chapter on the Carrel-Dakin treatment of infected wounds; this chapter contains a detailed description of the technique from the nurse's standpoint. Much of the material contained in the volume is of an advanced kind, and will be of more interest to the nurses attached to the operating room than to the ordinary pupil nurses. The book contains an adequate amount of surgical pathology and technique, and the supplementary chapters dealing with emergencies and common conditions can be specially commended. The book is well printed and of convenient size; the illustrations leave nothing to be desired.

NOUVEAU TRAITÉ DE MÉDECINE. Publié sous la direction de MM. les Professeurs G. H. ROGER, F. WIDAL et P. J. TEISSIER Fascicule VII. Avitaminoses; Maladies par agents physiques; Troubles de la nutrition. Price, 35 fr. net. Paris: Masson et Cie, 1921.

VOLUME VII of this system appeared at about the same time as Volume III. Its contents are vitamines and avitaminoses by Roger; scurvy by Benoit; infantile scurvy by Alfaro; pellagra by Perroncito; beriberi by Sacquépée; venom poisoning by Calmette; conditions determined by anaphylaxis by Pagniez; serum disease by Courmont; diseases caused by physical agents by Langlois and Binet; and diseases of nutrition by Le Gendre. More than one-half of the volume is devoted to the diseases of nutrition of which diabetes mellitus is the chief. The subject is discussed in detail but one cannot help feeling that the work of American investigators in this field should have received more consideration than Le Gendre appears to give it. The teachings of Allen and Joslin and their followers has effected a marked change for the better in the results obtained in treating diabetics in this country and it does not seem as though foreign writers could afford to ignore them. Roger's communication concerning vitamines is highly interesting. Calmette's paper on snake venoms is, of course, admirable and complete. Perroncito retains a conservative attitude toward the active discussion as to the cause of pellagra. Pagniez still includes the conditions which we are getting to know as hypersensitiveness, under the heading of anaphylaxis, but with some reservations. The volume is quite up to the high standard of the work as we have seen it.

ATLAS FOR ELECTRO-DIAGNOSIS AND THERAPEUTICS. By F. MIRAMOND DE LAROQUETTE, M.D. Authorized translation by MARY GREYSON CHEETHAM, with Foreword by ROBERT KNOX, M.D., Director Electrical and Radiotherapeutic Department, Cancer Hospital, London. Price, $4.50. New York: Paul B. Hoeber, 1921.

THE author is chief of the North African Electroradiographic Service at Algiers. The number of pages is 180, of illustrations 52. The nine chapters are devoted respectively to the sensory motor nerve paths, head and trunk, upper limb, lower limb, normal excitability of nerves and muscles, normal coefficients of excitability of the nerves and muscles, observations on electrodiagnosis, articulations and skin.

THE POCKET ANATOMY. By C. H. FAGGE, M.B., M.S. (Lond.), F.R.C.S. Eighth Edition. Fiftieth Thousand. Price, $1.75. New York: William Wood and Company, 1920.

THIS little compend is so well known that it is hardly necessary to draw attention to the appearance of a new edition. This work is more brief and condensed and also more accurate than most of its competitors; non-essentials are omitted, and stress is laid on the relations of the various structures. In this revision the old nomenclature has been reinstated throughout.

THE SPLEEN AND SOME OF ITS DISEASES, Being the Bradshaw Lecture of the Royal College of Surgeons of England, 1920. By Sir BERKELEY MOYNIHAN, Leeds. With Thirteen Full-page Diagrams. Price, $5.00. Philadelphia: W. B. Saunders Co., 1921.

HITHERTO the spleen, doubtless because of a lack of knowledge of its functions and importance in the economy, has enjoyed a fair degree of immunity from the surgeon's attacks, but this freedom cannot be much longer counted upon, for as the author of this most readable monograph remarks, "We are beginning to realize that the spleen, too, plays its part, perhaps a considerable one, in the etiology of diseases whose most conspicuous symptoms are evoked by associated or consecutive affections of other organs. We can no longer consider diseases which affect our abdominal organ as being restricted to that organ. . . . The spleen which has been little regarded in this connection, may now justly claim a measure of attention." The several diseases to which special chapters are devoted are pernicious anemia, leucemia, Hodgkin's disease, splenic anemia (Banti's disease), hemolytic jaundice, Gaucher's disease, von Jaksch's disease, and polycythemia. A feature of great value is the series of plates, many of them colored, showing diagrammatically the chief changes in the various diseases discussed. Sir Berkeley Moynihan illumines every subject to which he turns his attention and his essay on the diseases of the spleen and its relation to other diseases is no exception to this rule. The book is most interesting and full of suggestions that give much food for thought and inclines one to regard this long neglected and little understood organ as worthy of more careful study.

SECTION ON MEDICINE.

Stated Meeting, Held February 21, 1922.

DR. RUSSELL L. CECIL IN THE CHAIR.

The Constitutional Symptoms of Tuberculosis.—Dr. ALLEN K. KRAUSE of Baltimore, Md., presented this communication, in which he stated that the constitutional symptoms of tuberculosis should not call for description before an audience of this character. They were the evidences of intoxication born of the infection, expressed as unwonted fatigue response to even normal stress; overirritability of the nervous system, especially the autonomic part of it, with consequent disturbance of the circulation and digestion; fever, unusual daily range of peripheral temperature, yet frequently disregarded; loss of tone of the skeletal muscles, and undernutrition. There were not a few other constitutional symptoms, but those mentioned were the more common and prominent ones. One should not bear too hard on the conviction that regarded what might be called fatiguability as the leading constitutional symptoms of tuberculosis. A diagnosis of tuberculosis could not be made with finality by anyone, unless the existence of infection was proved by physical or *x*-ray examination, or by tuberculin or investigation of infected material. Nevertheless, a diagnosis of tuberculosis now demanded more than a demonstration of infection. In every case it was called upon to answer the question whether the infection was active, in the sense of whether it was causing physical disability or contributing to it. This question would be answered, one way or the other, only by the presence or absence of constitutional symptoms. And constitutional symptoms were no less momentous in the prognosis of tuberculosis. To quote Brown, "The pulse rate, together with the temperature and weight, formed the prognostic triad." Any statement, such as was frequently and loosely made, that the intoxication of tuberculosis was brought about by toxins of the tubercle bacillus was marred by the stigma of attributing plain effects to specific causes which were so obscure that the most exhaustive research had failed to indicate that they existed; indeed, it had suggested the contrary, namely, that there were no toxins referable to tubercle bacillus. However, tuberculous intoxication was real enough; and if it was not due to bacillary toxins, to what then was it due? The paper was concerned with the discussion of this question. Eleven years ago the writer put forward an hypothesis of tuberculous intoxication in disease and during the tuberculin reaction which made anaphylactic hypersensitiveness the underlying factor, and attempted later to prove the hypothesis by experiment. The latter proceeded from the premise that if intoxication was the result of an anaphylactic antigen-antibody reaction, through the absorption of noxious focal substances formed and released during the reaction, then these substances would be present in excess in foci undergoing tuberculin reaction and be capable of demonstration through their toxic effect on normal nontuberculous guinea pigs. The results of these experiments indicated that reacting tuberculous foci contained substances which were noxious for normal animals; but nothing could be read from the experiment to suggest that materials from foci at the height of reaction were more abundant or poisonous than those from foci that were just beginning to react. It was therefore decided to perform the same experiments with substances from normal nonreacting foci, in order to observe whether these were also inherently toxic for normal animals and to what degree. The outcome from these experiments compelled the belief that any tissue material, if in proper physical condition, and if put into the circulation in large enough amount in a given time, would poison an animal. To produce appreciable intoxication the material must be so constituted as to be capable of entrance into the circulation, and it must enter the latter in sufficient quantity in necessarily short time. Under these conditions any or all tissues, normal or pathological, might poison the body; no intermediate mechanism, such as the operation of the hypersensitive state, was necessary. It was very likely that the same factors were at work to bring about the well-known primary intoxication which might follow extensive burns, or severe comminuted fractures, or surgical operations without infection. It would seem that the intoxication of tuberculosis in the natural evolution of the infection was in large part a nonspecific process, brought about by the absorption of material from foci in amounts large enough to produce symptoms, and no doubt varying with the individual animal. The focal materials which were poisonous were derived from the constituent cellular elements of tubercle, rather than from bacilli. Yet to deny that bacillary constituents did not not or might not participate in the intoxication of tuberculosis was to disregard outstanding features of tuberculous infection which were well known to experimenter and clinician. If an animal with tuberculosis, even with relatively slight and nonprogressive infection, was reinoculated with living tubercle bacilli, it fell acutely ill. Constitutional symptoms became manifest within a few hours after inoculation and continued for a day or two, when the animal either died or started on the road to recovery. If autopsy was performed at the height of illness or after the natural death of the animal, two types of lesion were found. These were: (1) Inflammatory reaction of the old foci of disease resulting from first infection, and (2) acute inflammation of tissues at points where the reinoculated bacilli had localized. Living bacilli would act upon existing foci in the same manner as would tuberculin; that was, they would cause focal reaction and consequent general reaction with constitutional symptoms. To this extent they might conceivably contribute to the production of acute illness which followed reinfection. The writer's net impression, after having observed the reactions of many hundreds of tuberculous guinea pigs, both to living bacilli and to tuberculin, was that the intoxication after reinoculation with bacilli included elements which could be explained only by attributing some of the effect to the direct influence of bacillary constituents. This type of intoxication was apparently something a good deal different from the intoxication of ordinary, chronic, focal tubercle. It was encountered clinically at its best in those persons who, from apparent health and with no antecedent history of manifest tuberculosis, were suddenly stricken down with acute tuberculous pneumonia and with generalized miliary tuberculosis. The pathogenesis of these cases postulated that in every instance they were autogenous reinfections from older quiescent foci. Identical bacillary eruptions might, of course, occur in patients who were being treated for tuberculosis of whatever type, and the result would be the conversion of active, chronic tuberculosis into acute tuberculosis. The course of active tuberculosis in itself represented, no doubt, a well-nigh irresolvable complex. There were no doubt cases, many of them, which during their entire period of activity evolved and receded without bacilli being conveyed to points outside of the active focus and setting up reinfection elsewhere. There were other cases again, many of them, in which it was plain that massive reinfections, localized or disseminated, were taking place. There were still others, perhaps the majority of cases, in which the infection progressed through reinfection, occasional or frequently repeated, by comparatively few bacilli, which had been transported by way of lymph or blood or visceral duct. In all three types of cases it might be postulated that intoxication would take place from nonspecific focal materials. Dr. Krause stated that he was inclined to believe that acuteness of constitutional symptoms always meant reinfection, that was, the infection rapidly enlarging its boundaries and extending into healthy tissue, or infection conveyed from one point to another. This conception of constitutional symptoms gave one, at least, a perfectly rational idea of the operation and value of rest in the therapy of the disease. The day had long passed when one must defend rest as our one essential weapon to combat active tuberculosis, whether it be the bodily rest of partial or complete confinement to a reclining chair, or the local rest of fixation for a tuberculous joint, or of artificial pneumothorax for a diseased lung or of the voice at

a whisper for laryngitis. It could be taken as a good working rule that, under conditions of complete physical rest, as nearly as these were attainable, tuberculosis, unless very acute and active, took care of itself extraordinarily well.

The Mechanism of Compensation in Pulmonary Tuberculosis and Its Relation to Physical Findings.—Dr. H. A. BRAY of Ray Brook Sanitarium made this presentation, which he illustrated with lantern slides. He explained that he employed the word compensation in a limited sense to designate the means adopted by nature to overcome the loss of lung volume incident to tuberculosis. In this disease loss of lung volume occurred frequently and might be recognized by chest deformity, including spinal curvature, compensatory empysema, and displacements of the diaphragm and mediastinum. These compensatory factors were not infrequently impaired in function, due among other conditions to rigidity of the chest wall preventing its retraction, to pleural adhesions limiting the mobility of the diaphragm and mediastinum, and to inherent differences in the capacity of the lung to compensate. The degree of functional impairment might be extreme, yet with few exceptions, compensation was adequately established. This result might be attributed to the close interrelationship of function existing between the factors. Radiograms were presented illustrating the participation of the diaphragm and mediastinum in the compensatory process and their interrelationship of function. It must be remembered, however, that in this respect, lung emphysema and chest deformity played an equally important rôle, evidence of which might be partially or completely lacking on the plate. Elevation of the right diaphragmatic leaf was the essential factor in the readjustment incident to the pathological decrease in volume of the right lung. Attempts to establish the extent of pulmonary disease by the degree of diaphragmatics displacement, without consideration of other factors, frequently proved fallacious. The physical signs associated with upward displacement of one of the leaves of the diaphragm might be confused with those of pleural effusion and at times other methods were required for their differentiation. Where the left leaf was elevated cardiac disturbances might occur. From a casual study of the mediastinum it would be difficult to realize the extent to which this structure might be deflected by pathological conditions arising within the chest. Dr. Bray explained the movements of the mediastinum during respiration and showed that displacement of the mediastinum toward the center during inspiration should not be considered a manifestation of disease, as held by some observers. In disease the deflection might be accentuated and attributed to a tug on the mediastinum from a relative increase in the negative pressure due to delayed and improper expansion of the involved lung. Caution was required in the interpretation of deflections by the radiogram since the condition might be simulated by an artefact due to rotation of the patient at the time of *x*-ray exposure. Fluoroscopic study was essential in the study of the movements of both the diaphragm and the mediastinum. Deflection of the mediastinum might considerably modify the physical findings because of the altered anatomical relations. In particular, the percussion note over the deflected mediastinum was markedly impaired, which might suggest a dense lesion. Furthermore, on auscultation, because of the associated deviation of the trachea, and other causes not at present understood, the sounds over the diseased lung were decidedly accentuated, thereby tending to confirm the misinterpretation. When employing physical signs to determine the presence of mediastinal deflection, it was well to remember that the signs were more evident anteriorly, owing to the relative thickness of the musculature and the greater volume of the interposed lung posteriorly. Deflection of the mediastinum had been confused with hilum enlargement and cardiac hypertrophy. Many of the symptoms of cardiac hypertrophy were similar to those of cardiac displacement, thus adding to the difficulties of diagnosis. In other instances the diaphragm and mediastinum might reciprocate about equally in compensation, as shown by a radiogram in which the left leaf, normally below, was placed on a slightly higher level than the right, and the mediastinum was shifted correspondingly to the same side. In discussing emphysema, Dr. Bray recalled that pathological emphysema occurred in the zone of the disease, physiological hypertrophy in the health parts of the lung. In the latter the integrity of the alveolar wall was retained and with recovery the lung returned to its normal state. In this respect it contrasted with pathological emphysema which represented a permanent change in the lung structure. It was important to remember that the presence of marked compensatory emphysema might mask the other physical signs even in the presence of extensive involvement. In patients presenting extensive involvement of one lung, the scattered infiltration in the opposite lung usually remained concealed on physical examination owing to the associated hypertrophy. The thorax, owing to its rigidity, did not respond as readily as did other factors to the demands of compensation, an observation supported by noting this sign in pulmonary disease where rapid loss of lung volume occurred; as for example, in lobar pneumonia. A study of the accompanying radiograms established the existence of an intimate reciprocal action between the diaphragm and mediastinum in compensatory readjustments of the organs within the thorax. Mobility or immobility of the mediastinum was important in determining the position of the diaphragm and vice versa. Though more evident on physical examination, compensatory emphysema and local retraction of the chest wall played a similar and equally important rôle. In tuberculosis these factors varied in their function of compensation. To this fact might be attributed the impracticability of previous attempts to correlate the extent of pulmonary disease with any one of the compensatory factors. While many important points had necessarily been omitted from the discussion, sufficient data, Dr. Bray stated, had been submitted to establish the practical value of a study of the mechanism of compensation in the physical examination and in the interpretation of the chest radiogram.

Treatment of Tuberculosis by Immobilization.—Dr. JAMES ALEXANDER MILLER read this paper, which was illustrated by lantern slides. He stated that no principle of treatment in tuberculosis was of more value than that of rest. General bodily rest had been the accepted method of treatment in all cases of active pulmonary tuberculosis for a long time. Local immobilization in other forms of tuberculosis, as in joints or in the spine, was also of recognized value. It was only within the last ten or fifteen years that the same principle had been applied to the local treatment of certain forms of pulmonary tuberculosis. In general it might be considered that in certain classes of cases it had been demonstrated that immobilization of the chest was a very great aid to arrest the activity of the lesion and in a very considerable proportion of otherwise hopeless cases would restore them to economic efficiency. The definite indications for artificial pneumothorax were: (1) in chronic cases, largely if not entirely unilateral, in which the usual methods of regimen had failed; and (2) in cases with repeated large hemorrhages, in which the particular lung which was the source of bleeding could be definitely determined. There was a growing tendency to use this method in cases that had not yet become chronic or advanced. The dangers of the treatment had been greatly exaggerated, and in competent hands and with proper precautions could be reduced to a minimum. Rupture of adhesion and tearing open of the lung was a real danger, but should scarcely, if ever, occur when proper care was exercised. In cases of so-called flapping mediastinum the treatment must usually be discontinued. The results of pneumothorax in general showed that serious symptoms might be controlled, general health materially improved, and the duration of life definitely lengthened in somewhere between 25 and 50 per cent. of the cases treated. Adhesions played an important rôle in the results to be expected from artificial pneumothorax treatment. Methods for severing these adhesions had been suggested. Jacobæus of Stockholm had developed what apparently was the most satisfactory method and reported excellent results. The thoracoscope as developed by him was merely a modified cystoscope, and by it it was possible accurately to diagnose the position and extent of such

adhesions and to guide a thermocautery introduced through another portion of the chest wall in such a way as to sever the adhesions from their thoracic attachment without danger of hemorrhage or rupture into the lung. With experience this method was destined to be very valuable in diagnosis, as well as treatment of adhesions. Dr. Adrian Lambert and the writer were fortunate enough to secure one of these instruments and were gradually acquiring some experience in its use. In cases unsuitable for pneumothorax because air could not be introduced into the pleural cavity on account of extensive adhesions, and also in certain others in which only partial collapse could be obtained, radical thoracoplastic surgery had been attempted. The operation in general consisted in the resection of the upper ten ribs, taking out 10 to 12 cm. of the lower ribs and gradually diminishing the amount of resection to 2 or 3 cm. from the first rib. The operation might be done with entire satisfaction under local anesthesia, though Dr. Lambert preferred a general anesthetic. The mortality, of course, was high, not from the operation itself, but from the bad surgical risk which this class of patients represented. Dr. Adrian Lambert and Dr. Miller had begun the study of suitable cases at Bellevue Hospital, and Dr. Lambert had operated upon a few with encouraging results. The future held interesting possibilities in the development of these methods in the treatment of tuberculosis.

Dr. S. Adolphus Knopf said that when he was invited to discuss these three papers he knew that he could not add anything to the wisdom of these three wise men. There was nothing to add in reference to the papers, except to say in connection with Dr. Miller's remarks on artificial pneumothorax, that it was always advisable to warn the patient and his family beforehand that they should not expect too much from this procedure so that they would not be disappointed if it failed to do all that might be hoped. Dr. Knopf then went on to speak of present-day tuberculosis problems. He stated that the tuberculosis problem in Europe outside of England was appalling. In 1913 there was a tuberculosis mortality in New York of 171, during the war 164, and after the war 109 per 100,000 inhabitants. In Vienna the tuberculosis rate before the war was 302, during the war 425, and after the war 405 per 100,000 inhabitants. In Poland during the war it was 1164 per 100,000, and it was not yet reduced. This gave an idea of what the war had done to increase the tuberculosis death rate in Vienna and Warsaw. How much Russia, which always had the highest tuberculosis death rate, had lost in men and women and children under Soviet rule would never be known. In the United States the death rate from tuberculosis had decreased in spite of the war and the influenza epidemic. When one read the favorable reports he was apt to think that we need no longer worry about this disease, and that he might presume that in a decade or two at the longest the disease would disappear from among us. 'Alas, that goal was very far from us. More disturbing was the fact that in this city 14,000, or 52 per cent. of the total number of tuberculous patients, were not under medical care. It was to be hoped that the great number of tuberculous individuals without medical attention would receive attention and be placed in a hospital or under the care of a physician who would show them how to obtain at home conditions similar to those of a sanitarium. Besides tuberculosis in the civil population there were a large number of tuberculous ex-soldiers and sailors. However, the number of cases of tuberculosis among soldiers, either during or after the war, was indeed comparatively small. That was a fortunate circumstance due to the care exercised by the draft boards and examining boards in camps. Nevertheless, there were many ex-service men suffering from tuberculosis, and a further increase in the number was anticipated. In answer to the criticism of conditions at some of the hospitals caring for tuberculous ex-service men, it must be remembered that some of these buildings were very hastily constructed because of urgent need during the war, not thinking that they would be permanently occupied by tuberculous patients. The criticism in regard to the lack of care of tuberculous ex-soldiers, he felt, had very little foundation. The officers in those institutions had nearly all seen overseas service, were specialists in their work, and devoted to their task. Dr. Knopf said he had visited some of these Government hospitals and could speak from experience. In many of these hospitals the patients were given more liberty than in civilian tuberculosis hospitals. Some might think this was to be deplored, but the psychology of the ex-soldier was different from that of the civilian patient. An economic cure was looked for, and by that was meant putting the patient in condition so that he could work a few hours without collapse. The friends of the ex-soldier could rest assured that the United States was giving these men every care; they were better cared for than they would be in municipal and private institutions. Looking forward, the question might be asked as to what the prospects were of ultimately controlling the great white plague. The tuberculous individual, no matter what his circumstances, could nevertheless be greatly helpful in many ways. He could help by not being a source of infection; he could help by implicit obedience to the instructions of his physician. However, his greatest field of usefulness lay in his contact with his fellow patients. He could be cheerful and hopeful and encourage his fellow sufferers, instead of speaking of his unpleasant symptoms. He should refuse to talk about his troubles and speak only of things cheerful and hopeful. In that way he could help both himself and others. At Fox Hills Hospital, there were 700 ex-soldiers, and he had never seen a more courageous, helpful, sympathetic group of men than those tuberculous ex-soldiers. There was every reason why they should be hopeful, for tuberculosis was not a hopeless disease. Not only early, but many advanced cases, made favorable recoveries with rest, with the treatment of annoying symptoms, and under careful medical supervision, but where the patient was most hopeful and most contented he usually made the most rapid recovery. Finally every patient should endeavor to give as little distress as possible to others, by learning to control his cough and telling others that the cough was more or less the result of nervousness and could be controlled.

Dr. Charles E. Darrow of Rochester, N. Y., stated that he accepted the invitation to take part in the discussion with great reluctance, as he was not going to discuss the papers that had been presented, and with marked diffidence on account of the fact that he was going to bring forward for consideration a serum for the treatment of tuberculosis. We all looked askance at any remedy proposed for the cure of tuberculosis, because disappointment had so often followed close on the heels of hope, that he who suggested a new remedy must either be endowed with great temerity or a strong belief in justice of his cause. More than forty years ago, when he left New York City to begin the practice of medicine, the current advice given a tuberculous patient was an immediate change of climate, the substitution of an outdoor for an indoor life, the avoidance of physical fatigue and mental worry. It sounded like a death knell to the great number of tuberculous patients who were unable physically or financially to follow that advice. To be sure, Dr. Trudeau was beginning his pioneer work at Saranac Lake, but the sanatoria for the treatment of this disease were few and far between, so that the outlook of impecunious patients was very gloomy indeed. About twenty-five years ago the strange anomaly existing between two domestic animals in regard to the incidence of tuberculosis kept forcing itself upon his attention. The horse and cow, pastured in the same fields, housed under the same roof, would seem to present ideal conditions for the transmission of a communicable disease from one to the other. Yet the cow was frequently infected and the horse remained practically immune against tuberculosis. The question suggested itself, as to whether there was anything in the serum of the horse's blood that was inimical to the development of the tubercle bacillus. A number of guinea pigs were inoculated subcutaneously with successive doses of normal horse serum, and then inoculated intraperitoneally with tubercle bacilli. The results seemed to justify the belief that normal horse serum might be of some service in preventing the development of tuberculosis. At that time very little was known about

anaphylaxis and nothing about the mode of its prevention. It was deemed necessary to give 20 c.c. doses to the human being, and on account of the size of this dose a long interval (ten days or longer) was allowed to elapse before it was repeated; all patients given the second dose had more or less violent anaphylactic reactions, some very startling. Therefore, it was not strange that most patients refused the third dose, saying that they preferred to die more slowly. Two patients, however, continued the treatment. One was at death's door, but lived two and one-half years after the first injection. She perhaps might be living to-day but for the fact that the treatment had to be turned over to a physician who was not interested and failed to give it properly. The other patient was a man absolutely given up by the experts at Saranac Lake and elsewhere. He was alive and perfectly well to-day, and carrying on a large and active business. However, it became apparent from these experiments that this treatment would never become popular, unless the strength of the serum could be increased so that the effective dose could be smaller, and unless anaphylaxis could be prevented. A large amount of experimental work was done. It was finally found that by inoculating normal horse serum with diphtheria toxin and incubating it for three months at a temperature of 37.25° C., the antitoxic property of the serum (roughly speaking) doubled. This led to the hope that the antagonistic property of the horse serum against the tubercle germ might be increased in a similar manner. Varying quantities of normal horse serum and the serum of a tuberculous cow were mixed and incubated for various periods. Then normal horse serum was mixed with different quantities of the various tuberculins, and these mixtures were incubated for varying periods of time until fifteen years ago, when a formula was evolved which has been used without change up to the present day. This consisted of the addition of 0.02 c.c. of B. F. (human), 0.02 c.c. of B. E. (human), and of 0.02 c.c. of B. F. (bovine). Thus it would be seen that 0.06 c.c. of the combined tuberculins was added to each c.c. of normal horse serum. This mixture was then incubated for three months at a temperature of 37.25° C.; then passed through Berkefelt filters, and had added to it ¼ of 1 per cent. of tricresol. The final product was used in doses of from 1 c.c. to 1.5 c.c. subcutaneously. These doses were given three times during the first week, or the intervals between subsequent doses could be of any length that was considered desirable on account of the condition of the patient, without fear of producing any reaction either anaphylactic or otherwise. This mixture after incubation certainly contained no free toxin, for the reason that it produced no general reaction whatever in a tuberculous patient. Its use in cases of early tuberculosis had proved entirely successful, that was to say, all these cases had recovered. In cases of advanced tuberculosis, two out of three had made satisfactory recoveries. In very advanced tuberculosis there had been an occasional success. In glandular and other forms of localized tuberculosis the treatment had proved very successful. Dr. Darrow in closing said that he knew there were theoretical objections to the possibility of developing a serum for the treatment of tuberculosis, but nevertheless, this treatment has been on trial for the last fifteen years, and had been successful both in his hands and in the hands of several other physicians. At first it was used only in cases that were unable to avail themselves of the standard modes of treatment, but as success followed success, he had extended it to all cases of tuberculosis that had come under his care. He hoped that the profession at large would give it a trial upon a sufficiently large scale to prove its value beyond any peradventure.

Dr. MAURICE FISHBERG stated that usually in this section those who discussed papers confined themselves to the subject under consideration. He was not inclined to discuss the figures as to the prevalence of tuberculosis that had been presented, or the new cure for tuberculosis, but he did know that they had listened to three very excellent papers. Dr. Krause had placed emphasis, as it had recently been placed, on a consideration of constitutional symptoms. That point had been well brought out by Dr. Krause, and he had also covered the theoretical basis for that emphasis. He had frequently deplored the fact that too much reliance had been placed upon physical signs, and felt that we might have been better off if Laennec and Auenbrugger had not discovered percussion and auscultation, and if we had no *x*-rays. Of course, he had seen cases in which the opacities on the *x*-ray plate had been an aid in diagnosis, and physical diagnosis was useful. But at the present time he felt that the constitutional symptoms amounted to more than the physical signs, or *x*-ray plates. We knew the theoretical basis for symptoms and he would not enter into that phase of the subject. Dr. Bray had taken the same point of view. Dr. Fishberg said he was glad Dr. Miller had shown the limitations of artificial pneumothorax. Hardly three to five per cent. of tuberculous patients were suitable for pneumothorax and between 30 and 35 per cent. treated by this procedure were said to have recovered. Forlanini in his report did not say that 37 per cent. recovered but that 67 per cent. died. He did not say whether those patients were able to work, or not. At the present time they had 136 tuberculous patients at the Montefiore Home and 40 to 45 per cent. were able to do light work, though they had not received artificial pneumothorax. He had witnessed very dramatic effects from artificial pneumothorax and he had also seen very dramatic tragedies. He had seen patients with progressive lesions and a temperature of 103° or 104° F. drop to normal following artificial pneumothorax, and the patient would go along nicely for eight to twelve months and then there would be a perforation of the lung and a pyoneumothorax, and the patient would die in great agony. As to Dr. Jacobæus, he performed his operation on one patient at Bellevue Hospital and on one at Montefiore Hospital, with a 50 per cent. mortality. At Montefiore, the patient was a young man who had a pneumothorax and was doing well. Against Dr. Fishberg's better judgment he was submitted to the operation and died four days later. One should never judge of a procedure by a single case. Nevertheless he was discouraged in regard to Dr. Jacobæus' operation. He had looked up the literature and could not find that Dr. Jacobæus had reported a single fatal case, and he doubted whether this was his first fatality.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

AN INDEX OF TREATMENT. By Various Writers. Edited by ROBERT HUTCHISON and JOHN SHERREN, and Revised by WARREN COLEMAN. 1029 pages with illustrations. Price $12.00. Published by William Wood & Company, New York.

THE MEDICAL CLINICS OF NORTH AMERICA. Bi-Monthly. January issue. Vol. 5. 214 pages with illustrations. Published by W. B. Saunders & Company, Philadelphia, Pa.

TYPHUS, ETIOLOGY AND PATHOLOGY. By S. BURT WOLBACH, JOHN L. TODD and FRANCIS W. PALFREY. 222 pages with illustrations. Published for League of Red Cross Societies. Published by the Harvard University Press, Cambridge, Mass.

LE DIABÈTE SUCRÉ. By F. RATHERY. 294 pages without illustrations. Price 7 fr. Published by Ernest Flammarion, Paris.

BOOK ON THE PHYSICIAN HIMSELF. By D. S. CATHELL. 359 pages without illustrations. Published by the Author, Baltimore, Md.

PRACTICAL ORGANOTHERAPY. Third Edition. By HENRY R. HARROWER, M.D. 416 pages without illustrations. Published by The Harrower Laboratory, California.

THE PSYCHIC HEALTH OF JESUS. By DR. WALTER E. BUNDY. 299 pages without illustrations. Published by The Macmillan Co., New York.

XXVI. JAMES ATKINSON AND HIS MEDICAL BIBLIOGRAPHY A B.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

LET no man think he is buying a dull book if Dame Fortune smiles upon him and throws in his way that most remarkable of all medical bibliographies, that by James Atkinson, Medical Bibliography A B. He got no farther in the alphabet. In fact I do not think he ever had any intention of attempting more but made his string of authors and titles serve as frame for some of the most amusing comments ever made apropos of the dry as dust authors he so often considers. He says of himself and his writings "I am not the sort of fellow to undertake to write a sentimental journey; and, therefore, wanting better amusement, and through mere incident, I stumbled upon the dry, dusty, tedious, accursed, hateful, bibliography. It may, perchance, mollify duller than ordinary hours. It may kill time more circuitously, than in a direct manslaughtering way. And in a degree, which, if enforced, would kill the devil. But of profit, it is seldom productive. Should only one reader, even a destitute Unitarian, upon the occasion, honor my pages with his patience; this patience may inform him, and to his cost he would learn, how much or how little of this virtue may be required to effect the smallest impression upon a legitimate rock of literary granite: in distinction, to the task of his patience, in wading through the alluvium of my nonsense. And yet unless his instrument or perforator be smeared with a drop or two of the balsam of nonsense, he may labour through his days, and labour through his nights, but will never drill through the impenetrable medium of a dense and dolorous cloud of bibliography. He must at length be contented in concluding with me that bibliography is a doleful ditty. Or as Lambinet has it, "on ne peut se dissimuler que le plupart des ouvrages bibliographiques ne soient d'une secheresse soporifique (snort and echo) soporifique!"

A great fellow, a friend of Sterne, whose style he has unconsciously imitated. I imagine a thoroughly delightful man whom I have taken so to heart on short acquaintance that I shall find it hard work to return the volume which I should like to place next to my "Tristam Shandy" and my "Sentimental Journey." Perhaps some day Dame Fortune will smile upon me. Why this work has never been reprinted is a mystery to me. Dr. Osler said it was the most fascinating book on the subject ever written. I know of no book more amusing, excepting always "Tristam Shandy." If you like Sterne you will like Atkinson; if you do not like Sterne you will not like Atkinson. As I like Sterne immensely I would undertake the task of editing a new edition could an enterprising publisher be found. Trimmed of the bibliographic references and with some omissions the book would not be unwieldy and I believe its publishing would be fraught with little danger of financial loss.

Atkinson was the son of a physician of York. He himself for a score of years was York's most successful practitioner and from the title page of his book we learn that he was "Surgeon to H. R. H., the late Duke of York"; "Senior Surgeon to the York County Hospital and the York Dispensary;" and later Atkinson is mentioned in "Notes and Queries," 5th series X p. 474 and in Dibdin's "Bibliographical Tour."

Of his life we know little though if one were in York doubtless considerable biographical material could be discovered. He was respectable and respected and when he died in 1839 the York *Herald* gave him a good notice, a recommendation to St. Peter as it were, saying among other things: "Ever prominent with his aid at every benevolent institution, he possessed the blessing of the poor and afflicted whilst among them, and will live in their grateful remembrance beyond the grave." He was Vice President of the Yorkshire Philosophical Society. He was an enthusiastic member of the Musical Society and possessed a fine talent for drawing, no less than eight portraits by him hang in the National Portrait Gallery.

Atkinson has a curiously facile gift of expression and as one reads one finds old friends turn up again. The very first sentence in the preface was a favorite saying with Osler. Let me quote part of the preface:

> "There is not perhaps any man so good a judge of the difficulty of writing a book as an actual author. He soon discovers how many qualifications are necessary, how much science is required, and which are the points of most difficult access. He soon finds out his own deficiencies; and, as regards his powers, that some difficulties may be insurmountable. That essay, which sometimes originates in study and amusement, gets insensibly into growth, and is perpetuated. For, having been undertaken in the spirit of an inquirer, it is frequently carried on in the capacity of a student. This student, however, soon assumes the master, and pronounces his decisions on critical subjects, as authoritatively as if all learning and languages were at his fingers' ends."

The book of which I write and from which I shall quote extensively is a single volume, not too large to hold easily and can be read in two evenings, if perforce it must be done so rapidly. Such a method with such a book is much like drinking a bottle of liqueur Scotch at two sittings, rather too stimulating but one would do it were it to be taken away the third night, at least we unregenerate ones who scoff at Volstead would do it. The book has a motto, "Take me for better for worse, for richer for poorer," and is dedicated "To all idle medical students in Great Britain." Then follows the word "Sit" and a drawing of that part of the skeleton known as the sacrum. I puzzled over this somewhat but when I remembered what an inveterate punster our author was, light began to dawn. In his short article "Bigliographical References" included in the volume at hand he says:

> "For my part, although my sacrum and crista Ilei, are no harder, or become more cartilaginized by book-incubation and study than my neighbors, yet I have known the time when a very thin old black-lettered book has made my dull bones ache most confoundly; and after all, to very little purpose, and much less entertainment. And I should, out of mere curiosity, like much (in due, very due, time) to possess Mr. Dibdin's Osso Ischii, for my museum, as a vermin specimen of a literary incubator. By this sort of industry, how-

ever, we are taught to understand, that the duties of a critic, even to a competent sitter, are not so easily accomplished as 'le moyen de faire eclore'; or, by hatching fresh eggs in a graduated oven."

Is it not delightful? I should like to have a portrait of the fellow to see what manner of man he was. Of this subject of portraits he says in his conclusion:

"Having accomplished an imperfect, dry, and verbose Bibliography; it occurred to me, during the progress, that an illustration of Authors by their Portraits, as is frequently done, might be an useful and pleasing addition.

"In consequence, I have, for many years, collected Portraits of Medical Authors generally. And I have felt great satisfaction and instruction in confronting their works, their lives, and their faces. Casts of features, of thought, and expression, sometimes, though rarely, coincide. Whenever, however, it does happen, the coincidence and gratification are synonomous. Occasionally, also, as an amusement, I have sketched brief notices of the Medical and Literary History of those authors, after the example of other Biographers. So that when prosing over the heavy drag of some of those writers, and their editions, a mere glance at their portraits has occasionally awakened and delighted me: discovering, possibly, in their countenances traces of intellect which I did not see before, nor otherwise should have seen. Therefore I invite the student to follow me in this mode of interpretation; to collect and to arrange; to contemplate the man specifically in his mind; and that same man in his portrait.

"Whether I may be induced, in future, for the advantage of the young collector, to publish, after the manner of Granger, a partial catalogue of the different heads and portraits I possess; their respective eras; the number and variety of the same; and the names of the painters and engravers, as far as I know, may depend on circumstances. For I own that frequently I am out of love with everything I undertake. And am not unapt, by virtue of long living, to fall into that despondency and unchristian-like opinion; that the world is a naughty jade not worth serving!"

He starts off with Aristotle and then goes on alphabetically through the As and Bs. One of course does not go to Atkinson for scientific bibliography; others have done much more and much better in this line; one goes to him to be amused, for witty chit-chat about the authors and their works and other authors and their works far beyond A and B. In fact he gives a list of "A few respectable authors on theory and physiology, indiscriminately noticed." This comprises some hundred names, some well known, some familiar only to medical bibliomaniacs.

Atkinson must have been a collector of considerable ability even if his taste ran largely to several of the early printers. He pokes fun at the collectors who never read their books, a goodly crew even today.

"I am sorry to observe that in my Aldus' edition, of 1518, the book-worm has taken care not to indulge much, either in sleep or dreams. For he has made some very intrusive perforations. And I wonder, in what part of this book-worm's head, the most ingenious philosophers, the Craniologist, would affect to look for the organ of destructiveness. If all collectors of books were not more to blame than the book-worm, the worm would never have been there. Of all creatures, he is the most peaceable and retired. And nothing in life he detests so much, or is so fatal to him, as having a dust kicked up in an old library."

It is surprising how little comment such a writer as Atkinson admits of, I will not say needs. He needs none of course but I must not delay. How many have ever heard that the Eustachian tube was mentioned by Alcmaeon some five hundred years before Christ.

"If this author was the disciple of Pythagoras, in the 35th age of the world or about 497 years before Christ, as is reported; it well becomes me to beg pardon of his Manes, for not having already introduced him.

"He is mentioned as being the first Veterinary Surgeon, who wrote on the anatomy of animals. And was possibly a relation of the famous Milo, of Croton, who could bear a bull (I don't say bull and bear, 'ne quid nimis!') upon his shoulders. Milo might have been the apprentice of Alcmaeon; and now and then, pro re nata, in the way of his profession, have had occasion to carry a sick bull into the surgery to his master. Let us here observe, in a parenthesis, how surprisingly one trifling incident of history may clear up another, and the son of Alcmaeon shall never repine.'

"Goelicke makes a question, whether, in consequence of the observation of Alcmaeon, that goats breathed through a passage from the palate to the ears (and has not man, a more modest animal than the goat, the same?), the eustachian tube might have been known to him. Assuredly, if Alcmaeon knew that goats did breathe in that way, he knew there was a passage. And as he had not given it a name, Eustachius chose so to do—after himself, *i.e.* the Eustachian Tube.

"Was there not the via Appia, in Italy, and several other viae, named after their then respective masters or constructors? Nor was it a matter of course, that not any of these viae should have existed before there was a name affixed to them. But Plagiary does not at all appear to have formed any part of the character of Eustachius.

"Eustachius had a much broader passage for his fame than the iter a palato ad aures."

Averroes of Cordoba comes in for a small quotation which has been marked in the borrowed edition on my desk, doubtless by the owner whom I fail to name. I am afraid the censor might object if I translated it—but I forget they do not censor medical books and the flood of pornographic literature masquerading as sociology is remarkable. Last summer I sat next to a well known writer at one of those luncheons given weekly by certain clubs, suspiciously like uplift organizations, which now abound in this peaceful land. I started a story about alcohol and other things. "I beg your pardon," said my neighbor, "In these meetings we never mention alcohol or women, but," he added smilingly, "we can discuss sociology, go on with your story." Oh the delightful hypocrisy—most of them do not see it and the others grin. But to get back to the story, it is a good one:

"The edition of 1542, of the Colliget, may be more barbarous than some of its contents; for in 'De Sanitatis Functionibus,' of the former edition, this author appears equally good tempered, as credulous, which is a quality ill adapted, and seldom seen, in a parish officer of the present day. 'Porro Matrona quaedam a regione aedium nostrarum, habitabat, juravit nobis vel conceptis verbis, cum balneum intrasset, in quo improbi quidem homines antea dum lavarent, semen genitale profudissent, statim concepisse: quod etsi incredibile videretur, fecit nihilominus vitae ilius anteactae integra atque inculpata castimonia, ut fidem verbis suis adhiberem.'—Vide ed. 1537."

Of that patron saint of lovers of good brandy, the first distiller, or at any rate the first to publish the use of Aqua Vitae, Arnold of Villanova ought in these dry days be given his due. His biographers always fail. They go off on a tangent missing much that should receive favorable comment. I shall have to try some day to remedy all this. Atkinson no better than the rest in this direction, but much more amusing, makes some comments, à la Sterne.

"Arnoldus, de Villa Nova, was, what is usually stiled 'rather a comical fellow.' He could not be content with his proper profession, but must undertake to dogmatize (I do not mean to go a hunting) and to write on theology. But in 1317, he was called to account, and his works and errors were condemned by order of the brother preachers at Tarragona; he was hence obliged to quit Paris (who would not quit such a place?), and, being sent on an embassy, to Pope Clement the 5th, he was unluckily drowned at sea.

"The Pope ordered De Profundis's for him, (too shallow resources I doubt, considering the depth of water,) and much regretted the privation of a work which Arnoldus had always promised him. He inserted this into his Pontifical letter, of the 19th of May, 1312; endeavouring by this means to recover it, if in existence; but sorry I am to record, that neither was the Pope's Pontifical letter able to produce the work; nor, the De Profundis's to bring Nova de novo, to dry land; so both were lost.—No dry joke, at any rate, unless to his brotherhood.

"The poor author had been condemned by his brethren, (Cannibals), on nineteen different articles, and if they had it in their power,—say on the thirty-nine, one of which was, for foretelling that the world would be at an end in thirteen hundred and thirty-three. They were, therefore, thirteen hundred thirty-three times obliged to him, for allowing such rascals time to prepare themselves; and the remaining articles, (nine of which are in the Castilian language, and five in Latin, as seen in a MS in my edition), were all alike condemned by them; and of course without benefit of clergy; nay, even Pope Innocent the 2nd, (don't suppose he was only the second innocent Pope, for they are all innocent), in 1539, by no means thought Villa Nova's works so innocent, as to allow his clergy to read them;—but mark ye now, they stole a sly peep at them whenever they could, for he was a tasty Villa, in his descriptions which, ad Morbos Mulierum spectant; and Monks are mortal men. Nova, however, non obstante, was, pro Haeretico, to the black dog damnatus,—which, as an anathema, is a serious business.

"SOLILOQUY.

"It is to be feared, and must be owned no doubt, that in many opera, where Abbots and their Similes grace the pages, there exists, in their language, a degree of pruriency, (like an esprit du corps.) which should not be evinced, either in the titles of such books, by the Abbots, or in the subjects. In this work, among others, we have instances; for who should expect in so chaste a title as De ornatû Mulierum, (into the contents of which, the vanity of the sex might reasonably induce them to inquire,) to find a recipe from Villa Nova, 'ut desiderium et dulcedo augeatur,' which has nothing to do with eating or drinking, or dress; or encore un coup, (shocking) ad virgam erigendam.'"

Of Aepinus and his book on the similarity of electricity and magnetism Atkinson has little to say but he has a great deal to say when he starts off on the subject of electricity. When I read the following paragraph I immediately thought of Dr. George Crile:

"To draw into resemblance the affinity; I would compare the brain itself to the cylinder of an electrical machine. External objects I compare to the atmosphere, from whence animal fire is collected; in the same manner as the fire is from the atmosphere or the electric. The soul I compare to the rubber, which being set in motion, by the wheel of external objects, throws the fire or ideas it collects upon the brain. The brain discharges it upon the nerves, its conductors; and the muscles and other parts become electrified bodies."

And now we must take leave of this dear old York friend, I feel as if I knew him intimately. He closes the last article on his book by saying: "It will behoove me, in common, to apply a passage, extracted from the sixth Book of the Epistles of Saint Ambrose, 'For you shall rarely find a man who is not deceived by his own writings.'" At the very end of the volume is a page of conclusion which ends:

"But a man's book is to him either like a legitimate or natural child: for however heterogeneous the constituting materials may be, or have been, the parent usually clings to his offspring for better or for worse, from natural affection: and retains to the last a selfishness of respect for it, which nature also dictates and he adopts."

Medicine in the Far East.—Professor Tuffier, the distinguished surgeon, has recently returned to Paris after a journey through the Far East. He had been invited to participate in the opening ceremonies of the Peking Medical School and took advantage of the proximity to study the condition of medicine in Japan, along the Chinese coast, and of course in French Indo-China. Of the new Rockefeller Foundation Hospital at Peking he states that it is the finest he has ever seen. Without any tinge of bitterness he seems to regard all such undertakings as in a way hostile to French prestige in this sphere of influence. The French practitioners are of a high morale but too few in numbers in comparison with the medical men from other lands, who are constantly increasing their numbers and prestige. After an appreciative account of the new Rockefeller college and hospital he mentions some of the native and other foreign medical institutions in Peking. There is a French hospital of 200 beds in charge of the Sisters of Saint Vincent de Paul, near the Cathedral. It is free to all, without distinctions of race or creed. Two French medical men are on the staff. Three of the Sisters recently perished of typhus contracted professionally. Father Henri of Shanghai has founded a chain of medical schools under French auspices for the instruction of Chinese students. This medical missionary was responsible for the excellent medical institution known as the École de médecine de l'Aurore. At Canton there are only four French medical men, but these have founded and conduct an improvised hospital-school. In Hong Kong there is but one French medical man who is in charge of a very good hospital. In Indo-China, which is a French colony of 21,000,000 people, French medical prestige is naturally high. The medical college at Hanoi is the central institution for all medical activities. The number of French medical men in the colony is so small that each man may be said to be responsible for between 600,000 and 1,000,000 natives. Native practitioners are relatively few in number. At Saigon the medical center is reinforced by the local Pasteur Institute, in charge of Yersin and another able scientist, N. Bernard. These men are responsible for holding in check and preventing the great epidemic plagues. Tuffier cites the case of a colonial French medical official of Cambodia who, when his term of service expired, entered the Pasteur Institute from choice and did most valuable work. The great curse of the country was amebic dysentery until, thanks to the introduction of large quantities of emetine, the population, once decimated by the ameba, became disinfected with surprising promptness, this mass result suggesting the similar conquest of the hookworm in the southern United States.—*La Presse Médicale.*

REEDUCATIONAL TREATMENT OF CONFIRMED STAMMERERS.*

BY L. PIERCE CLARK, M.D.,

NEW YORK.

POSSIBLY no one can fully analyze and synthesize the complexities of normal speech. Even looked at anatomically the subject is shrouded in difficulties which arise from the uncertainty of so-called facts and the obscurity caused by a redundancy of theory. Often a clear diagram showing the anatomy and physiology of speech covers much deficiency of evidence. We may be spared enunciating here the little definite knowledge we have of the speech as a brain mechanism, as it is as yet too meagre in scope and too hesitant in final assertion. However, by recognizing our deficiencies we may forestall a displaced confidence. If we follow the more modern tendencies and recognize the faculty as having an immeasurably remote origin of self-expression in feeling and ideas in all living activities, and see how, step by step, the faculty has developed, we can grasp some idea of how difficult a comprehensive explanation must be. Speech is so much a gesture of the whole personality that it will defy analysis until we have a better understanding of character and personality. If we look at it purely as a sort of complex neuromuscular mechanism of the midbrain or even a highly trained cortico-bulbar reflex, we fail to grasp the complex association which this faculty has with all emotional expression. If we find normal speech beyond exact interpretation, we are still more confounded in the presence of its disorders.

Perhaps most children who stammer† do so as a result of inadequate early training in normal speech expression. If the defect is not deeply rooted it is soon corrected by simple processes of speech gymnastics, voice culture, and similar training too well known to warrant detailing. But not infrequently one encounters a peculiar type of individual in whom the stammering is by no means benign, and which defies all systems of mechanical correction. If even under the happiest circumstances the speech disorder is temporarily improved, the patient suffers a relapse sooner or later and becomes as bad as before speech training was undertaken. It is a wide and popular belief that in youths thus afflicted the stammering has not only cramped and distorted the personality but has actually ingrained traits of character which never would have been present but for the youth's early acquirement of his disorder. This is not so; but the innate faults of the personality become steadily worse and the more obvious as the stammering endures. That the stammering in itself can ingrain anything new not previously innate and a part of the personality, is as absurd as to believe that the neurotic constitution of the psychoneurotics is induced by their particular conflicts. It is possibly quite true, however, that the syndrome brings out latent personality defects, but it cannot be responsible for the innate foundations of these personality faults.

It would be beside our main subject to lay down here the main defects of personality from which the confirmed stammerer suffers. His heightened self-awareness, his timidity, his lack of social courage to develop his living relations as well as his innate inflexibility to make easy social adaptations, are all quite well known. In the majority of instances the forces which retard the development of the personality are quite unconscious or at least are imperfectly brought under the control of the will in any natural manner of social life. In some individuals the character builds the speech perversion into itself as a real part of it. Thus attempts to remove the speech defect may set up a series of defenses and resistances so that the sufferer never entirely loses his stammer or his defects of personality. In still others a slight stammer does duty as a sort of beauty spot in a character otherwise not colorful or charming.

The two points which I wish to make in this paper are (1) that in the more enduring types of stammering the essential fault lies deep in the character formation of which the stammering is but one of the symptoms, often the lesser; and (2) the manner of treating these types successfully includes painstaking, consistent analysis and synthesis of the personality as well as proper systems of speech gymnastics. This viewpoint is not new; almost all workers upon speech defects take the same position but fail to indicate more pre-

*Read at a meeting of the Section on Pediatrics of the New York Academy of Medicine, March 9, 1922.

†For the purposes of this paper I have used the term *stammering* solely. Some authors make no differentiation between this term and that of *stuttering*. According to the medical dictionaries consulted, *stuttering* is a spasmodic speech disorder in which certain words are enunciated with difficulty through inability, as it were, to pass the initial consonant; it is distinguished from the hesitating form of *stammering* which is not due to spasm, but to faulty innervation or to psychic causes. In my cases reported the patient has at different times both stammered and stuttered. My main concern, however, being to remove the psychic causes for the stammering—*i.e.*, hesitation in speech, repetition and mispronunciation by reason of embarrassment, agitation, unfamiliarity with the subject, etc., I have limited my designation of these speech defects to what has seemed to me the more euphonious term, that of *stammering*.

cisely the system of mental therapeutics for the personality as a whole by which we may overcome these essential or malignant types of stammering.* All agree that the *individual* must be treated, and not the stammering. Again, the awakening attitude that speech trainers have assumed shows a renewed sense of the value of handling this disorder along psychobiologic lines. To do this a psychiatric training is essential for the teacher's equipment. No mere training in academic psychology will be found to prepare one for this particular type of work. The confirmed stammerers have long remained in the hands of physicians who look upon them as suffering from a single faculty disorder and have therefore sent them to teachers for speech training only. The disappointment such individuals have experienced in consequence has caused them most frequently to look upon their stammering as incurable, and they have adjusted their lives accordingly. On the other hand it is a mistake to consider these confirmed stammerers as individuals suffering from a peculiar neurosis which may be cured by psychoanalysis as a hysteric or anxiety neurotic may be. It is really as profound a disorder as a compulsive neurosis, or even a convulsive tic to the makeup of which it is not essentially dissimilar. When an analysis of the morbid trend in the developing character has been made as thoroughly as possible, a whole system of synthetic reëducation is necessary. This method will be more thoroughly detailed after the case histories are presented.

To sum up, it would seem that confirmed stammering should be ranked as a syndrome of the effective life of self-expression. When we fully realize that the consideration of this speech disorder purely as such is but mere surface plowing, and that a mechanistic treatment of the fault solely is bound to prove a failure unless a good understanding therapy of the underlying defect present in each case is made, only then have we made a real advance in handling these speech disorders. As careful practising physicians we should not turn these cases over for diagnosis and treatment to laymen. One cannot believe this attitude will long prevail when modern systems of mental analysis and therapy are better known and understood. I do not refer to the relatively benign errors of speech seen in many young people wherein simple lines of training easily correct the speech fault, but in those confirmed stammerers who go on year after year, and in whom the defect cripples and distorts the whole life of its unhappy victim. Nothing less than a thorough neuropsychiatric training treatment will permanently relieve it. When we shall reach this position, the failures and relapses in stammerers will be much less a mockery to our science.

I shall cite briefly three cases of confirmed stammering and give *in extenso* that part of the history which has a bearing upon the contention of our thesis. The types of stammering presented are based upon as definite a constitutional defect as the severest forms of neuroses, or tics. Fortunately, primary instinctive defects are usually easier of socialization than many another form of defect.

*See E. W. Scripture, Stuttering and Lisping, Macmillan, 1912. M. G. and S. Blanton, Speech Training for Children; the Hygiene of Speech, Century Co., 1919. S. Blanton, The Medical Significance of the Disorders of Speech, *Journal A. M. A.*, July 30, 1921.

Case I.—A young aviator, twenty-nine years of age, who was killed in the World War, came under my observation when twenty-one years of age during an indifferent undergraduate college record. His social activities, although unpleasant and at times painful, were not to his personal discredit. In a year's treatment he recovered sufficiently to mend his undergraduate standing and enter on a successful career as a special student in another university, which in turn was cut short by his entering the Aviation Corps. His childhood history was as follows:

He was born of sound stock. His father was of a stern nature, who maintained a certain aloofness from his large family of children. They never "got acquainted" with him. He invariably treated them with an austere kindness and rarely disciplined them by physical punishment. He remained a distant arbiter of authority. The mother showed but little outward warmth of sympathy, although the sons believed she felt it, but failed to express it except in times of serious illness or family disaster. No disorder of speech existed in any of the ascendants. Our patient was the oldest in a family of five—four boys and a girl. His childhood was uneventful as to physical disease. He was a shy, timid child, in awe of his father, and half afraid of his mother. He learned slowly in nursery training largely because in this large well-to-do and extremely religious family the children were left to nursemaids and governesses, who often frightened and punished them. He was taught his letters in spelling and reading, and not by phonetic methods. He was very slow in learning the fundamentals of education except in mathematics. By dint of hard work his school standing was fair. His hold upon concrete facts was poor, hence his memory was not retentive. The teachers' uninviting manner of presenting subjects seemed to increase his poor attention. He even observed poorly. He was quick and impulsive in judgments and not very certain in purpose and foresight. He was a restless, active child, intent upon being active, but rather clumsy and awkward in co-ordination. He had a lively imagination and read a great deal. He was inclined to be talkative, but had a keen self-depreciatory attitude; he had no genius for making friends and got on slowly in boy acquaintanceships, although as a very young child he possessed a mild desire for companionships of all sorts. His shyness and timidity caused him to be alone a good deal. His feelings were sensitive and rather easily hurt. He could not be induced to meet adult strangers, especially men. He was fond of animals, was generous, tactful in boy associations, and could co-operate well once he became acquainted. He was not stubborn or difficult to discipline. His sensitiveness naturally inclined him to see a slight when none was intended, but he held no grudges and was not resentful. He was frank with both parents, but always felt as though he were going through an ordeal in being so. Even as a very young child he was indecisive, was blocked by scruples and doubts, and was inclined to be led. He was a highly fantastic dreamer as a young child before his stammering neurosis appeared at six years. Although naturally enthusiastic he easily became overserious and not too brave in "facing the facts of life." He was not easily frightened by the dark, but had many forebodings regarding his ability to carry out tasks alone. He gave up easily. His temper was slow, but once aroused he was quite implacable.

In brief, we have here a boy obviously of the hypersensitive type, who got on fairly well with self-expression until six years of age, when without obvious cause he began to stammer. The stammering steadily increased year by year until he was almost speechless at nineteen. He could not recite in his classes and limited his activities to such a degree that life itself became a burden. Much of his stammering anamnesis is epitomized as follows:

As a child from his fifth to tenth year he was under the instruction of a French governess at home, and afterward had a tutor. During this time he exhibited a moderate degree of stammering. He had a certain agitated, shy attitude toward other boys and toward adult strangers. At ten he entered a boys' school and

there met with a great many difficulties, particularly in regard to reciting in the classroom and his association with other boys. He entered the school two years in arrears of boys of his age, and it was several months before he got acquainted with either the manner of study and recitation or the boy group in play and drill. He succeeded in accommodating himself to the new situation at the end of the first year and by tutoring. In the fall he succeeded in making up one of the years he was behind. The second year he caught up with his grade and was in very fair social relations with all the boys in his class group of about twenty.

He then went West for a year, and this was largely a year lost from the school work aside from a short time spent with a tutor. He then returned East and entered a preparatory school for a four years' course. There his difficulties of getting acquainted with boys and with the manner of school work were reemphasized, but were not so great as on his entrance to the first boy school at the age of ten. He disliked all the social features of meeting girls, dancing, etc., and avoided them as much as possible, as he had nothing to say and felt very awkward. He made fairly good contact with the other boys and made some very good friends, but always with a small group. The same difficulty of adaptation was again apparent when he finally entered college at seventeen. Coupled with this situation he began to have very decided doubts in regard to the religious faith of his parents and began to shed all religious authority. He was not frank in this respect, for he did not tell his parents of the disestablishment of his religious faith. He continued to attend religious service, but ceased to believe in any phase of religious practice and became decidedly agnostic. His dreams were largely of the unfulfilled type. He always had grave doubts about his being able to pass in his examinations, felt confusion and an increased nervous tension in classwork. His first release from nervousness was with natural associations with boy students, and then the recitations became easier. Coupled with the state of negation in regard to religion was an uncertain attitude as to his future in the world. His physical health was excellent.

For several months he was given uninterrupted psychoanalysis, which, because of the nature and extent of his speech defect, was immeasurably slow. The analysis disclosed the enormous overconditioning of the father authority. Fully a half of his normal speech was released in the analysis. Thereafter he was placed for several months in a sympathetic general physical and mental training. Speech gymnastics also were employed. At the end of a year he was completely cured and so remained. Speech training by mechanical principles alone by three competent masters had previously been a failure.

Case II.—This patient, a young man of twenty, had been a stammerer since his sixth year. The alleged cause of the speech defect was stated to be a great fright resulting from a fall. The degree of exaggeration of his innate self-consciousness is shown when he is asked a question; he cannot answer; and if he himself wants to tell you something he cannot speak at all, for he is muscle—as well as mind—bound. Mental confusion is experienced. But when he is not consciously concerned in the outcome of the conversation, no difficulty whatever is encountered in speaking. When absent minded he also speaks normally. When keenly engaged in sports, in which he excels, he speaks fluently.

This patient is the second and older child in a family of two living members. He had an excellent school record in spite of his speech defect. His standing in all his sports was excellent. He was a very intelligent, resourceful child and did well in any line of work he undertook. The family atmosphere here, again, was a peculiar one. The father maintained a military aloofness in discipline. He had "few words, and those were to the point." The mother, although an intensive "worrier," had little to say. The whole environment was one of a quiet and suppressed warmth. The son stood greatly in awe of his father, with whom he was never on terms of good comradery. He was brought up under military discipline which followed an educational training in a military school and a college of the same type. The boy naturally grew up constrained and unnatural. Before he experienced his fright following an accidental fall which, though the latter was of great moment, preceded his speech disorder by a year and a half, his attitude was of an intense self-centered and opinionated one.

The actual training record of this patient at the outset showed not only a lack of ability, but also unwillingness to join with the group life at the training school. He avoided placing himself in any socially prominent position in the group. He showed no real desire to be useful in any way that promoted sociability. His timidity and shyness were so extreme that he even blushed when spoken to. As at first he was quite speechless, the immediate training was to give him oral gymnastics; he could not open his mouth fully or protrude his tongue without muscular spasm and pain. This and vowel elongation in speech finally allowed fair speech, whereupon the psychophysical training was begun. Even here progress was slow, as the pupil could not be made to understand the importance of even superficial social interest. Inasmuch as he was greatly interested in all forms of athletics, bowling was undertaken to show the advantage and pleasure of team play, physical as well as social. He soon lost his rigid, unconcerned manner as he became engrossed in the games. He lost his self-consciousness and spoke without difficulty; he gradually shed his constrained, retiring personality and became for the time quite a different fellow. So long as the group spirit endured he possessed normal speech. This was then used as an object lesson to point the former teaching moral which had previously fallen upon such indifferent soil. Primarily we found that his family training of cool indifference to social reciprocity hindered our work. Time and again the game and group spirit, with the free natural manner and speech that accompanied it, was placed before him and yet he would relapse. Mental analysis of his conscious history brought out again and again his boyish indifference to any real social feeling and how his military training further fostered his shy, timid and at last stubborn indifference to playing a sincere social part. His stoical indifference and narcisism slowly underwent a transformation, although he often boasted of the great personal advantage an indifferent and callous social spirit brought its possessor. A real conflict ensued and retarded this boy in making good progress. His training was interrupted after a few months, but we have learned since that he has made consistent progress and rather boasts of living more vitally into his social environment. He rarely remains by himself as formerly, rarely confines himself to writing out what he wishes to say, and uses the telephone. He has joined a social and athletic club. A final good augury is given in that he now rather despises his former boast of having a narrow view of the advantages of social life.

Case III.—This patient was a young man of eighteen, who has had his stammering since eight years of age. The onset was gradual, rather than sudden, as in the preceding cases. The family stock from which he recruited his stammering was not free from a history of such defect. A paternal cousin and an uncle had a moderate degree of enduring disablement of the same disorder. The family situation fitted well the boy's diffident and timid nature. The father was keen on discipline and little infringements were so scrupulously noted and corrected that no large ones were encountered. The family being socially prominent and well to do much of the child training was placed in the hands of governnesses and tutors, who were "expected to get results" in the form of obedience, attention being given to the fact that "children should be seen and not heard," and the like parental authority saws. The child life and activity was almost the exact counterpart of Case I. The boy showed a shrinking timidity when three years old, and while not actually unhappy seemed never to have had a real good time. At first impression the meagerness of his emotional life with the great opportunities he has subsequently had for rich expression of it is almost astounding. But it becomes the more understandable when one recognizes that his very timidity and shyness has permitted him to merely participate as a spectator at the rich current of life which has eddied about him and his family. He was not even emulous, much less jealous or envious

of his fellows at school. His "boy times" were never talked over with anyone at home. As might be expected his educational work was rather indifferently poor, but this worried him little. The gradual growth of his stammering so handicapped and distorted his preparatory school work that he gained little good scholarship. He was therefore removed for speech reeducation. Here it was found as in the other cases that the personality faults were fundamental and instinctive and had the same essential lack of harmony and free expression as that of the speech itself. After six months of training he is able to speak over the telephone naturally, and can meet strangers with free self-expression in both manner and speech. He can get on conversationally with a group of three or four fairly well. He is developing a feeling of confidence and initiative and has a small business of his own started entirely on his own effort. The feeling of inferiority is steadily diminishing.

In this boy we recognized at once that we had to do with a gentler, more cultured nature than in the preceding case. But here again we faced an unconcern which, though not stubborn or callous, yet showed no great evidence of a real whole-hearted interest. However, he was willing to comply with social demands when his training warranted that he make the trial. This he did even though he stammered fearfully in the attempt. Later he got to taking on the social tryouts because of a real interest in the game. After speech gymnastics had unfettered the cruder exhibitions of speech cramp and he began to make his daily activities of vital purpose he got on more rapidly. His articulatory defect was that of the so-called initial consonant defect type. Although speech cramp in set lessons was removed, he would still retain his shy, timid, constrained personality in social activity. We then began to make the speech lessons more like social settings, first bringing in one or two other companions in the lesson work and then finally making the patient himself the master teacher. Mental analysis produced little desirable results chiefly because the disorder had little other than an infantile timidity and feeling of inferiority toward elders (of the father type). However, the conscious analysis continued to disclose the meagerness of childish experience in little social excursions among his playmates. Finally he gained sufficient mastery of his social group to direct the game activity, run his own car and take his companions about the country with a variety of social experiences. At last he got to understand the real importance of self-control of his own social and economic interests. Under business experiences there lay concrete illustrations of the importance of a change in his former shy, timid, infantile personality. This, perhaps, was the most convincing experience of all. It showed that, as in the former pupils, as soon as he himself could be made to fully realize the importance of changing or shedding his infantile fixation of habit and manner the stammering disappeared and full power of self-expression in a normal manner began to take its place.

As a general comment on these three cases we may say that the statement of a need of a change of personality, or, better, a development of the existing personality, is of little effect until the concrete means and a demonstration of its more enjoyable benefits are adequately placed before the pupil. Only then do we see them improve. First find the basic interest, then employ or mold it into a trial social group and we are then on the way to a lasting betterment in these cases. The first was in the possible social usefulness of a medical career, the second in athletic and engineering interests, while the third was in that of a business training and a possible financial career.

Discussion.—I think it is shown in these few citations that there is a basic character fault preceding the stammering. In the main it is summated in a shyness and timidity toward all forms of self-expression. The supersensitive nature marks the infantility of these youths; it is perhaps the least objectionable form of egotism and only negatively social. The feeling of inferiority soon engendered in the stammerer is accentuated by the active or passive resistance which he exercises toward the great nucleus of authority, the father. Perhaps one may recover in every case a specific instance in which the one in authority in the home has repeatedly repressed the self-expression of these constitutional stammerers. This would not be of such signal moment if these children, because of their inheritance and makeup, did not so illy bear such repression. The removal of the maladaptive wrappings of habit and manner which the stammerer's personality possesses is the real purpose in analysis and treatment. Viewed in this light of origin there can be little wonder that the confirmed stammerer has produced such a distorted personality which he must first be taught to shed and then to make the proper social and self-expression consonant with his innate desires and station in life. He has to unlearn and relearn anew. The amount of sympathetic tact and inculcation of habits of broadly constructive effort which the trainer must exercise can hardly be overestimated. Nearly all confirmed stammerers are chiefly intent upon ridding themselves of their speech handicap solely. When they comprehend that only by consistently modifying the whole personality, especially that which underlies full free self-expression, they usually shrink from the task. Bald preaching is not only time consuming but most sterile of results. The habit training should perhaps begin or at least be consonant with the first efforts to overcome articulatory defects. As has been shown, this habit reëducation can be illustrated by concrete living examples of free and easy speech in newspaper and storied accounts and finally by creating situations requiring spontaneous natural effort at self-expression. At first we can create changing situations and then introduce a judicious admixture of varied personnel in the conversational group. But one—either the situation or the personnel—should at first be changed; later both may simultaneonsly be modified, thus increasing the agility of both adjustments. The manner and substance of the first lessons in training must of course be suited to the individual pupil. Oftentimes the discouragement of previous failures in training has calloused a flagging interest of ever getting back normal speech. This discouragement is only exceeded by the ease with which the pupil may go stale soon after a plan of treatment has been inaugurated. The work has then to be discontinued for a time, or better, change of scene and personnel may be required. In many pupils the degree of repression has been so marked that many of the mental attributes, such as attention and memory, have suffered dwarfing. The earlier mental training must then be reviewed to intensify the concepts of reality and enlarge the association memory of things, for largely upon these two factors a keen and resourceful mind depends—this and the comparative and competitive interchange of ideas with one's fellows lies at the very basis of developing intelligence in any large sense. The neglect of this review work often renders the mental life of the confirmed stammerer lacking. One should always be on the outlook for the pupil being easily persuaded that when he has gotten about so far in the riddance of his disorder and its person-

ality congeners he may quit or that he may seize upon any convenient excuse to stop training for a complete cure. This is said in no meticulous or carping sense, but the half-cured stammerer is a potential confirmed stammerer whenever some great social stress is reinvoked. Even those heretofore using articulatory methods of training solely, realize how common is this experience. Perhaps relapses of incompletely cured cases by the comprehensive neuropsychiatric method detailed here are much less common than those following more mechanical methods of training, but they are sufficiently numerous to warrant to the full this injunction. Usually the very affectless attitude the confirmed stammerer shows in the analysis proves that there is essentially a weakness in the will as well as in the emotional trends of the libido. This alone proves that the confirmed stammerer is not a neurotic in the ordinary sense of the word but that the early defect in speech expression is a part of an inherent weakness and that all analysis must finally end in psychic *reëducation* covering months or even years. The warm, friendly attitude toward the trainer which is necessary on the part of the patient is usually little in evidence, and to make it more operative for reëducation it must be continually heightened by a rather intense sympathetic interest in the stammerer's earlier conflicts. An intensive transference is absolutely essential for the synthetic reconstruction. Thus many a stammering youth has been "brought out" of his stammering diffidence of speech and manner by some resourceful, sympathetic woman, only to relapse when her influence is removed. If a proper analysis of the personality faults has first been made in such, this wise and subtle feminine influence may be of the greatest value in the reconstruction. The analysis should not greatly precede the synthesis, the two should rather go hand in hand, the analysis after a time being used only to get at the deeper roots of some morbid trend of manner or speech. The speech disorder of the confirmed stammerer is quite different in makeup from the fanciful speech defect of the neurotic and especially the hysteric. The seeming neurotic element in the confirmed stammerer is confined solely to his substitutive reactions in seeking expression, and not to the fundamental defect of speech itself.

In conclusion, it would seem that we have proven that the inherent defect of the confirmed stammerer is due to an arrest of the whole instinct of self-expression; that this personality defect is often summated or most marked in a later development of a disorder of speech. This being the case, the removal of the latter as well as its cognate personality defects is best brought about by intensive and thoroughgoing special speech gymnastics but more particularly by analysis and reëducation of the personality defect as a whole.

Acknowledgment is hereby given Mr. T. E. Uniker and Miss A. G. Brill for their assistance in training several of my cases suffering from speech defect.

Chilblains Readily Cured by the X-Ray.—Lenk states that in the majority of cases chilblains are cured by a single treatment with the roentgen ray.—*Wiener klinische Wochenschrift.*

NEURASTHENIA: ITS TREATMENT BY MASSAGE AND KINESITHERAPY.

By DOUGLAS GRAHAM, M.D.,

BOSTON, MASS.

CONSULTANT AND INSTRUCTOR IN MASSAGE.

"I fear too much rubbing; good-night, my good owl."
—*Love's Labor Lost.*

Leonato: Indeed, he looks younger than he did by the loss of a beard.

Don Pedro: Nay, he rubs himself with civet.
—*Much Ado About Nothing*

Neurasthenia, as I understand it, may be either general or local, affecting the nerves or nerve cells of all or any part of the cerebrospinal or sympathetic system. Its manifestations are those of exhaustion or too easy exhaustibility of nerve force; and its pathology, malnutrition of the nerve cells involved, with concomitant instability of their circulation in the form of anemia or hyperemia, or alternations of these. It predisposes to, it accompanies, it results from disease; the nervous shock and the tedious recovery from injuries point to other sources, and it may be caused by overwork, worry, or sheer laziness. The agreeable fatigue after a satisfactory day's work that insures sound sleep may be regarded as a healthy form of neurasthenia, if the Hibernianism may be pardoned.

It is a matter of common observation that those who are compelled to hard manual labor seldom suffer from nervous prostration; and among the more fortunate who may be predisposed to neurasthenia those who are deeply interested in some hobby or occupation that keeps mind and body active have found the best means of prophylaxis. The same means that serves for its prevention also supplies us with a clew to one of the most valuable agents that can be employed for its relief or recovery. Exercise keeps the circulation active, but requires effort of brain, spinal cord, and nerves, as well as muscles, at a time when our object may be to afford rest to one or all of these parts of an overtaxed nervous system. Massage supplies this want, and will keep the circulation going with a minimum or no expenditure of nerve force from the patient; and deep massage without friction will lessen the beats of the heart and afford it rest also. Yea, more, for it is getting to be the fashion not only among the laity, but also with some physicians, to say that massage imparts energy to the patient, though I confess I do not exactly understand what this means. Certainly, many who submit to massage feel much more vigorous, light, and supple after even the first application than they did before it. But may not this be rather owing to the rousing of their latent energies, and restoring the equilibrium of their forces, by facilitating the circulation of blood, the flow of lymph, and the transmission of nerve force?

I have previously stated elsewhere that in cerebral exhaustion the relative value of massage was almost *nil, and* that out-of-door exercise was of paramount importance; but I have since found reason to modify this in favor of more massage and less exercise. In such cases massage of the head alone daily or every other day is better than applying it all over the patient, unless there be a rare idiosyncrasy that will not allow the head to be manipulated.

There are people, not a few, who, when using their brains, suffer from uneasy sensations in their lumbar or dorsal region, and these discomforts continue after the cessation of study, causing wakefulness. Generally there is also some spinal irritation in the region affected. In such cases massage of the back alone will often induce sound sleep, and next day the patient feels inspired with faith, hope, and courage, in place of doubt, and fear of meeting appointments. With these cases a much more marked effect is produced by local than by general massage, except when the tenderness of the muscles and spinal irritation are extreme, unfitting them for every kind of work, and then the massage should be general, omitting the back at the first séances, but gradually approaching it at subsequent ones.

In other cases of what may be called local neurasthenia, if the term can be allowed for this purpose, such as writer's cramp, or the cold, small, and feeble muscles resulting from injury, disease, or disuse, massage and exercise, carefuly adapted, have given excellent results. To these have recently been added another affection, namely, laryngeal cramp of musicians and speakers, for the local treatment of which electricity and massage are considered the most effectual measures.

It will doubtless be a revelation to many to experience either in their own heads or to observe in those of their patients the light, comfortable, delightful feelings that are produced by the resistance of a skilled manipulator to forward, backward, and lateral movements of the head. The impression is that the interior of the head has been benefited, and the effect is hardly secondary to massage, which rather gives the impression that the exterior has been improved.*

It is not so very many years ago that the existence of such a disorder as neurasthenia was doubted and even denied by distinguished neurologists, some of whom have since found out by personal experience that it is a dread reality, no longer to be made fun of. And now nearly all of them are ransacking the misbehavior of every organ of the body, from the eyes to the anus, for some cause, proximate or remote, of this disturbance of the nervous system. I have seen quite a few of these unfortunates, and it has been gradually impressed upon me that those of traumatic origin do much better under treatment than those that are not—the so-called idiopathic, essential, or constitutional cases; and it has also been strongly impressed upon me that when it comes in those past middle life its duration is very much shorter than when it occurs in young adults. On reflection this is what we might expect, for the nerve cells of the young are much more impressible than those of the old. I have seen several cases of severe shock from injury to the aged completely recovered from in an astonishingly short space of time. I have seen the whole gamut of neurasthenia gone through with in elderly people and recovery take place in a few weeks under massage. Some people are decidedly neurasthenic in cold northern climates, who are not at all so in warm, southern latitudes. Six weeks of general massage every other day will rouse the circulation and depressed energy of such so that they can resist the cold rigorous climate of the North and go through the winter with comfort.

A stranger traveling in southern Illinois will often be surprised and delighted, on asking a native who is recovering from malaria how he feels, to hear the answer, "Oh, powerful weak! powerful weak!" That is how neurasthenics feel.

Neurasthenia, the background to the picture of nearly all diseases and injuries, whether of an organic or functional nature, for our present purpose may be regarded from other points of view. First, there is the natural and not unpleasant fatigue, the result of an active and satisfactory day's work, from which we recover by food and sleep.

Then comes the fatigue from which we do not recuperate as usual, the fatigue of being overworked, worried, or, in common parlance, "played out." Here rest or change of scene is of the first importance, and may be all that is necessary; but if this be impracticable or without effect, tonics and sedatives may suffice. Before rest, change, or medication had been resorted to, it has been my lot to have tried massage in several cases of this class, where it has "lifted them up out of the rut" and been the means of procuring good sleep with vigor of mind and body, so that they were able to proceed with their duties uninterruptedly and as easily as ever.

Thirdly, there are the continually wearied, wakeful, and nervous business or professional men with numerous and varying ailments, who have learned by experience that "the labor they delight in physics pain," and who find more relief in work than in rest. Massage will sometimes put such on a higher plane of existence and give them a zest for work which they have not derived from any other source. But, unfortunately, the interest they gain on their stock of vitality in this way is apt to be used up as fast as it accumulates.

Fourthly, there are the neurasthenics who are simply spoiled children, who have plenty to live on without work, and usually more, who have little or no object in life, and who can do what they please and cannot do what they don't please, who take delight in telling of all the eminent medical authorities whose care they have been under without any benefit resulting, and who are never happier than when they can be regarded as interesting by trying some method of treatment that is novel to them in order that they may have the final satisfaction of saying that it did them no good. I well remember one such who defiantly said she would like to see any physician who could benefit her. Serious disease came upon her. She could not or would not understand the nature of it, and allow herself to be treated as other people, and she prematurely lost her life. There is no help for such but to lose their fortune and be obliged to work. However, they form a large part of a clientèle of massage.

Fifthly, there are those who, in spite of rest, change, and medication, have become chronic neurasthenics, the result of business reverses, overwork, worry, loss of relatives, disappointed hopes, or as a sequel of some affection that has existed in some part of the system, but which has disappeared

*A distinguished lawyer of my acquaintance always had his head masséed before he went into court, and he always won his case.

or become of secondary importance. If in these the symptoms point most prominently to spinal exhaustion—myelasthenia—where exercise easily tires and aggravates, massage will be of marked benefit as a tonic and sedative and corrective of morbid sensations; of less advantage, but not useless, in cases where the symptoms point about equally to easy exhaustion of spinal cord and brain. I used to think that, in cases of cerebral exhaustion —cerebrasthenia, as some call it—where as a rule physical exercise can be freely taken, this would be of greater benefit than massage, and that the value of the latter here was almost nil, and might be dispensed with, unless it were for a luxurious *placebo* to fill up time and keep the patient from trying something worse; but time and experience have changed my opinion.

The links in the chain of symptoms that point out neurasthenia or nervous exhaustion, so that they could be clearly understood as indicating deficiency of quantity or impairment in quality of nerve-force, were best connected by the late Dr. George M. Beard of New York City. His statements will hardly be appreciated until they are independently thought out from observation and one's own conclusions compared with his. Take, for example, the following paragraph, the import of which I have known to be overlooked by three of the most eminent neurologists on this continent, to whom Dr. Beard was a next-door neighbor: "In cerebral exhaustion, active muscular exercise in reasonable amount and variety may be allowed and enjoined; in spinal exhaustion, relative and in some cases absolute rest is demanded, or only passive exercise for a shorter or longer time, as may be, according to the special peculiarities of the individual."

It does not help matters much to coin a Greek or Latin name for every symptom connected with neurasthenia; and with all the care in naming and accounting for symptoms that Dr. Beard has shown, there are, I think, two which have not yet been mentioned, and which are, like the others, only exaggerations or perversions of natural occurrences. First, there is what almost everyone has experienced, namely, an inadequate conception of passing time. Even with the same person at different times and under the same or different circumstances time may drag along slowly and heavily; at others it will seem to pass so quickly that it is impossible to accomplish anything, even if working in the greatest hurry. Haste is generally a sign of weakness. Secondly, the cause of wakefulness in some cases of neurasthenia is doubtless due to a languid condition or want of nerve-force in the respiratory center, so that lessened respiratory movements have to be supplemented by voluntary ones which require the patient to wake, the *besoin de respirer* becoming so urgent that respiration cannot longer go on involuntarily.* Even in health excessive fatigue may prevent sleep. The cardio-inhibitory and the vasomotor center in the neighborhood of the respiratory center may be affected by sympathy with the latter, or they may suffer from impaired nutrition, deficient nervous energy, or irregular blood-supply, as may other nerve centers. But to return, for the relief of incorrect appreciation of time and frequent repetitions of waking up at night, as well as for the majority of other symptoms of neurasthenia, massage has proved an efficient agent in my hands. The feeling of loneliness and depression that is so apt to come in the night-time when people are run down or in ill-health is usually dispelled very promptly by means of massage. In this and other respects its action is similar to the primary and agreeable effects of opium and alcohol in restoring tone to the respiratory center and vascular system without, however, the injurious after-effects of these internal remedies. In place of headache, drowsiness, and disordered digestion, which are so apt to result from the use of hypnotics and stimulants, after sleep from massage the patient is refreshed and buoyant in mind and body. Massage does more than this: it will often counteract the disagreeable feelings that result from the necessity of taking sleep-producing medicines or too free indulgence in alcoholic stimuli. In several instances I have noticed that patients were more susceptible to the agreeable influence of massage while they were taking morphia—the opposite of what might be expected. I know of at least one physician who considers Mr. Bombast, who pretends to have rubbed all the royal highnesses in Europe, a good man to finish off a fellow who has been on the spree by a rubbing.

There are some people who are born neurasthenic, go through life neurasthenic, and die neurasthenic. Some of these never know that they are lacking in nerve-force, while a few of them do find out, from an occasional day of good feelings or lucid intervals, if one may say so, that their customary vigor is far below what it ought to be. If this class could have massage for a long period or all their lives, they would get a great deal more out of what makes life worth living. There are those who seldom feel any lack of energy so long as they are occupied, but who have a hard struggle to rest and go to sleep; and these are benefited by massage. Massage is often the only remedy for numerous and indescribable unpleasant feelings, and the subjects of these who have experienced the relief it affords crave its application as they do food and drink when hungry and thirsty. But most physicians know how fickle neurasthenic patients are; for, even while improving, they will often suddenly give up treatment, for no apparent reason except it be that they are afraid of getting well.

In these and other cases where massage seems to be indicated, it may be given daily or every other day, locally or generally. If there be no apparent effect from this treatment at or soon after its application, it is well to repeat it daily until the latent energies of the patient seem to be rousing, as shown by increase of comfort, vigor, and sleep. Then the intervals between the massages may be lengthened, but not to the extent that the effects of the preceding manipulation may have entirely passed away before another is administered. In some patients

*This sentence was published by me in 1884. In 1897 Dr. S. Weir Mitchell wrote: "When for some reason the respiratory centers are diseased or disordered, a man may possess enough ganglionic energy to carry on breathing well while the waking will can still supplement the automatic activity of the lower centers. But in sleep, these being not quite competent and volition off guard, there ensues a gradual failure of respiration and the man awakes with a sense of impending suffocation."—Clinical Lesson on Nervous Diseases.

reaction is slow, and they feel better the day following that on which they have the massage than they do the remainder of the day on which it is given. In such cases every other day is sufficiently often to manipulate. Massage of the back alone will often relieve fulness of the head and headache, and this repeated may be all that is necessary. Massage of the back and head will more frequently be used, but general massage is the best for the majority. I have more than once defeated the object in view by overdoing massage on starting, when, as the sequel showed, fifteen minutes would have been all that the patient could take with advantage. I have sometimes overdone the matter at the patient's own request for a longer application, though I had warned him beforehand; and, following the advice of an eminent physician, I have sometimes used massage too freely. The argument too often used, that massage can do no harm if it does no good, is a dangerous one. When a man understands one branch of the medical profession well, one of the commonest errors is to suppose that he understands all the rest equally well, as if our knowledge of massage, like everything else, did not come through experience.

The time of day at which massage should be given is in some cases of importance. If a patient be not very weak, as a general rule, I prefer the time of day at which he feels the worst, or just before this, so as, if possible, to tide him over this period, which can sometimes be done. When a patient does not sleep well, the later in the day massage can be done the better. When a patient of a nervous temperament sleeps well, massage should not be administered in the evening, as it is very sure to make him wakeful, and this applies to such as are well in their nervous system, but may require only local massage for a joint or muscular affection. These are so refreshed after the massage that they do not feel the need of sleep. The antitoxins of fatigue work better when the patient is awake and resting than when asleep. Patients may be benefited by massage when they are too weak to travel. It requires a certain quantity of nerve-force to sustain life at its lowest ebb; more than this, to receive massage with benefit; still more, to be able to travel; and more than all, to exercise freely.

Endocrinology and other ologies are still being invoked to explain the causation of neurasthenia, forgetting the excellent theories of their predecessors. Thus George M. Beard many years ago thought that it probably consisted of malnutrition of nerve-centers followed by disturbances in their circulation from weakened innervation. These secondary disturbances consist of local anemias and of local hyperemias. In other words, in that equilibrium of wear and repair which means health, a disturbance occurs which means disease. There will be sudden ebbs and flows of impoverished blood in the various vital organs—the same kind of surface flushings and blanchings going on in the deeper structures. Thus we may see in the same person, and starting from one cause, alternations of anemia and hyperemia of brain, stomach, or spine. The cerebral exhaustion or irritation manifests itself by clavus, wakefulness, heaviness, asthenopia, and by inability to read or write, or to concentrate the thoughts on any given subject; the exhaustion of the stomach by flatus, nausea, gastralgia, capricious appetite, and so on; the spinal exhaustion by tender spots, backache, and weariness. The anemia of the reproductive organs is exhibited by amenorrhea or by scant menstruation, by neuralgic and hysterical pains; the hyperemia by congestion, dysmenorrhea, menorrhagia, and leucorrhea, by uterine flexions and dislocations, and by a variety of subjective and objective phenomena with which every physician is familiar.

Physiologists and neurologists are still searching for hidden treasures in the superficial and deep reflexes of the human body, overlooking the sound principles inculcated by Maudsley many years ago in his "Physiology and Pathology of the Mind" (page 178). "As in the action of nature upon man the stimulus which is not reflected in the spinal cord passes upward and excites sensation, and the stimulus which is not reflected in sensorimotor action passes upward and becomes idea, and the stimulus which is not reflected in ideomotor action passes from cell to cell in the hemispheres and excites reflection; so in the action of man upon nature the force of the will passes downward through the subordinate centers in an opposite direction; the will involves a conception of the result, or a definite ideational action; the conception of the result demands for its further transformation the appropriate motor intuition; and the motor intuition, in whatever center, spinal or cerebral, it is organized, demands for its due expression in movement the perfect function of muscular feeling and the integrity of the motor nerves and muscles."

Intercepted is doubtless the meaning of the word reflected, as it is in the first place here used. Massage then excites sensation, therefore it is not reflected in the spinal cord, but rather dispersed. Neither is it reflected in sensorimotor action, save when painfully applied, hence it gives rise to idea. Nor yet, when passively administered is it reflected in ideomotor action, therefore it ought to excite reflection or thought, to the reality of which result French authors and all who have properly undergone such treatment can testify. On the other hand, what may be called the objective evidence, whereby the will accomplishes its desires, depends largely on the perfect function of muscular feeling. Experience proves that massage excels in restoring the lost or perverted function of the muscular sense by aiding nutrition in the elimination of débris and by equalizing the circulation, as well as by the more normal impulse it seems to communicate to the cellular forces whereby endosmose and exosmose work more in equilibrium.

If space permitted one might give numerous cases illustrative of the following conclusions which ought to be well known by experience and observation to every physician:

1. That massage induces sleep.

2. That even when massage is applied in the forenoon its soporific effects may not disappear before bedtime; though in general the later in the day massage is used for promoting sleep the better.

3. Disagreeable feelings of drowsiness and languor do not necessarily intervene between massage in the forenoon and sound sleep at bed-

time. Aptitude for rest or work generally follows massage. The mind is clearer, the mental faculties work easier and longer, the muscles are suppler and do not tire so soon.

4. When people are wakeful after massage they may not be restless nor feel the loss of sleep on the following day. Athletes find that repose without sleep best relieves fatigue after prolonged strain. The reason is that the internal secretion antidote to fatigue-products is more rapidly formed during waking hours and more freely supplied to the muscles when the blood is not accumulated in the splanchnic area.

5. Spinal irritation is relieved or disappears under massage.

6. For local neurasthenia there is no need of general massage, unless the whole system be secondarily affected.

7. When affections have come to a standstill under massage, improvement may yet go on after massage has been discontinued and without any suggestion to that effect.

8. For improving the nutrition of nerves and muscles, restoring natural sensation and motion, massage may succeed when other means have failed.

9. Deep massage without friction has proved of more value in my hands than all other forms of massage put together.

10. Massage can be overdone, producing opposite effects from a moderate application.

11. Besides massage, carefully graduated exercises at regular times are valuable accessories in the restoration of motion.

12. Massage is not the only means of treatment for neurasthenia. Its selection is usually decided upon after the failure or exhaustion of every other means, in the same manner that the shrewd old divine decided that it was not wise to let the devil have all the good tunes to himself.

13. From a consideration of this it will be seen that, in general, massage produces a normal cenesthesia, *i.e.* a combination of all the good feelings, mental and physical, sometimes called the sixth sense, which is different from that produced by either rum or religion, and has no bad after-effects.

520 Boylston Street.

PHYSICAL TREATMENT OF FORMS OF ARTHRITIS.*

By WM. BENHAM SNOW, M.D.,

NEW YORK.

The classification of the types of joint inflammation is made with reference to their cause or origin as (1) traumatic, (2) gouty, (3) toxic, and (4) infected. Those arising from infection may be subdivided into (*a*) locally infected and (*b*) toxic in origin.

The treatment of each case must depend upon the cause and the conditions presenting. Diagnosis, therefore, at the outset, as to the cause, is imperative if success is to be obtained.

It is the disposition of many in the medical profession to refer to painful conditions as "rheumatic," and to treat them too often from this point of view. The exploded notion of uric acid poisoning is also still inherent in the minds of some of those who have not kept pace with the distinctions which modern research has revealed.

It is common also to hear a patient, and occasionally a physician say, "I hurt the joint and then it became rheumatic," instead of recognizing the fact that an inflamed joint, particularly if kept at rest, has little if any tendency to recover, but a likelihood of becoming chronic. This is particularly true of the inflamed conditions of traumatic origin, as arising from sprains or contusions. The disposition on the part of some orthopedists to keep an inflamed joint at rest, in plaster or in other splints is one of the greatest mistakes that these respected members of our profession are prone to make. The patient himself is ever disposed to rest a joint as much as is necessary, or more.

As a matter of fact, experience has taught that an inflamed joint of traumatic origin, in which no rupture has taken place of bone, ligament, or muscle, should not be kept at absolute rest or placed in a splint. As Dr. Watson Savage once said to the author, "The boy on the football team, who sprains his ankle and goes on with the play soon recovers, as he must, or be counted out the eleven." The coveted place on the team induces him to stand the suffering during the activity in which he is engaged, and very soon the muscle tension and the swelling which were present diminish and the part gradually assumes a normal condition. There are relatively few physicians who have recognized this point of view.

It is readily demonstrated that the swelling present following trauma or arising from toxic or infectious causes is the source of the pain which is aggravated by movement or pressure. In 1902[1] I first called attention to the fact that local *stasis* with infiltration in the normal tissue could be readily removed by electrostatic methods, and that the time to treat a traumatic injury was as soon as possible after the accident had taken place; before there had been a tendency to organization of the exudation or before plastic adhesion had taken place in a joint or elsewhere. I have never had occasion to change my opinion and we have always been able to demonstrate the correctness of this point of view.

When it is generally recognized, as it has been by a large number of physicians, that the static current is capable of dissipating the infiltration present in swollen tissue whether associated with a congested joint, uterus, or prostate gland, it will not be necessary to enter into the description of methods so explicitly.

This contribution was an innovation to the older dictum, that "electricity should not be used in acute inflammatory conditions." In discussing the paper which was read in Buffalo before the American Electrotherapeutic Association, Dr. William J. Morton confirmed the opinion expressed by me, basing his views on cases observed in his own practice. At the present time it is generally known that the static and high frequency currents are indicated in acute inflammatory conditions.

*Read by invitation before the National Society for Physical Therapeutics, Washington, D. C., June 21, 1921; and before the New York Electrotherapeutic Society, April 5, 1922.

The older notion referred to the use of the constant or induced current, and the dictum resulted from some accidents which had occurred from the early employment of these methods. These older currents are not effective in removing the exudation from the swollen tissues, except when very superficially located in the skin or surface. The same is true of the applications of radiant light and heat—often incorrectly called baking; though by this method the heat is induced well into the tissues by the transformation of radiant energy into heat. With the use of *dry heat*, properly called baking, when employed at high temperatures, it is impossible to give relief from the induration except in the early stages of an inflammatory condition, when it may be possible so to dilate the lymphatics as to assist the flow. When a condition of stasis is once established, however, and the tissues are indurated with the capillary and lymphatic vessels dammed up by the swollen, hardened condition of the tissues, it requires some measure which will act as a *vis a tergo* to force out the accumulated exudate, that is blocked up in the lymph spaces. The static modalities—the wave current, sparks or brush discharge, applied over the tissues so engorged—produce sufficient alternating contraction and release of the infiltrated tissues to drive out most of the exudate through the lymph channels and coincidently to relieve the muscular spasm and so relieve the condition.

When this was first revealed to me, I was treating a case of sprained hand with the static brush-discharge, and observed the swelling disappearing under the aministration. The hand, which was too painful to be manipulated before the treatment, after the first application could be handled and moved without pain. Before this I had treated cases of arthritis of the ankle joint and other joints with success, but had not appreciated the *modus operandi* of the method, attributing the relief to removal of the hyperemia instead of the *stasis*. From the date of this observation in the year 1900, the effects of and indications for the employment of the static modalities have been unquestioned. Since then the results have been verified in all inflammatory conditions not the seat of local infection, in which they are naturally contraindicated.

This consideration of the principle of the action of the static current is made in order to explain its effects as a means of meeting the indications in the treatment of many cases of arthritis. The only cases in which the method is not beneficial are those of ankylosis, of malignancy, or when germs are locally present in the joint, as in the case of tuberculous arthritis, or in rare cases in which pyogenic infection is present.

The method employed in the cases of arthritis is as follows: With the patient seated upon the insulated platform, encase the joint with metal for electrodes and connect it to the positive pole of the static machine with the negative pole grounded, and apply the current with an increasing spark-gap as the measure of dosage. The length of the gap will depend upon the part that is to be treated. For example a short spark-gap used for a small joint should be just short of causing muscular cramp. The same rule obtains with all joints. With the knee joint a spark-gap of from 6 to 10 inches will be required, varying with the size or development of the part.

The muscular tension, always present in cases of arthritis, involving the long muscles crossing the joint, should be relaxed; because the relief of the tension will remove much of the discomfort and relieve the pressure upon the surfaces, which if persistent, in cases of chronic arthritis, as in rheumatoid arthritis, will interfere with circulation and lead to erosion of the opposing surfaces.

Following the applications of the static wave current, static sparks should be vigorously applied to the joint and to the tense muscles, to remove the deep infiltration from the joint. When properly applied along the contracted muscles the sparks will completely remove the muscular tension.

Another method, which is employed in the inflammatory conditions of small joints, and as a part of the treatment of ankle sprains, is the static *brush-discharge*. Not the so-called blue pencil discharge, but the static brush-discharge proper, applied with the patient connected to the negative side of the static machine with the positive grounded and the electrode moved about at a distance at which the discharge will produce a distinct sensation as of hot sand projected against the skin. This application is made for the purpose of removing the superficial infiltration, and to hasten the absorption of the ecchymotic area where the blood is extravasated beneath the skin. The application is made usually until the skin has become distinctly hyperemic, not carrying it so far that too great irritation of the skin is produced. This method of applying the static current is also used for removing induration around the margins of ulcers, and wherever superficial induration is present, as with delayed union or with a traumatic injury with swollen margins, when a healthy condition can be restored which will heal without leaving scar tissue.

Muscular spasm as associated with all inflammatory conditions, as previously stated, is relieved by the static wave current or sparks applied over the contracted muscles.

In the management of uncomplicated *traumatic arthritis*, as previously stated, no treatment is required except the static applications unless ankylosis has occurred; when frequent applications of diathermy through the joint will prove effective as an aid in breaking up the adhesions, which may be accomplished when they are not too extensive or chronic.

In the management of *toxic arthritis*, due to the presence of foci of infection, as in the teeth, tonsils, vesicles, or elsewhere, treatment should be directed first to the source of the toxemia, which must be corrected as the initial part of the treatment. Cases of involved tonsils, in the light of modern science are treated by operation, the *x*-ray, as outlined by Dr. Byron S. Price or Dr. Witherbee, by desiccation, or by the application of the ultra-violet rays through the mouth to destroy the infection in the tonsils. They need rarely be removed, however, but left to perform the function of removing the germs in the secretions in the mouth.

These conditions should be treated, as are the traumatic cases, with the static current or dia-

thermy along the lines suggested, and as indicated in every case of toxic arthritis or neuritis.

As for the treatment of infected teeth there is but one indication—their removal. Furthermore, any tooth in which the nerve must be killed to save the tooth, should be extracted instead of being capped and filled, when it would sooner or later cause trouble. The *x*-ray will as a rule find these capped teeth the ones causing the trouble.

In *gout* other indications must be considered. Gout is undoubtedly due to a deranged condition of the liver caused by certain errors of diet or habit; very often attributable to alcoholic drinks, particularly champagne. There are patients who will have an attack after a champagne dinner, so certain that eventually they will anticipate the effect of such indulgence. The treatment of these cases is most satisfactory, and must include the vicinity of the liver, as well as the local condition. The application of the static wave current is made with an electrode applied over the liver and epigastrium. The electrode should be about 4 inches in width and from 10 to 12 inches in length applied along the margin of the ribs, and the spark-gap should be long enough to cause marked contraction of the muscles beneath the electrode, in order that it may so affect the liver as to accelerate its function. The treatment of the local condition should begin with the static brush-discharge, which should be applied until a marked degree of hyperemia is produced in the skin; then to be followed by the application of short static sparks. This will remove at the first application most of the infiltration, pain, and tenderness. After the treatment, in an acute case, the patient will put on his shoe and leave the office with very little, if any, discomfort. In cases that are not chronic two or three of these routine treatments will entirely relieve the conditions. In chronic cases, it will be necessary to treat the patient for his general metabolism, employing both radiant light and heat in addition to the local treatment, and treatment of the liver will be necessary. A longer time may be required to effect a cure or relief of the condition in chronic cases.

There are two types of conditions of toxic origin, arising from intestinal infection, one acute which, if any type of arthritis may be correctly called "*rheumatism*," it is this type. The other type is chronic—rheumatoid arthritis. In both the affection is bilateral, more or less acute in its onset, and generally involving many joints of the body.

The indication in the treatment of the former is to clear out the alimentary canal, and keep it clean. A strict non-protein diet, and castor oil followed by high colonic flushing daily with local static treatment as outlined will relieve, and generally cure the acute cases in a few days. In bed-ridden cases clearing out the alimentary canal, as previously stated, with applications over the abdomen of radiant light and heat and administrations of salicylates or other intestinal antiseptics until the patient can go to the physician's office for the static or diathermy treatment is a rational course to pursue.

Rheumatoid arthritis, like rheumatism, as previously stated, is a condition of intestinal origin, subacute in character, caused, as a rule, by constipation with intestinal absorption of decomposing protein products which support and favor pyogenic bacterial growth. It is insidious in its onset. The uniform bilateral involvement of the joints is characteristic of this affection. It usually begins with the small joints, as the joints of the hand, and extends to the larger joints, and ultimately may involve all the articulations of the body. Without going further into detail as to the etiology and pathology of these cases, the treatment must depend upon the relief of the local condition, together with the removal of the bacteria and accumulated feces—the source of toxemia. This affection was one of the first types of cases coming under the writer's observation when he began his service in Dr. Wm. J. Morton's clinic, at the New York Post Graduate School and Hospital in 1898, and awakened an appreciation of the value of the static modalities. It was the results obtained in the treatment of rheumatoid arthritis that demonstrated their important therapeutic value. At first the only treatment given for these patients was the static treatment of the local condition and of the liver, which included applications of the wave current over the liver and the administration of the static wave current and static sparks to the joints.

In a paper read before the annual meeting of the American Electrotherapeutic Association at Washington, D. C., in 1899,[2] I reported a number of cases which had been relieved or clinically cured by the static treatment.

For several years in the treatment of these cases the static modalities alone were employed, without reference to the alimentary canal and with relative success. Later we became convinced of its infectious origin in the intestinal tract, and the patients were put on a meat-free diet, and daily colonic flushings were prescribed until the feces were normal in character. It is a part of the regular routine now to employ the static modalities, and control the intestinal infection, which is greatly facilitated by instituting a diet free from animal protein, and the use of high colonic flushing.

The application of the static wave current and static sparks to the joints in these cases relieves the local infiltration; and the dietetic regimen and the intestinal washings remove the cause. Such uniform success has been derived from these methods in rheumatoid arthritis, that the routine method is followed with enthusiasm. If the treatment above described is followed in cases where there has been no destruction of joint surfaces the case can be clinically cured, and in cases where there are structural changes such as erosions of the articular surfaces of the finger joints, these can also be relieved from an extension of the process.

Still's disease, a form of general arthritis, was described by Spender as rheumatoid arthritis in children, but was later shown by Still to be associated with an enlarged spleen. We have had two of these cases under observation—one an advanced case in a child of eight years in which the chance of marked improvement was impossible, on account of the structural changes and contractures already present in many joints. With the application of the static wave current to the joints, it was possible, however, to remove all of the tenderness and pain, which had been of years standing and make the little fellow fairly comfortable.

The other case came under observation before there had been any structural changes. It was a child two and one-half years of age and was referred by a surgeon of the New York Hospital for Ruptured and Crippled. The joints in this case had had one year of surgical management, a part of the time at the hospital in plaster, and with massage, but had not improved. With the use of the static wave current applied with metal electrodes over the joints daily for a period of six weeks we were able to accomplish an effectual cure. This case and the other case were reported and published in 1904.[1]

This case was again exhibited before the Orthopedic Section of the Academy of Medicine five years later, showing absolutely no recurrence of the trouble, and the young woman is now twenty years of age, well and without recurrence. We are justified in calling this case a cure. No part of the result in this case can be attributed to anything but the static wave current, for no dietetic or hygienic methods were or could have been employed in this case.

In the treatment of sprains and trauma or the forms of arthritis, or following dislocations in our own experience, and from reported cases by orthopedists, it is justifiable to state that no such results are to be obtained by other methods as with the static modalities as included in the consideration of the management of the various types described.

While diathermy is useful in some cases, as a rule its employment is redundant, except in cases of infected joints, of tuberculous and pyogenic infections, and in ankylosis. In these cases, the joint employment of diathermy with the *x*-ray will be found to be useful in the earlier stage.

In cases of fibrous ankylosis, physicians whose experience has been large in army practice and others, have been successful with diathermy. In bony ankylosis there can be no hope of relief from electrical treatments.

There is no class of conditions, however, in which greater satisfaction has been obtained with the static modalities than in the forms of arthritis as enumerated, when the methods are correctly employed.

A HERETOFORE UNKNOWN MENACE INHERENT TO THERAPEUTIC SERUMS.

By Ferdinand Herb, M.D.,

Chicago, Ill.

The following consideration rests upon the now firmly established fact that blood ferments, or antibodies, cannot perform their work without the presence of another substance, commonly known in America as "complement."

The exact composition of complement has not as yet been ascertained. However, it is known to be present in fresh serums. If serums which contain complement are heated to approximately 60 degrees C. for several hours, the complement disappears. Ferments that may at the same time be present in the serum are not affected by this temperature and are just as active after heating as before, if new complement is added. It is the universally accepted view that the disappearance of complement upon heating is due to its destruction. Bordet, Metchnikoff, Ehrlich, Wright and their many collaborators and followers have held, and still hold to-day, this view without a dissenting voice. In fact, this viewpoint has never been challenged. Complement is, therefore, called "thermolabile."

There are, however, experimental and clinical phenomena that can hardly be reconciled with the thermolability of complement. Nor has anybody ever furnished the proof that the disappearance of complement is due to its destruction. This subject, therefore, deserves reviewing. Aside from its enormous clinical importance, the correct interpretation of the disappearance of complement upon heating concerns us here particularly, as it has a direct bearing upon the disclosure of the heretofore unknown menace inherent to therapeutic serums.

Though this is intended to be clinical paper, it will be necessary to adduce one of those experimental findings that cannot be reconciled with the thermolability of complement. I refer here to what is called the "Neisser-Wechsberg phenomenon." Only those data, however, will be given that are absolutely necessary for the proper understanding of the experiment.

If 1/5000 mil of a fresh broth culture is mixed with 0.3 mil of fresh, normal serum and heated immune serum is added in increasing quantities, most perplexing results are obtained. The details are shown in the accompanying table.

Broth Culture	Heated Immune Serum	Fresh Normal Serum	Colonies Developed
1/5000 mil in all cases	1 mil	0.3 mil in all cases	infinite
	0.5 "		infinite
	0.25 "		many thousands
	0.1 "		several thousands
	0.05 "		about 100
	0.025 "		about 50
	0.01 "		none
	0.005 "		none
	0.0025 "		about 100
	0.001 "		infinite
	0.0005 "		infinite

The 0.3 mil of fresh serum added in all instances contains the complement and furnishes a like amount in all tests. The heated immune serum contains only antibodies. Its complement has disappeared in consequence of the heating, while its antibodies are not affected by the heat and are potentially fully active. The number of antibodies increase in exact proportion to the amount of heated serum added. Thus, 0.001 mil of heated serum contains twice as many antibodies as does 0.0005 mil; and 1.00 mil contains just 2000 times as many autibodies as does 0.0005 mil.

As the table shows, culturing the different mixtures has yielded the strange and puzzling fact that the microbes contained in the broth culture are killed only if between 0.01 and 0.005 mil of

the heated serum is admixed. If more or less is added, the bactericidal power of the mixture is decreased in the same proportion as the addition of heated serum deviates from the amount between 0.01 and 0.005 mil.

The reason for the decrease of bactericidal power if less than 0.005 mil of heated serum is added seems obvious; not enough antibodies are contained in these small quantities to be effective. But why does the bactericidal power decrease proportionately as more than 0.01 mil of heated serum is added?

The puzzle has never been solved satisfactorily, though the great masters in this field, past and present, have tried their best to find the solution. For want of something better, most of them accepted the makeshift view that upon the addition of more than 0.01 mil of heated serum the individual antibodies are not supplied with sufficient complement and, therefore, lose their bactericidal power. However, the correctness of this view has since been disproved conclusively.

Of the few who dissented and suggested a different explanation Gay came nearest to what I consider the correct viewpoint. He attributed the loss of bactericidal power on increasing doses of heated serum above 0.01 mil to complement fixation by soluble substances given off by the microorganisms. Gay is correct in so far as the loss of bactericidal power is due to complement fixation. He is not correct in so far as the complement fixing bodies do not come from the microorganisms, but from the serum itself.

In order to prove this statement to be correct, I wish to recall the well-known phenomenon that trypsin loses its power to digest casein if blood serum is added. Rosenthal[1] investigated this phenomenon and came to the conclusion that the antitryptic action of the blood serum is due to the presence of digestive split products. This conclusion was upheld by Rusznack[2] among others. He demonstrated that in the anti-anaphylactic state or during recovery from an anaphylactic shock the blood is laden with digestive products and the antitryptic action of the serum is greatly increased. Very recently, I have shown[3] that the antitryptic action of digestive split products is due to their avidity to unite with, or "fix," complement. This avidity to unite with, or "fix," complement is common to all split products of albuminous substances of whatever origin. The momentous importance of this phenomenon from a practical standpoint can to-day only be divined. The few glimpses at its influence upon clinical pathology, given later, may serve to open our eyes to the vista of possibilities. A concrete example is furnished in the Wassermann reaction. Here the digestive split products originating from the decomposition of dead treponemas are, as I have shown elsewhere,[4] the complement fixing bodies that lead to the inhibition of hemolysis and make the reaction positive.

The tendency of albuminous substances to disrupt increases as the temperature rises. Clinically we know that some of our body substances, especially those within the brain, are seriously injured at long continued high fever temperature. Experimentally we know that some of the substances of the blood and milk decompose at a temperature below 50° C. At 58 to 60°, at the temperature when the complement disappears, even more stable albuminous substances decompose; and with superheated steam all of them can be split into their component parts.

That the disappearance of complement upon heating the serum is not due to the direct influence of the heat upon the complement itself, is shown definitely and conclusively by the following experiment. Precipitins are ordinary ferments, or antibodies. They obey the same laws as other antibodies. Consequently, they require complement for their action. If serum containing complement and precipitins specific for egg albumin is heated, the complement disappears and no precipitation occurs upon the addition of egg albumin. If, instead of the serum, the egg albumin is heated and added to the fresh, unheated serum containing both complement and antibodies, precipitation, too, remains absent, because the split products now formed in the egg albumin fix the complement of the non-heated serum and prevent the action of the ferments. This experiment proves further that the split products of the different albuminous substances—serum albumin and egg albumin—are equal in their ability to fix complement.

This new phenomenon—the complement fixing avidity of digestive split products—becomes operative clinically in countless cases of acute and chronic infections. Wherever microbes settle, digestive split products form and accumulate in the surrounding tissues. Whether these split products originate from the host's own tissues in consequence of the activity of the microbes or from the disintegration of the microbes themselves—they fix complement. Thus, a "zone of inhibition" is formed around the site of any microbic settlement, in which complement is fixed the moment it arrives. Under such circumstances pathological foci are established. No matter how many antibodies attain the microbes, they are inert and completely harmless to the germs, if they are deprived of the necessary complement in this "zone of inhibition" before they reach the infesting foes. The number of clinical cases in which these conditions obtain is legion and their clinical varieties and shades are as yet beyond calculation.

In acute cases, in which the infection is not localized and the microbes infest the blood and lymph stream, the body fluids become glutted with digestive split products especially at the time when the reaction of the host's system leads to the killing of germs in large numbers. In cases where the complement is scarce or comes near depletion, any therapeutic substance that causes an additional fixation of complement is a menace to the patient and is apt to hasten death. It is under such circumstances that the therapeutic use of serums may incur the gravest danger and even decide the fatal issue. All serums contain a large proportion of albuminous substances. These albuminous substances are in a labile state from the moment the blood is shed. The complement which serums may contain gradually diminishes and finally disappears even at ice-box temperature for exactly the same reason, though much more slowly, as it disappears when serums

are heated. For instance, no matter how carefully the guinea pig serum used for the Wassermann test is kept on ice, its complement gradually vanishes. This fact is only too well known to those who engage in making Wassermann tests and is a source of constant annoyance and infinite work, as fresh and active serums must be provided continually.

The same is true of all therapeutic serums. The complement they may at first contain is readily fixed by the first split products that form in consequence of aging. As more split products come into existance and these unsaturated complement fixing bodies increase in number, the avidity of the serum for complement grows. In old serums and in fresher serums that have been kept at improperly high temperature this complement fixing avidity may reach that of heated serums. This fact can readily be demonstrated by repeating the experiment given in the above table with such old serums instead of with fresh heated serums. The results are much the same. This complement fixing avidity of serums may develop to a high degree in spite of the fact that their content of active specific antibodies remains unchanged, as in heated serums.

This menace of older, though still fully active, serums has never received attention. Nevertheless, it exists and should get due consideration. It is true, the danger thus pointed out may not exist for the majority of patients who have a liberal surplus of complement at their disposal. But with those whose life trembles in the balance for want of complement, the injection of a serum with high avidity for complement may prove the straw that breaks the camel's back. To-day we do not know how many of these cases we meet in practice. But signs are multiplying that in an uncomfortably large percentage of cases dying of infectious diseases not the lack of specific antibodies but the lack of complement is the cause that kills.

This possible menace should, therefore, always be kept in mind when using therapeutic serums. Definite data on this point are much needed. They can readily be obtained, as the complement fixing avidity of the different serums at their different ages can quickly be determined by simple tests.

Hyperemesis Gravidarum.—According to Harbitz this affection is seldom fatal. In one autopsy case he found diffuse parenchymatous degeneration of the liver and kidneys, in another fatty liver, degeneration of the kidneys and heart and in a third marked degeneration of the three viscera. While the chief clinical symptom in these cases was the incoercible vomiting, there were also pregnancy kidney, high blood pressure, edema, etc. There were no convulsions. The autopsy finds differed from those of eclampsia, in which there is a characteristic infarction of the liver not found in the present series.—*Norsk Magazin for Laegevidenskaben.*

A SUCCESSFUL TREATMENT OF PULMONARY TUBERCULOSIS IN THE FIRST AND SECOND STAGES.

By J. Zachary Taylor, M.D.,

Baltimore, Md.

For fifty years the writer has practised on land and sea, and now at the age of 73 is compelled by a failing heart to retire from active practice. And in doing so he wishes to make known to the profession the following plan of treatment of pulmonary tuberculosis which he has found to be almost invariably successful in all but the final hopeless stage.

The following is the composition of a tablet I have always used and which I call the T-B tablet (the drugs used should be the purest and best to be had):

℞	Red iodide of mercury	1/250 gr.
	Manganese iodide	1/8 gr.
	Sodium cinnamate	1/12 gr.
	Copper phosphate	1/24 gr.
	Sodium formate	1 gr.
	Arsenous acid	1/60 gr.
	Strychnine hypophosphite	1/128 gr.
	Iodized calcium	1 gr.
	Oil of cinnamon	1/20 min.
	Charcoal	1 gr.

M. To make one T-B tablet.

Dose.—One tablet to be taken half an hour after each meal, for 15 days at a time; then a rest for 5 days, followed by another 15 days of treatment, and so on alternately. By this plan all danger of arsenical poisoning is obviated and the treatment may be kept up from two to twelve months to perfect the cure. T-B tablets are indicated in all forms of tuberculosis and also in cancer and other blood diseases.

Prof. J. M. DaCosta in the year 1874 said in one of his lectures at the Jefferson Medical College, Philadelphia, that arsenous acid was the nearest approach to a specific that we have for consumption of the lungs, and I have found it to be so. The very first patient I had to treat was cured by this remedy in conjunction with other appropriate treatment, and from that day until I perfected my treatment I have experimented in order to find a cure. (No single drug or remedy will ever be found to cure). This assertion by Prof. DaCosta was made long before the germ theory was brought to the front. I also cured syphilis with mercury and arsenic long before salvarsan was ever dreamed of.

The physiological action of T-B tablets is to revive cell life, promoting rapid corpuscle building, accelerating retarded metabolism and increasing phagocytosis. Sodium formate is a reducing agent and antiseptic, and, when absorbed in the blood, gives off oxygen and vivifies the blood. Sodium cinnamate stimulates phagocytosis. Strychnine is a vital tonic. Arsenous acid is antiseptic, a primary constituent of the living cell, a heart food. Arsenic and iodine feed the ductless glands which play so extraordinary a rôle in the preservation of health and life. The thyroid and suprarenal glands are interdependent, the secretions of the suprarenal are oxygen carriers, those of the thyroid are destructive to pathogenic germs. Manganese is an alterative tonic. Copper is antituberculous, useful in anemia, chlorosis, and diseases of the ductless

glands. Iodized lime is eutrophic, constructive, and soothing to nervous system. Lime starvation and lime assimilation are the real issues behind the masks of vulnerability and resistance in tuberculosis, bronchitis, scrofula, and glandular enlargements. Mercury is alterative and germicidal.

Treatment in Detail.—One T-B tablet one half hour after meals for a period of 15 days, then a rest for 5 days before starting with the tablets again for 15 days, etc. Every day give a tablet or capsule of iodized lime (containing lime, iodine, and starch) gr. ii, creosote ♏ iv, guaiacol carbonate, ♏ ii, 3 times a day, and at the same time 2 grains of quinine. As soon as the stomach can bear it, increase the dose of the iodized lime, creosote, and guaiacol to 2 or 3 capsules or tablets a dose, and the quinine to 6 to 10 grains a day in divided doses.

When hemoptysis is profuse or frequent give 10 to 20 grains of chloride of lime, as needed. For the racking cough give a capsule or tablet of codeine phosphate gr. 1/3, terpin hydrate, gr. ii, phenacetine, gr. ii, every 3 hours and to relieve the paroxysm whenever needed. Locally apply over congested area where there is soreness, pain, pleuritic stitch, tightness and difficult breathing, libradol, which is a mixture of dracontium, sanguinaria, ipecac, melaleuca, lobelia, capsicum, tobacco, and camphor.

Sun and Shade.—One hour before and two hours after sunrise out-of-doors in summer time are worth more to consumptives than the balance of the day. Look at growing plants at this time of day and behold how proud they look. Then again, see how they curl their leaves to shade the life stem of the plant from the scorching noonday sun, and learn a lesson from nature. Live out in the open and bask in the sunlight, seeking the shade when the birds and fowl do on a hot summer day, and be wise. Sunlight and heat through glass do not possess the healing properties that they do in the open. The potency of the sun's rays is intercepted by the glass.

Diet.—No raw eggs, for they, like milk when it disagrees, pass out undigested, thus causing diarrhea. If milk is relished and agrees with the patient, take from one to three quarts a day from a nursing bottle such as used for infants and suckling babes. It is thus quickly assimilated and builds up the entire body rapidly. Clabber, curd, buttermilk, cod liver oil, sliced onion sandwiches, and all foods containing the vitamines in particular, are to be largely used. No cold baths unless the patient is strong and robust. Warm or tepid baths should be taken on an empty stomach in the morning—none at night. A sick lung, like a broken bone, should be put in splints until in a fit condition for service and work. Remember this. Prevent, as far as possible, constipation.

Inhalant.—Take a small lump of unslaked lime (whitewash lime) and pour a little water over it, and as it slakes breathe deep into the lungs the fumes, night and morning. Use wood or metal to slake the lime in. This is a specific inhalant in pulmonary troubles.

The above constitutes the drug and general treatment, which, when conjoined with vaccine injections, actually works wonders. The vaccine treatment forms a wall around the diseased structure to prevent further inroads of the tubercle bacillus. A patient should never be sent away from home when the environments are inviting and healthy, because when a patient improves or recovers in a distant point from home and returns, the disease is liable to return with more virulence than at first. Treat at home if possible, with vaccine and drug treatment combined.

The treatment herein outlined heals, destroys the tubercle bacilli, and causes a cicatrix to form and practically prevents further invasion.

Vaccine injections are given subcutaneously in the arm every third or fourth day, using an all-glass aseptic hypodermic syringe after sterilizing the short needle in boiling water. Before inserting the needle touch the spot with tincture of iodine and apply the same again after the injection. When the catarrhal vaccine is used alone the initial dose should be 5 minims, increased 5 minims at a time up to 15 minims, maximum dose every third or fourth day. The non-virulent tubercle vaccine may be given, combined with every *second* injection of the catarrhal vaccine, in doses of 1 minim, increased 1 minim at a time, but not to exceed 15 minims as the maximum dose. As just said, the catarrhal vaccine is to be injected every third or fourth day, and with every second injection from 1 to 15 minims of the tubercle vaccine is to be administered.

This treatment faithfully and conscientiously carried out will never disappoint you unless some unforeseen complications exist.

My last case was my granddaughter, 18 years of age. By test and examination by the health department of this city, Jan. 9, 1921—swarms of tubercle bacilli were found—distressing cough, hectic fever, hemorrhages, a cavity, etc. After three months of treatment she was pronounced cured, and six months from the date of beginning the treatment she married, and is now a happy wife in splendid health. All I ask is that brother physicians shall try it and honestly carry out the plan as described.

1215 Edmondson Avenue.

THE REAL DANGER IN PRESENT-DAY CASES OF BLENNORRHEA OF THE NEW-BORN.

By WILLIAM MEHL, M.D.,

BUFFALO, N. Y.

The real danger of blennorrhea is no longer to be found in the gonococcus itself, though we know this to be a virulent infective organism, but in the fact that, thanks to the general use of Credé's prophylactic method, the majority of cases of blennorrhea of the new-born, at the present-day, are non-gonorrheal or inclusion blennorrhea. This statement may appear absurd and contradictory on the surface, nevertheless it points out a serious practical condition to which attention needs to be called for a number of reasons.

The general application of silver nitrate has reduced gonorrheal blennorrhea cases to an almost negligible percentage, with the result that midwives and general practitioners, at present, meet practically only with benign or non-gonorrheal cases. Believing it to be important that all who take care of confinement cases should know the causes of non-gonoblennorrhea and understand the reason why

they come across so many cases of this nature, I have gathered together from trustworthy sources the best available information and offer it with such comments as personal experience suggests. In this I have had the valued advantage of frequent consultation with Dr. Karl Lindner, of the University of Vienna, whose researches in this particular field have cleared up many former difficulties and who is recognized as an eminent authority here.

Shortly after Neisser announced the discovery of the gonococcus it was found that a marked proportion of cases of blennorrhea of the new-born could not be ascribed to the presence of gonococci. Many investigations were made in an effort to learn the exact cause or organism responsible for cases of this peculiar form of blennorrhea. No satisfactory proof was produced to establish that the disease was due to any organism. At last, about 1909, Lindner showed that the non-gonoblennorrhea cases must be ascribed to a definite virus which is transmissible from human beings to apes. He proved, further, that the character of this virus is like that of the virus responsible for trachoma, both being transmissible to apes, and in fact being the only virus transmissible from the eyes of human beings to the eyes of apes and causing a conjunctivitis. The virus responsible for non-gonorrheal blennorrhea is called inclusion virus and is derived from the genital passages of the mother. The non-gonorrheal blennorrhea was, therefore, called inclusion blennorrhea.

A peculiar feature of this inclusion blennorrhea is that it is not influenced in the least, nor is it preventable, by the use of Credé's method. In other words, the instilling of silver nitrate after birth does not in any way prevent the outbreak of inclusion blennorrhea. Credé's, therefore, is a prophylactic only for gonoblennorrhea but not for inclusion blennorrhea.

Inclusion blennorrhea is not a dangerous disease, as the cornea is practically never involved. The disease is a self-limited one, and all that treatment can accomplish is simply to reduce the duration of disease. Even without treatment of any kind there is practically never any involvement of the cornea and hence no consequent loss of eyesight such as we find as a more or less constant rule, in untreated or improperly treated cases of gonoblennorrhea. It is just because the usual cases of blennorrhea of the new-born, under present-day regulation, are found to be harmless that we are now facing a new danger—the danger of having blennorrhea treated lightly.

The number of cases of gonoblennorrhea has by the careful use of silver nitrate been decreased to so small a percentage that the majority of general practitioners and midwives come in contact only with cases of inclusion blennorrhea. Watching the clinical progress of this comparatively harmless disease they are impressed with the fact that it runs a seemingly benign course and never involves the eyesight. As a result many lose their fear of blennorrhea of the new-born, together with their former wholesome respect for it. When blennorrhea of the new-born ceases to be regarded as perilous, the use of Credé's becomes perfunctory, if it is not neglected altogether. Unless the greatest possible care continues to be exercised in every case of blennorrhea neonatorum there are likely to be unfortunate consequences.

Gonoblennorrhea cases, in the first stages, usually show less clinical evidences than the comparatively benign cases of inclusion blennorrhea, and yet the character of the infecting organism constitutes a most serious menace to the eyes.

Midwives are not allowed to treat disease, so that there is small danger of their attempting to treat a case. And yet, since many midwives have had some experience in clinics, where Credé's method was being used, and having noted that practically all cases of blennorrhea of the new-born are cured without especial effort, they gather the impression that the disease is a trivial affair. The practical consequence is that they are inclined to minimize or underrate the importance of calling in a specialist in every case of discharge from the eye. They are not aware that the harmless cases observed in the clinics were those of inclusion blennorrhea, while there is such a thing as gonoblennorrhea which requires prompt and careful expert treatment. The only safe rule for them to follow would seem to be to refer every case of blennorrhea at once to a specialist.

Treatment of Blennorrhea of the New Born.—It is exceedingly important that there be in every case of ophthalmia neonatorum an immediate examination of smears of the secretion and of epithelial smears taken from the conjunctiva directly. If gonococci are found to be present—which is easily determined during the first two weeks of the disease—the case should be referred at once to an eye specialist or a physician experienced in handling such cases. If, on the other hand, the case proves to be one of inclusion (non-gonorrheal) blennorrhea, then treatment with a 2 per cent solution of silver nitrate, once a day, is sufficient. First the secretion should be cleaned away carefully in order that the solution of silver nitrate may act upon the conjunctiva and not be used up by the secretion. Cases of this kind always make an uneventful recovery and may be treated successfully by the general practitioner.

In the treatment of gonoblennorrhea we have quite a different proposition. These cases should come directly under the care of an oculist, or one having an especial training and experience in the handling of eye cases. At the beginning of the disease and until it has subsided, treatment should be applied twice a day. This treatment should consist of a thorough and careful cleansing away of all secretions, observing the utmost care not to abrade the corneal epithelium. Following this the lids should again be everted and a 2 per cent solution of silver nitrate applied with a cotton tipped probe. The eye lids should be opened and closed several times so as to make sure that the silver nitrate reaches all the recesses or folds in the conjunctiva. The silver nitrate should then be neutralized by a normal salt solution.

Of late we have learned that the duration of gonorrheal blennorrhea of the new-born can be shortened by the milk treatment which operates fully as efficaciously here as in the case of adults similarly afflicted. The amount of milk to be used in the case of infants is from 2 to 3 c.c., injected

into the gluteal muscles. It is important that the milk shall have been boiled exactly four minutes, after reaching the boiling point. What we look for is a considerable rise of temperature. This is in fact necessary in order that the disease may be overcome. The high fever is a desirable result, as it is followed by the destruction of the gonococci. Under ordinary conditions the treatment should be repeated on the second day. These two injections suffice as a general rule. However, if further treatment appears to be desirable a third and fourth injection may be made on the fourth and fifth day. Experience suggests these final cautions:

1. Regard every case of blennorrhea of the newborn as a possible dangerous gonoblennorrhea until microscopical examination of smears of the secretion and epithelial smears have established the absence of gonococci.

2. When suppuration appears it is advisable to apply a two-per-cent solution of nitrate of silver, twice a day, until a cure is effected.

3. Let it be an absolute requirement, whether enforced by the law of the State or not, to instill in the eyes of the newborn, immediately after cleansing, a one-per-cent solution of nitrate of silver as a preventive or prophylactic. (Departure from such generally approved practice may subject a physician to serious embarrassment.)

4. It is imperative that whatever solution of silver nitrate is used should in no case be older than one month, no matter what the character or color of the bottle or container may be.

PEDICLED FLAPS AIDED BY FREE FAT TRANSPLANTATION.

By WELLER VAN HOOK, A.B., M.D.,

CHICAGO, ILL.

ALL experienced surgeons recognize the very great advantages inherent in the use of pedicled flaps rather than free ones. The comfort of an assured blood- and lymph-supply enables one to attack with confidence a great variety of complex problems. Even the danger of infection loses some of its terrors when we have this aid of the nutrient pedicle.

My own practice in plastics is to make use of nutrient pedicles in transplantation as frequently as possible, choosing tissues for grafting in such a way that the blood-vessels running into the structures transplanted are left uncut, if they need transection, until after the pedicle has fully served its purpose.

An additional safeguard lies in raising the flap to be transplanted at a first sitting and immediately suturing it back into its original seat with such accuracy that no granulation tissue is produced about the edges. This forces the uncut blood-vessels to dilate, and prepares the flap for its new bed in a most satisfactory manner by assuring adequate vascularization through the pedicle. The actual transplantation takes place two weeks or more after this maneuver has been practised.

I have recently added to this well-known procedure the implantation beneath the flap of a mass of adipose tissue derived from the thigh or other convenient region in order to give mass to the transplanted structures and fill in a defect. The fat healed into its new bed and was lifted with the flap when it was raised and rotated into its final resting-place. It healed without the least irregularity and filled out the space which it was designed to occupy in a very satisfactory manner.

In all plastic work in which the element of appearance is a desideratum, contour, line, and mass are of supreme importance. Color and texture, though of great value, are of far less consequence in comparison. Hence in all such work the operator considers well, before proceeding to operate, what will be the best way to fill depressions or to reduce elevations, how to modify masses so that their surfaces when seen from a little distance will present agreeable masses or, if viewed in profile, will present contours that harmonize with the other beauty elements of the personality.

The transplantation of masses of areolar tissue enclosing fat constitutes a surgical measure surprisingly well adapted to a great number of practical uses. The areolar tissue is sometimes spoken of as the atmosphere of certain structures and organs. Its presence often prevents adhesions and protects delicate structures that would otherwise be exposed to minor traumatism. And it may be used by the surgeon to facilitate the movement of one set of structures upon another.

The principle, then, of implanting fat masses under structures such as skin, or skin and fascia, that are temporarily raised and sutured down preliminary to transplantation with the aid of pedicles is obviously of great practical value.

The case in which this method was successfully put to the practical test was the following:

Girl, ten years of age, presented herself with an extensive defect of the right sternomastoid and neighboring muscles, together with the loss of much subcutaneous fascia and fat, due to the action of a phlegmonous inflammation of the lymphatic glands of the region half a dozen years before. The skin, also, had sloughed away, but had been replaced by new-grown cutaneous tissue, which was very thin, drawn here and there by bands of scar-tissue, and discolored on account of its irregular blood supply. Moreover, in the region of the lost sternomastoid there were several bands of dense scar-tissue which seriously limited the movements of the head and neck and threatened to bring about permanent derangement of the cervical statics.

The right side of the neck from the hyoid level to that of the supraclavicular space and from the region of the scaleni forward almost to the thyroid neighborhood was so defective as to present a most unsightly hollow, bordered outwardly by the longitudinally contracted bands. It was planned to transect or even to dissect out the scar-tissues in so far as they caused deformity or interfered with movement; to utilize fatty connective tissue to fill out the hollows of the neck and to support and to render mobile the skin; and finally it was found necessary to readjust and to replace skin tissue.

At the first operation the scar-tissue was transected or excised and a little minor plastic work upon the skin was carried out. But the principal effort consisted in raising a large flap from the scapular region where the skin was loose and pliable, with a pedicle lying upon the shoulder itself. This flap was raised with its associated thin layer of subcutaneous connective tissue, the bleeding vessels were clamped until hemostasis had occurred, and then stitches were introduced to hold the flap in its original bed, except that at one side of the graft the wound was left open for the reception of the fat which was to be implanted.

At this stage gentle pressure was applied by the whole hand of an assistant over the graft, to still finally all oozing while the fat from the thigh to fill the defect in the neck was prepared for its temporary resting place.

A generous incision was accordingly made in the outer surface of the thigh and the thick fat of the part exposed. With a sharp finger-knife the skin was separated from the fat quite widely and then the fat-mass was separated with the same knife from the deep fascia. It was then easy to remove the large fat-mass by cutting away its lateral attachments. A large quantity of this tissue was thus quickly obtained and each piece removed was at once laid carefully under the pedunculated skin flap. The suturing of the flap was then completed. The thigh wound was quickly closed.

About four weeks later, the wounds having healed and light massage having been kept up, the child was again anesthetized. First the anterior wound was reopened and all oozing stopped after minor improvements in local conditions as to scar deposits had been made. Then the flap was raised, together with its associated fat-mass, extreme care being taken not to disturb the relations of the fat to the skin. The condition of the fat and the transplanted fat, which had grown closely to it, was excellent. The capillary return circulation quickly responded after pressure with the finger and there was almost no edema.

The flap was then turned to its new position and the fat carefully adjusted to fill in the mass defect, which gave rise to the most disfiguring phase of the lesion.

Slight puckering occurred at the inner margin of the pedicle, but the main masses of the large flap and the transplanted fat fell into place almost without a fold.

Primary healing occurred throughout and only slight stretching of the scars at the lines of union occurred. The general appearance was so satisfactory that a further intervention to smooth up the relaxed scars may not seem necessary when the patient is again seen in a few months.

31 North State Street.

NEW IDEAS ON THE CAUSATION OF VARICOSE VEINS, LEG ULCERS, AND PRURITUS ANI.

By GEORGE EDWARD BARNES, B.A., M.D.,

HERKIMER, N. Y.

On March 2, 1920, I gave an address before the local county medical society in the course of which I presented some original ideas on the causation of varicose veins and leg ulcers. I wish to place these ideas in more permanent form.

Of course, the usually described factors in the causation of varicose veins—superficial location of veins, length of the column of blood moving against the force of gravity, paucity of valves, obstructions to the flow of blood, etc.—retain their validity. But why is it that, when these factors are active, some cases do and others do not develop varicose veins? For instance, why do some pregnant women develop varicose veins while others do not? This is a real, scientific question. The very important and unknown cause is pathetic affectivity, for example the emotion of love, which radiates through the nervous system to the blood vessels and causes them to relax. Indeed, I believe this cause to be the most important and usually the primary one, for apparently it must act in ordinary cases before the other accessory causes can act. In proportion as it is great, the less active may be the accessory causes, and in proportion as it is slight, the greater must be the accessory causes. Fortunately the activity of pathetic affectivity can be quickly detected in the relaxed arteries by the skilled finger.

There is indication that hypothyroidism predisposes to varicose veins. We should expect this, for we find that hypothyroidism is a frequent accompaniment of pathetic affectivity. Hypothyroidism would tend to weaken the walls of the veins.

It appears that the inner lower aspect of the leg is particularly affected by affective currents, for many nervous people say that when they are momentarily disturbed by any happening they feel a thrill or tingling in this region. Why this local susceptibility should exist I cannot say. However, it may be that the veins of this region are acted on with exceptional facility by affective currents. Similarly, in another region where varicose veins frequently occur, *i.e.* in and around the anus, we often find a disturbance in the nerves in the form of pruritis. By the way, this ailment is not caused by any infection, as is now generally believed, for it occurs characteristically in certain "nervous" people who, are disturbed by pathetic affectivity the moisture of the region acting as a further direct excitant to the over-sensitive nerve bulbs. (Abrasions arising from careless scratching aggravate the irritation.) A gentle cleansing and the application of a drying powder often stops the itching *at once*—a result that could not be obtained if there were a causative infection within the tissues. Any existing infection is secondary, not caustive, and pathetic affectivity is also the cause of the excessive moisture which predisposes to infection.

A form of obstruction to the flow of blood through the internal saphenous veins which I have never seen mentioned may sometimes be a factor in causing varicosity in these veins. While a person is reclining on the side one leg may be placed over and across the other above or below the knee so as to press on the vein.

Since varicose veins are frequent cause of leg ulcers, what I have said about the causation of the former applies to the causation of the latter.

Furthermore, I have observed that the skin of some people, particularly nervous people, is often more easily irritated in the lower tibial region than elsewhere. This irritability is most definitely shown by the eruptions in this region caused by the ingestion of certain substances. These eruptions seem to bear a definite relation to the irritability of the nerves in this region. Though I cannot explain the phenomenon, it seems that this odd local irritability of the skin is of importance in the etiology of ulcers. (It is not dependent upon varicosity.)

Much can be accomplished in overcoming the effects of pathetic affectivity by administering drugs, particularly those of the digitalis group, to increase the tonicity of the heart and blood vessels.

For further information on affective disturbances and neurasthenia see the following articles by the author:

THE HOMIGRADE THERMOMETER.

By F. E. ASPINWALL, M.D.,

WILSEYVILLE, N. Y.

THE Homigrade thermometer scale and its system of temperature measurement are based on the following two facts: (1) The freezing point is also the vital heat zero. In any organism or part thereof this or any lower temperature is incompatible with vital functioning. (2) The human normal within the radius of common sensation is man's natural unit of temperature value and criterion of temperature measurement. With it he compares all of his sensations of temperature and thus estimates temperature values. These two points in the scale are cardinal and deserve fitting figures to mark them and express their values.

With these ideas in mind, 0 was placed at the freezing point and 270 at the boiling point of water, the latter figure being chosen because of consequent desirable figures at other important points in the scale, especially 100 at the human normal. The two fixed points of the scale, therefore, are 0°H. and 270°H., the latter figure, like the number of degrees in a circle, containing even nines.

Like the compass the Homigrade thermometer has four cardinal points, each being marked with the most perfectly fitting figure, as follows: 100 marking the human normal and the upper limit of normal summer heat; 50 marking the line between spring and summer and summer and autumn temperatures; 0 marking the point between autumn and winter and winter and spring temperatures, the point at which with a falling temperature ice forms and with a rising temperature ice melts; —50 marking the lower limit of normal winter cold. These points, therefore, divide the seasonal normals into measures of 50 degrees each.

Thus we have a scale absolutely fixed, with short degrees that necessitate comparatively little use of fractions, and with the most perfectly fitting figures at all important points in the scale. Also the value of every degree and every figure in the scale is definitely and clearly understood, inasmuch as the human normal, which is expressed by the figure 100, is a measure of 100 degrees from the freezing point, each degree therefore being one per cent. of that measure. Hence, every figure in the scale expresses the temperature relatively to both the freezing point and the human normal, a definitely understood measure from the former and a true percentage of the latter. Thus every figure furnishes two definitions for the temperature that it expresses.

In the clinical use of the scale its advantages become clearly apparent, inasmuch as it expresses every temperature as a percentage of the human normal. Thus one knows instantly the percentage of each variation from the normal. And it is most remarkable that it is by variations of 5, 10 or 15 degrees respectively that the temperature reaches a point that is usually safe, dangerous, or fatal. Thus 100°H. (taken preferably in the axilla) signifies a normal temperature; 105°H. or 95°H. a safe departure, often lasting only a day or less, when there is a return to normal; 110°H. or 90°H. a dangerous departure; 115°H. or 85°H. usually a fatal departure.

These figures greatly simplify clinical temperature studies, besides throwing a flood of light on the whole subject. Indeed, the entire Homigrade system is so very simple and natural that but a few minutes' study enables one to master it perfectly.

Notwithstanding the simplicity and naturalness of the Homigrade system it took many years of desultory thought and finally several months of exclusive study to bring the scale out of the unknown; but once it was brought to view its remarkable features and advantages were almost instantly apparent, and it was at once seen to be as perfect as the numerals that compose it; never therefore to be changed the least fraction of a degree.

The socalled Absolute scale which was heralded with no little enthusiasm a few years ago has fallen because it was built on the shifting sands of error. Other scales will fall or be discarded for the same reason, or because their figures are misfits, meaningless or misleading as to values, or because their degrees are too long for use without a constant resort to fractions for ordinary precision. The Homigrade scale will endure because it is founded upon truth and is itself ideally perfect.

Medicolegal Notes.

Liability of Unlicensed Physician for Improper Diagnosis.—A Chinese physician, who, being consulted by a victim of tuberculosis, made merely a superficial diagnosis, informing the patient that his trouble was not tuberculosis, but a disease of the kidneys, and who advised the patient to discard the diet prescribed by other physicians and to take herbs, to the patient's detriment, was held liable in damages under the rule that when one holds himself out as a physician or surgeon, whether licensed or not, and accepts employment as such, he assumes toward the obligation to exercise such reasonable care and skill in that behalf as is usually exercised by physicians or surgeons of good standing of the same system or school of practice in the community in which he resides, having due regard to the condition of medical or surgical science at the time.—Hansen v. Pock, Montana Supreme Court, 187 Pac. 282.

Powers of Local Boards of Health as to Preventing Spread of Garbage.—The Court of Appeals of Maryland holds that a bill by the board of health of Baltimore County to enjoin the City of Baltimore, and one under contract, from spreading garbage in Baltimore County, in that it would prove a source of disease and pestilence and a menace to the health of the people, at least required an answer, in view of Code Pub. Loc. Laws, art. 3, § 247, authorizing the board to apply for injunction to restrain nuisances such as were alleged. The court said, in part: "This is one of the delicate cases courts are sometimes called upon to decide. On the one hand, we have involved what is alleged to be the health of the communities near where the garbage was to be placed, and, on the other hand, we have a large city, with many tons of garbage to be disposed of, and the comfort, safety, and health of its citizens require the garbage to be collected and disposed of in some proper way. . . . It is not possible for courts to always know in advance what the consequences of acts complained of will be, if permitted, but when such facts as are in this bill are admitted, it would scarcely be worth while for the Legislature to authorize and empower either a local board of health or the State board of health to apply for an injunction to restrain and prevent such alleged nuisances, if the parties complained against can simply demur, and not be called upon to answer."—Mayor, etc., of Baltimore v. Coglan (Md.) 115 Atl. 43.

TRAUMATIC AND SPONTANEOUS RUPTURE OF HYDROCELE.

RUPTURE of a hydrocele is not a rare accident and usually does not offer any gravity. Normal physiology and anatomy give data of only secondary importance as to the site and manner of rupture. Rupture gives rise to pain in the scrotum, the disappearance of the preexisting hydrocele, subcutaneous edema, ecchymosis, and occasionally the formation of a hematoma. After rupture, the hydrocele may not recur, but generally the fluid collects in the vaginalis, then presenting the same characters as those of hydrocele. There is a fact which dominates the pathological history of the vaginalis in cases of hydrocele, followed by rupture, no matter what may be the modality or cause of this rupture, namely, the constant considerable thickening of this serosa. It would appear that Reverdin was correct in his surmise that in cases of hydrohematocele from rupture of the vaginalis there are always signs of a chronic inflammatory process made evident by thickening of this serous structure which may even be so considerable as to give the membrane a cartilaginous consistency. Burdet also maintained Reverdin's point of view, while fourteen cases were collected by Bailly in which at operation the vaginalis was thick-lined to the extent of from three to five millimeters. The thickening is not uniform, but occurs in areas giving the vaginalis an irregular aspect. There may be a series of calcareous plaques, and even complete calcification of the vaginalis has been observed. Usually, however, the lesions are composed of irregular whitish or yellowish areas which are a certain indication of advanced fatty degeneration. Briefly, the lesions are thickening of the vaginalis from sclerosis, and hyaline degeneration of the connective tissue sclerosis, which is so common when the sclerosis is of long standing in the arteries, viscera, and serous membranes. The lesions arising in the vessels of the vaginalis, especially in the paravaginal space, are considerable. Their walls, like the serosa, undergo degeneration and then rupture. Changes in the fibrous tunic are represented by a more or less marked thickening but it can be peeled off from the subjacent vaginalis. The vessels running through it are thickened and dilated.

As to the site of rupture of the distended vaginalis, it would appear that this occurs preferably at its upper juxtafunicular part which normal anatomy shows to be the weak point of the serous membrane of the testicle. This point of view has been confirmed by Delore in spontaneous rupture, but for the traumatic variety many observers believe that the point of application of the traumatic agent is more important. In ten cases of operation for ruptured hydrocele the rupture was found at the upper part in four, four times at the anteroinferior aspect, once below and to the outer side, and once near the raphe. It is also possible that the point of application and direction of the traumatic force may sometimes explain the position of the rupture, but when the vaginalis is torn at several points, it is more likely that these occur at areas of pathological change in the serous membrane.

The shape and size of the rupture are also variable. These may be a slit with even or ragged edges or a rounded or stellate opening, or simply a small aperture through which the hydrocele fluid escapes. It is probable that the fibrous tunic remains intact, its rupture being exceptional. The small vessels are involved in the rupture and hence hemorrhage adds to the size of the swelling. Hematoma is not infrequent when the hemorrhage is considerable and will be seated in the potential cavities of the region, namely, the paravaginal and scrotal spaces. A hematoma may also develop in the cellular tissue of the scrotal septum. In fourteen cases the hematoma was as follows: eight times there was both a vaginal and a paravaginal hematocele; a vaginal hematocele in two, once a paravaginal and scrotal hematocele and lastly, one case of parietal hematocele from infiltration, the vaginalis containing typical hydrocele fluid tinted pink.

The blood comes from either ruptured veins or arteries; the capillaries are distended in hydrocele, and the very vascular fibrous tunic is an evident source of the loss of blood. It is possible that when the bleeding takes place from the vessels of the vaginalis the blood will collect in the cavity of this membrane, and when it is due to injury of the vessels of the fibrous tunic the blood collection will be both intra and extravaginal.

SYNDROME OF TEMPORAL LOBE TUMORS OF THE BRAIN.

THE many symptoms presented by tumors in this locality give special interest to the syndrome, for naturally in brain tumors we first think chiefly of such symptoms as result from intracranial compression. Epileptoid crises are especially common in these cases and according to Mingazzini psychic symptoms of some sort are practically never absent. In an article by Constantini in *Il Policlinico*, for November 11, 1921, xxviii, 11, two case histories are given. In the first the initial symptoms were psychic disorders—a depressive state, followed after several months by disorientation, motor dis-

quietude, mutism, lacrymose state, sitiophobia, inability to comprehend questions and orders, and among nonpsychic symptoms, headache and marked vertigo. The tumor was seated in the posterior part of the left temporal lobe. The other patient presented at the outset psychic disorders with great motor restlessness, coprolalia, ideas of persecution, disorientation, suicidal tendencies, transcortical sensory aphasia; later there were depression, mutism, refusal of food, insomnia, etc. In this case the seat of the neoplasm was the median-posterior portion of the fusiform lobe and third temporal convolution, with some involvement of the second and first.

In cases with epileptoid seizures there have also been noted post-convulsive confusional states with hallucinations having a religious coloring, oniric delirium and visual hallucinations under the form of an aura. Hallucinations of the other special senses are even more common. In some cases euphoria is present, as in frontal tumors: in others bulimia or alteration of character. As to the rationale of these symptoms the greatest divergency is seen. A number of psychiatrists look on the temporal lobe as the seat of definite psychic functions. But the great number and variety of psychic symptoms make this physiological explanation confusing and unsatisfactory. The termination of these cases in apoplectic ictus is also paradoxical, although of course there are minute hemorrhages in the neoplastic tissue.

In tumors of the left side the psychic symptoms may be brought in association with the sensorial aphasia so often present. Knapp mentions paraphasia in this connection as having marked diagnostic significance and Oppenheim particularizes amnesic aphasia as a symptom of left-sided temporal tumors. But aphasia of any type is often absent. Mingazzini, in the interest of diagnosis purely, makes four regions each with its clinical picture. These are the anterior half or two-thirds of the convex aspect of the temporal lobe, the posterior half or third, the inferioposterior aspect, comprising the lingual lobe and posterior half of the fusiform lobe, and the region of the hippocampus and anterior extremity of the fusiform lobe. Leading symptoms of tumor in the first region are defective motility, and on the left side speech disorders; in the second region hemiparesis of the opposite side including some ocular pareses; in the third region general symptoms are chiefly absent and the focal symptoms are pareses of some of the ocular muscles or the facialis, hemiparesis, and hemianesthesia. In the fourth region there are hallucinations of smell and taste. This special symptomatology for regions is not only meagre in the extreme but often overlaps. Since the neoplasms are usually not limited to these arbitrary regions the totality of the clinical picture varies indefinitely. To have value the locality of the point of origin should be determinable, for after the progress of the tumor the number of symptoms, as already seen, is rapidly increased.

AUTOSEROTHERAPY OF CARCINOMA.

THE opinion has repeatedly been expressed that on account of the strong individuality of cancer it cannot be reached save through an autogenous extract. It had been proposed to use both the blood serum and tumor extract of the patient, the latter being practicable, of course, only when extirpation has been practised. In addition to any specific antidotal properties such products would also act by protein shock. The first efforts in the direction of autoserotherapy of cancer were made by Widal, Abrami, and Brissaud in 1913, but the results were practically negative. In 1921 Gaudier of Lille published the outcome of 24 cases of inoperable malignancy, including cancer of the tongue and breast. The effects were an improvement in all directions. Both Widal and Gaudier practised only autohemotherapy. In *Le Progrès Médical* for February 18, 1922, l, 7, Chauvin and Bec give their experience with the same resource. They used the simple technique of Gaudier, which consisted of taking 20 c.c. of venous blood from the patient and reinjecting the serum on the following day. The injections were repeated every third day. The drawn blood was not kept in the incubator for fear that autolysis would occur and anaphylactic properties develop. Room temperature was preferred. Gaudier had learned that intravenous injections were unsafe, and the authors threw the serum into the subcutaneous cellular tissue. Thus used, no reaction of any kind was noted, and while blood counts are not mentioned there was no evidence of a nonspecific reaction.

The first case was one of inoperable cancer of the uterus. The vagina was simply kept clean and blood serum injections were given every three days. Although the general condition improved in several directions, the mass did not diminish to the touch. Death took place rather suddenly and there was no autopsy.

In a second similar case there was no improvement of any kind noted, although the injections were kept up for over five weeks. The third patient was a man of 60 with a cancerous growth of the cheek. It had responded nicely to radium but there was a recrudescence later in which radium would have been contraindicated. Six injections of blood serum were quite without effect, either local or general. The authors' experience was therefore less favorable than that of Gaudier and even Widal's, for the latter obtained some positive benefit, although not in true carcinoma. Gaudier advised at least 20 injections, and the most given by the authors in any case was 11. Of the two women with cancer both were in poor physical condition, presenting fever and the yellowish pallor of the disease. The cancer in the man had attained the size of a mandarin and there was much lympnode enlargement.

It may be recalled in this connection that Bier once obtained most violent local and general reactions from injecting pig's blood into cancer patients (by local is meant reaction in the tumor itself).

This was probably protein shock. The authors are naturally puzzled over the negative outcome of their experiments, although they adhered as far as possible to Gaudier's technique. The latter's report was most thorough, he having made use of controls throughout; and in some subjects, even in advanced cases with cachexia, the improvement was very striking, this class of patients resuming their previously active lives.

The Onion in Medicine.

The ancient Egyptians it is said, were forbidden to eat the onion, garlic, and leek. According to the priests of Pelusium the onion was barred because it caused a flow of tears, hunger, and thirst, and hence was manifestly out of place in fasts and during religious ceremonies. It did not seem right to weep on occasions of joy or to be tormented with hunger and thirst on days set aside for fasting. The Hebrews regarded the onion purely for its culinary value. The Greeks were fond of both onions and garlic. The former were apparently used when drinking to increase thirst and enhance the pleasures of the cup. But in the palmy days of Rome the two vegetables had become largely the badge of the rabble. In the Middle Ages any well-set table contained a plate of red onions. The chief repute of the onion in medicine was as a diuretic and remedy for dropsy. This belief has persisted up to the present time and it is somewhat strange to find that as early as 1853 onions and a milk diet were pronounced the best remedy for dropsy. In 1868 Trastour reported that a case of parenchymatous nephritis, with edema and albuminuria, cleared up under the onion-milk regimen. In addition to anasarca of both legs there has been a hydrothorax. The treatment had provoked a strong diuresis. In 1910 Mongour saw a still more remarkable case of cirrhosis of the liver with ascites clear up, after three days of onion eating, with a critical polyuria. Cruchet had seen a patient with dropsy recover after a period of onion eating—15 or 20 daily. In 1912 Dalche published his article on the "onion cure." He spoke of a case of a three-quart diuresis produced in a dropsical patient by this resource. During the war Leclerc to whom we are indebted for the preceding information (*La Presse Médicale*, February 25, xxx, 16) frequently witnessed this diuretic action in soldiers, notably in a Senegalese with serous effusions and dropsy due to nephritis.

Extraprostatitis.

The continual introduction into medical literature of new terms believed to be applicable to newly recognized conditions is a custom to be deplored, especially when, as usually happens, some term in familiar use covers the condition satisfactorily. The situation is the more confused when the old designations are ignored entirely, this omission leaving the reader in doubt of the attitude of the writer toward the old nomenclature. As a case in point we may cite an article by Aversenq in the *Journal d'Urologie* for December, 1921, xii, 6, entitled "Sur les extraprostatites d'origine uréthrale." The author had made some elaborate studies on periprostatic and perivesical abscesses which included injection of the connective tissues with colored gelatine. Pockets or potential cavities were found on either side of the posterior periprostatic aponeurosis, which distinction suggested the use of a term "extraprostatitis" as a contrast to periprostatitis. It should signify the presence of suppuration in the extraprostatic spaces which is cognate with similar suppuration in the extravesical space. According to the author these terms were first proposed in 1910 and again in 1913, but whether by himself or others is not mentioned. The ordinary medical reader would doubtless note the complete omission in this article of the term paraprostatitis, which leaves him quite in the dark as to whether this is regarded as an entirely distinct condition, or as a term to be superseded by one more appropriate. The author refers specifically to a case of extraprostatic phlegmon originating in urethral infection, with perirectal extension.

News of the Week.

Sale of the Medical Record.—This journal has been sold to Mr. A. R. Elliott of New York City. Its last issue as an autonomous medical weekly, under the present editorial management, will be that of April 22.

Mortality from Typhoid Fever in the United States.—The Department of Commerce, through the Bureau of the Census, announces a steadily decreasing mortality rate from typhoid fever. The figures show a decrease in the registration states from 13.3 per 100,000 population in 1916 to 7 in 1920. In 1920, of the States in the registration area Massachusetts and Wisconsin share the honor of having the lowest rate (2.5), while the highest (22.4) appears for South Carolina. Of the eleven States showing rates by color, the lowest rate for the white population was 3.6 and the lowest for the colored was 4.6, both for New York State, while the highest rate for the while population was 19.1 for Kentucky and that for the colored was 30.2 for the same State. Of the 33 States tabulated for 1919 and 1920 only nine show higher rates for 1920 than for 1919.

Precautions Against Typhus Necessary.—Colonel Edward C. Gibbs, who was sent to Poland by Health Commissioner Royal S. Copeland to study typhus conditions, states that strict precautions are necessary to prevent the scourge from spreading to this country. He was informed by the Soviet Minister of Health that there are only 3,000 doctors for the entire 30,000,000 population of Poland. Rovno, the principal port of entry for people coming from Russia, is badly overcrowded and typhus is rife. The death rate from the disease is said to be 25 per cent.

Uniform Budget System for State Hospitals.—A uniform budget system for all State hospitals and those that receive State aid became effective in Pennsylvania on March 1, according to an announcement made by Dr. John M. Baldy, Commissioner of the Department of Public Welfare. Pennsylvania is the first State in the Union to have uniformity in its hospital accounts. Such

a uniform system of accounting will furnish information to the Legislature in regard to State and private institutions asking appropriations, and according to Dr. Baldy will eliminate the log-rolling during legislative sessions in connection with these appropriations. It will also make possible a comparison of the work done by one hospital with that of another and will lead to a more equitable distribution of funds.

To Investigate Alleged Irregularities in Issuance of Licenses.—Governor Small of Illinois has appointed Dr. E. P. Sloan, president-elect of the Illinois Medical Society, the third member of a committee of physicians who are to investigate alleged irregularities relative to the issuance of licenses and certificates by the State Department of Registration and Education. Dr. W. L. Noble of Evanston is chairman of the committee, and Dr. W. A. Evans secretary. The names and addresses of the committee have been published, with an invitation to all who have any information bearing on examinations or the issue of licenses to voluntarily communicate with one or all of the members.

Kings County Doctors Discuss Workmen's Compensation Act.—A joint meeting of the Medical Society of the County of Kings and the Professional Guild of Kings and Queens Counties was held on the evening of March 30 for the purpose of establishing a better understanding between physicians and insurance companies in relation to the Workmen's Compensation Act. Among the speakers were Henry D. Sayer, Industrial Commissioner of the State of New York, and Thomas D. Curtis, vice-president of the State Federation of Labor. It was argued by the doctors that if the bill which has been introduced in the State Legislature at Albany during the past several years is eventually passed the compensation act will indeed become worth while, as the bill will give injured employees the free choice of physicians and thus eliminate the insurance companies' practice of dictating to employer and employee as to the selection of a doctor.

Clean Up Week.—The week beginning April 17 has been designated as Annual Clean Up Week in New York State by Dr. Hermann M. Biggs, Commissioner of Health. In a letter to mayors, village presidents, and boards of health the Commissioner calls attention to the practical importance of civic cleanliness in the promotion of order, decency, and public health. Local authorities are urged to take all necessary steps to secure cooperation of citizens in the collection and disposal of accumulated refuse. Suggestions for the formation of local committees and the organization of the work in order to obtain effective results are included with the letter.

Epidemic Encephalitis Increases in New York.—The New York City Health Department reports that there has been an increase in the number of cases of epidemic encephalitis in this city during the past two weeks. About 300 cases of the disease have been reported since the first of the year, with 70 deaths. In 1920 there were 654 cases and in 1921 528 cases. There were five more deaths from the disease during the week ended March 25 than during the corresponding week of 1921. The increase in the prevalence of the disease is not considered sufficient to cause alarm.

To Aid Mental Health.—In a State-wide effort to inform the general public how to preserve mental health, the Mental Hygiene Committee of the State Charities Aid Association has obtained the voluntary services of thirty-one psychiatrists and other authorities on mental hygiene for public addresses. These lectures will emphasize the fact that mental health is within the reach of many people who are at present afflicted with mental disease. Speakers will be made available upon application to Stanley P. Davies, secretary of the committee, 105 East Twenty-second Street.

Infant Death Rate Inquiry.—The United States Public Health Service advocates a Government inquiry into the reasons for the annual death toll of American babies. In a statement issued April 7 the service states that more than 100,000 of the 250,000 children who die every year die from causes connected with their birth and the need of further study and investigation of these causes is urgent.

Hospitalization Measure Passes Senate.—The disabled soldiers' hospitalization bill, appropriating $17,000,000 for increasing hospital facilities for disabled service men, has been reported to the Senate without changes in the form in which it passed the House. The bill will be acted on at an early date.

Tonsil Operations Increase.—According to a recent report of the Hospital Bureau of the Public Health Committee of the New York Academy of Medicine, the percentage of children needing tonsil and adenoid operations has increased from 10 per cent. to 15 per cent. in the last ten years. Tonsillitis, it is asserted, causes more absences from school than any other one illness. To relieve the general hospitals of the large number of tonsil cases with which they were overtaxed, the Tonsil Hospital, at 153 East Sixty-second Street, was established about two years ago. It has a capacity of 2,000 cases a year, and during the year 1921 over 800 free tonsil operations were performed for those unable to pay the usual fee.

American Physicians Meet in Rochester.—The American Congress of Internal Medicine and the College of Physicians held its sixth annual meeting in Rochester, Minn., during the week of April 2. The program included four days of clinical work and conferences at the Mayo Clinic and a two-day session at the University of Minnesota School of Medicine. Changes in the constitution and by-laws of the organization have been agreed upon which, according to the statement of Dr. Frank Smithies of Chicago, secretary-general of the organization, will place the practice of internal medicine on the same high plane ethically that surgery now enjoys through the efforts of the American College of Surgeons. The requirements for fellowship in the American College of Physicians are as follows: Each must be a graduate of a medical school of the first rank. He must be a member in good standing of his local, state, or national societies. He must be a licentiate in the State wherein he resides, or engaged in practice or scientific research in a hospital or recognized institution. He must be at least 25 years of age

and have received his diploma at least five years before receiving his fellowship. He can be in no way connected with any organization which commercializes the practice of medicine. In addition, it is required that the applicant for membership be engaged in teaching or research, in charge of a hospital of 100 or more beds, or affiliated with medical or laboratory departments of the United States or Canadian Army, Navy, or Public Health Service. In default of these attainments, he must have submitted a clinical report of fifty patients who have been actually under his care.

National Hospital Day.—The celebration of National Hospital Day last year was found to be so generally helpful that the United States Public Health Service heartily approves its repetition this year on Friday, May 12, the anniversary of the birth of Florence Nightingale. On that day the public will be invited to visit the hospitals in their vicinity as guests and to familiarize themselves with their methods and aims.

Hospital Notes.—The First Institute of Podiatry has purchased property at 51 and 53 East 124th Street, where it will erect a clinic for the treatment of foot ailments and a school for the training of students of scientific podiatry.

The West Texas Hospital, located at Lubbock, was opened to receive patients on March 15. The cost of the new institution was $125,000.

A State charter has been granted to the Drayton Community Hospital Organization, which plans to build a community hospital at Drayton, N. D.

The Allentown (Pa.) Hospital Association has purchased a tract bounded by Gordon, Chew, West and Seventeenth Streets, upon which a new hospital building will be erected.

The Convalescent Home for Hebrew Children at Rockaway Park, New York, was formally dedicated on April 8. The old buildings have been renovated and two new wings added. The home is now open all the year for the care of crippled children.

A campaign has been initiated by the American Legion posts of Minnesota to raise $250,000 for an American Legion Memorial Hospital to be built at Rochester, Minn.

The cornerstone of the Northern Liberties Hospital, Philadelphia, was laid on April 2. Governor Sproul, Mayor Moore, and prominent clergymen and physicians participated in the ceremonies. The new hospital will cost approximately $100,000.

The board of directors of the Bushwick Hospital, Brooklyn, contemplates the erection of a new wing to the institution at Putnam and Howard Avenues.

What was formerly known as the Baer Maternity Hospital at Allentown, Pa., has changed its name to "Baer Hospital for Women." The change has been made because the old name was misleading, leaving the impression that only one line of work was done at the institution, whereas surgical work in general is practised at the hospital.

The Oklahoma State Soldier Hospital Commission has awarded the contract for the soldiers' memorial hospital to be built at Enid, Okla., at a cost of over $200,000. Plans have been prepared for additions to the Warrensville (Ohio) Tuberculosis Sanitarium, which will double the capacity of that institution. The estimated cost of the proposed improvements is $250,000.

The new municipal hospital at Youngstown, Ohio, is about completed and will be ready to turn over to the city in a short time.

A campaign is being conducted to raise $1,000,000 to build, equip, and endow the new Homeopathic Hospital of Rhode Island, located in Providence.

Tentative plans have been approved for a $25,000 addition to the Irene Byron Tuberculosis Hospital at Fort Wayne, Ind. Dr. Charles Teall has been appointed to the Board of Managers of the hospital for a term of three years.

The West Duluth Commercial Club has started a drive for funds for the proposed Miller Hospital and free dispensary to be located in the western section of Duluth, Minn.

The formal dedication of the new $3,000,000 hospital building of Mount Sinai Hospital, New York, took place on April 9, when Myron S. Faulk, chairman of the building committee, formally presented the buildings for acceptance by George Blumenthal, president of Mount Sinai.

Ground has been broken for a new hospital to be erected in San José, Cal., at the corner of Fourteenth and Santa Clara Streets. The hospital will have 85 rooms and be thoroughly modern in every respect.

The Board of Hospitals and Homes of the American White Cross of the Methodist Episcopal Church is conducting a campaign to raise $175,000 for the hospital building being erected at Eighth and Faraon Streets, in St. Joseph, Mo.

The Fairmont Hospital, at 1055 Pine Street, San Francisco, has been sold to Dr. A. W. Morton for $150,000, and was opened April 1 as the Santa Fé Hospital with 100 beds. This hospital has no connection with the Santa Fé Railroad.

The contract for the $500,000 soldier memorial hospital at Muskogee, Okla., has been let.

Testimonial to Dr. George E. de Schweinitz.—A banquet was tendered Dr. George E. de Schweinitz of Philadelphia by the Philadelphia County Medical Society on the evening of April 4 in honor of his election to the presidency of the American Medical Association. The speakers included, in addition to the honored guest, Dr. J. Norman Henry, President of the Philadelphia County Medical Society; Dr. Edward Martin, Pennsylvania State Commissioner of Health; Dr. Hubert Work, President of the American Medical Association and Postmaster-General of the United States; former Surgeon-General Dr. William C. Braisted; Dr. Ross V. Patterson, Dean of Jefferson Medical College, and Dr. John G. Clark, Professsor of Gynecology in the University of Pennsylvania. By arrangement, the subjects discussed had to do mainly with medical education, preliminary or preparatory, undergraduate, and postgraduate, including a form of university extension. Dr. Hobart A. Hare acted as toastmaster.

Dinner to Dr. S. Josephine Baker.—The date of the dinner which is being arranged by various organizations and friends in honor of Dr. S. Josephine Baker has been changed and it will be held at the Commodore on April 25.

Dr. William S. Halsted of Johns Hopkins Uni-

versity was presented with a gold medal by the National Dental Association on April 1, in recognition of his work in neuroregional anesthesia. The Maryland State Dental Society was host at the dinner in honor of Dr. Halsted. Among the speakers was Dr. William H. Welch, who told of his association with Dr. Halsted in New York nearly forty years ago when he made the discovery for which he was now being honored.

Dr. Oscar M. Craven has been appointed Health Commissioner of Springfield, Ohio.

Dr. Joseph Rubsam has been elected president of the staff of St. Joseph's Hospital, Logansport, Ind.

Prof. William Duane of the Department of Physics of Harvard University has been awarded the John Scott medal and certificate, with premium of $800, by the Board of Directors of City Trusts of Philadelphia for his researches in radioactivity and *x*-rays. The award is made annually for scientific achievement in accordance with the terms of a bequest over a century ago by John Scott. Last year the winner was Mme. Curie.

Vacancies for Physicians in Indian Service.—The United States Civil Service Commission announces an open competitive examination for Junior Medical Officer in the Indian Service and in the position of surgeon in the Coast and Goedetic Survey, at salaries from $1,000 to $1,200 a year with maintenance, transportation, drugs, and equipment. Appointees whose services are satisfactory are allowed the increase granted by Congress of $20 a month. Applicants should apply at once for Form 1312, stating the title of the examination desired, to the Civil Service Commission at Washington, D. C., or to the Post Office or Custom House of any large city in the United States.

Positions for Occupational Therapists.—The New York State Civil Service Commission announces a written examination to fill six positions for chief occupational therapist in State and county institutions. Candidates must have had special training in occupational therapy and experience in the treatment of mental patients by occupational therapy. A vacancy is also announced for a director of occupational therapy at a salary of $3,500 to $4,000 with full maintenance while on duty at hospitals. Candidates must have had special training in occupational therapy for mental patients, experience in the training of occupational therapists, and experience in the organization and direction of occupational therapeutics. A total of at least five years' experience is required. Applications for examination for the former positions may not be accepted after April 19, and for the latter not after April 27. Application forms may be had by addressing the Civil Service Commission, Albany, N. Y.

Medical Society Elections.—The Panhandle Medical Association, at its annual meeting held at Amarillo, Tex., March 25, 1922, elected the following officers for the ensuing year: *President*, Dr. Winfred Wilson, Memphis; *First Vice-President*, Dr. H. L. Wilder, Clarendon; *Second Vice-President*, Dr. G. A. La Grand, Hereford; *Secretary*, Dr. J. J. Crume, Amarillo.

The Asbury Park Medical Association, at a meeting held March 25, 1922, elected the following officers for the ensuing year: *President*, Dr. Joseph Ackerman; *Vice-President*, Dr. Earl C. Wagner; *Treasurer*, Dr. James Fisher; *Secretary*, Dr. R. E. Watkins, Belmar; *Censors*, Drs. Charles Prout, C. M. Trippe, Asbury Park, and C. J. Massinger, Ocean Grove.

The Kansas City Academy of Medicine, at its thirty-second annual meeting held on March 31, 1922, elected the following officers for the ensuing year: *President*, Dr. George E. Bellows; *Vice-President*, Dr. Joseph Lichtenberg; *Secretary*, Dr. W. A. Myers; *Treasurer*, Dr. Joseph W. Kimberlin; *Censor*, Dr. Eugene P. Hamilton.

Public Health Clinics in Philadelphia.—The Department of Public Health has established at the Philadelphia General Hospital five clinics—genito-urinary, heart, prenatal, neuropsychiatric and radiological—to meet the need for the care and treatment of cases which do not require bed-side care, and for the purpose of preventing certain diseases by the early study and correction of physical defects. A Medical Social Service Department follows the cases closely.

The School of Medicine of the University of Alabama, which has recently been reorganized, has been recognized as a Class A school by the Council on Medical Education of the American Medical Association.

Charitable Bequests.—By the will of the late John E. Baird, formerly of Philadelphia, and who died recently at Honolulu, bequests are made as follows: Hospital for Diseases of the Chest of the Protestant Episcopal City Mission at Chestnut Hill and Kensington Hospital for Women, each $5000.

By the will of the late Henry Alexander Laughlin, of Philadelphia, formerly of Pittsburgh, the sum of $50,000 is bequeathed to the Passavant Hospital of Pittsburgh.

Obituary Notes.—Dr. George Gordon Needham died of heart disease and pneumonia at his home in New York on April 5, at the age of eighty years. He was graduated from Bellevue Hospital Medical College in 1865. He was a member of the American Academy of Medicine, the New York Academy of Medicine, and the County and State Medical Societies, and a Fellow of the American Medical Association.

Dr. Joseph Simpson Wise of Lincolnton, N. C., a graduate of the Kentucky School of Medicine, Louisville, in 1890, died on March 12, at the age of fifty-three years.

Dr. Ernest William Downton of Starrucca, Pa., a graduate of the Medico-Chirurgical College, Philadelphia, in 1902, died of scarlet fever on March 12, at the age of forty-nine years.

Dr. John F. Butler, for many years a practitioner of medicine in Wylie, Tex., died on March 11, at the age of eighty-five years.

Dr. Robert C. Cottingham of San Francisco, a graduate of the University of Missouri School of Medicine, Columbia, in 1883, died suddenly on March 11, at the age of sixty-nine years.

Dr. Louis W. Schultze of New York died of heart disease on March 24, at the age of sixty-five years. He was graduated from the College of Physicians and Surgeons in 1881. In 1888 he became

coroner of New York County, holding this position until 1894, when he was appointed medical inspector of the Department of Charities, in which capacity he served for eighteen years.

Dr. V. E. Max Koehler, formerly of Cincinnati, Ohio, died at his home in New York on March 16, at the age of sixty-nine years. He received the degree of Doctor of Medicine from the University of Leipsic in 1875. He was for many years instructor in the Ohio Medical College, Cincinnati. He was a member of the American Medical Association.

Dr. John Erastus Weaver of Elmlra, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1875, died on March 17 at the age of seventy-four years.

Dr. Joseph Walter Bannan of Providence, R. I., died in a local hospital following an operation, on March 16, at the age of thirty-two years. He was graduated from the Medico-Chirurgical College, Philadelphia, in 1915.

Dr. J. Eugene Jordan, a former member of the Seattle Board of Aldermen, died on March 21, at the age of seventy-seven years. He was a graduate of the Hahnemann Medical Institute, Chicago.

Obituary.

HENRY LOWNDES LYNAH, M.D.

NEW YORK.

Dr. Henry Lowndes Lynah of this city died at Charleston, S. C., on March 31, at the age of forty-three years. He was graduated from the Medical College of South Carolina in 1900. He was a member of the American Laryngological, Rhinological and Otological Society of the New York Academy of Medicine, of the Medical Societies of the County and State of New York, and of the American Medical Association. He was laryngologist to Riverside and Willard Parker Hospitals; laryngologist and otologist to the Kingston Avenue Hospital; assistant surgeon to the New York Eye and Ear Infirmary; assistant laryngologist to the University and Bellevue Dispensary. Dr. Lynah was chairman of the Section on Laryngology of the Medical Society of the State of New York this year and also of the Section on Laryngology of the New York Academy of Medicine. He was a recognized authority on bronchoscopy and esophagoscopy.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, March 24, 1922.

The Needs of the Hospitals.—One of the predominant questions of the medical world here to-day is the plight of the hospitals. While there has been almost endless discussion of the subject no really workable decision has been reached of solving the problem. After all, the situation is extremely difficult and no doubt a compromise is the only way out. An important conference of medical representatives of voluntary hospitals in England and Wales was held in London on March 22 last to discuss a report issued recently by the Council of the British Medical Association on the hospital policy. The debate dealt chiefly with the fact, that although hospitals are to continue their purely charitable work for indigent patients, they are concerned also at the present time with tariff patients, and the British Medical Association was successful in securing the approval of the conference in its endeavor to insure the payment of medical staffs for services which they now give gratuitously. It is proposed that it should be optional whether such remuneration should be personal or whether it should form a fund for medical research and education. The part of the report which refers to this matter reads as follows: The association recognizes a dual policy as regards the voluntary hospitals: (1) That the purely charitable side should be continued wherein the whole cost of the maintenance of indigent patients is met by the gratuitous contributions received by the hospital and on whose behalf the services of the honorary medical staffs are given gratuitously; (2) that other patients who are not indigent may be received for treatment at voluntary hospitals when adequate treatment cannot be obtained elsewhere and that for them payment should be received by the hospital either from the patients themselves or on their behalf from the authority or body referring them to the hospital, and that on account of their treatment some method of remuneration of the honorary medical staff should be arranged. The reception of the report was moved by Mr. Bishop Harman, chairman of the Hospitals Committee and the following amendment was moved by Mr. Batt, Bury St. Edmunds, and West Suffolk Hospital. That the report of the council of the British Medical Association, be not received in its present form; but that this conference maintains (1) That payment of the honorary medical staff in any form in incompatible with the maintenance of the voluntary system and must lead ultimately to State control; and that (2) that payment by or on behalf of patients, other than private patients, for a part or the whole of their maintenance does not necessitate any payment to the honorary staff. He pointed out that the essential principle upon which they had to decide was the question of payment or nonpayment of the staffs, and he was of the opinion that the conference should give a clear decision thereon before proceeding to any other business. He said that he and his colleagues felt that the voluntary system was intimately bound up with the honorary

position of the medical staff and that the payment of the staff in any shape or form was going to expedite the end of the voluntary system and they asked the conference to face that problem. The amendment was defeated by a large majority and the report was received. There was a great deal of discussion on the paragraph in the report in which the voluntary hospital was defined. Some delegates contended that any payment to the medical staffs was inconsistent with the word voluntary, on the other hand, it was urged by many members that the payment of an honorarium to the honorary staffs out of fees received from patients well able to pay for treatment did not destroy the voluntary principle. Eventually the paragraph recording the belief of the association "that the voluntary method of administration of the voluntary hospitals of the country is to the advantage of the public medical science, and the medical profession, and that it should be maintained and that the essence of the voluntary hospital system is the independent and voluntary management, and that this is not necessarily related to the conditions of service of the medical staff" was carried by a large majority. As said before, although the discussion on the question of the payment of medical staffs was hot and furious it was finally decided that that part of the report advocating their payment should stand. However, no ultimate decision regarding the management of hospitals here has been arrived at. It is difficult indeed to upset traditional methods, even if it were advisable to do so, at least, not all of them at once, and this seems to be the case with the British hospitals. The motto seems to be to move slowly, but this matters but little if the movement is progressive, sure and to the best advantage of all concerned.

Colored Vision.—A meeting of the Section of Ophthalmology of the Royal Society of Medicine held on March 10, a discussion on colored vision was opened by P. G. Doyne, F. R. C. S., who pointed out that colored vision was associated with a variety of conditions, physical, and pathological, the most generally familiar form being, perhaps, that following exposure to snow, or that which may appear to those who have had cataractous lenses removed. Mr. Work Dodd had described in Vol. 19 of the Transactions of the Ophthalmological Society, a state of green vision in a man the subject of tabes dorsalis, and in the next volume he presented records of thirteen cases of the condition: three of them had lead poisoning, three were myopic, one had detachment of retina, one had tabes, in three there was active choroiditis, two had migraine, and one had wound of the cornea with prolapse of iris. Mr. Treacher Collins had told Mr. Doyne that colored vision might be associated with (1) changes in the visual media of the eye; (2) after images; (3) might depend on the position in which light impinges on the eye; (4) pathological retinal and nerve irritation; (5) cortical disturbance; (6) functional. Mr. Doyne during the past few months had collected eleven cases of various forms of colored vision. In the discussion that followed Mr. M. S. Mayon described a case of colored which came to him for treatment, the subject was a taxicab driver, who dare not take his cab out at night as he saw approaching lights as a red wall, and could not discern whether lights were approaching or receding. Nothing wrong was found in the fundus, but probably there was present some arteriosclerosis. He was about 50 years of age. He became much better in four months and resumed work. Mr. Leslie Paton said tabetics seemed often to have had green vision, but no cases of red vision in subjects of this disease were on record. In connection with the amaurosis associated with cerebral tumors the temporary attacks of blindness were sometimes accompanied by definite color scotomata, now and then in the form of a golden meshwork. Color scotomata were also seen sometimes in patients with migraine. The president, Dr. James Taylor, said that some patients with optic atrophy saw a pale blue mist in times of twilight. Mr. Frank Juler referred to a case of a medical man who five months after a cataract operation had erythropsia and purple vision. The patient himself, who at one time was a professor of physiology, suggested that the phenomenon was due to a change induced in the reaction of the visual purple by the excess of blood which got in; that there might be some disturbance of the vitreous which acted chemically upon the retina. Mr. Affleck Greeves told of a case of a lady with central cataract, who was given weak atropine drops and who complained that when she went out of doors everything looked green, and when she returned to the house everything had a red coloration. Mr. W. I. Holmes Spicer referred to the blue vision of people just after an extraction of cataract had been done; also, people with retinal hemorrhages were able to see patches of blood in their retinae. Fuch's explanation of the purple vision after the dazzle of snow was that the glare exhausted the visual purple and this was followed by a rapid resecretion of the visual purple.

Jenny Lind Hospital for Children in Norwich.—This hospital, named after the celebrated Swedish singer, has an interesting history. In 1849 Jenny Lind gave two concerts in St. Andrew's Hall, Norwich, and expressed a wish that the proceeds should go toward the founding of a new charity of the poor of that city. The first building of this foundation was situated in the center of Norwich, but in 1900 was replaced by an up-to-date modern hospital erected on the outskirts of the city. The annual report for 1921 has just been published and it is stated therein that great progress has been made and a record established in every department. The committee expressed themselves as gratified by the large number of cases stated to be "cured," viz.: 75 per cent.; 7.5 per cent. were marked "relieved"; 8.5 per cent. discharged for special reasons or remained *in statu quo;* 5 per cent. died; and 4 per cent. remained in hospital at the end of the year.

OUR LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, April 1, 1922.

Regulating the Sale of Narcotics.—On January 23, 1912, an agreement was concluded at the Hague which regulated the sale of opium and its deriva-

tives and cocaine, an agreement signed by Switzerland, but which has not as yet been ratified. This agreement had especially in view the restraint of the illegal sale of narcotics and for this reason is of utmost importance to Switzerland just at present where the abuse of products such as morphine and cocaine begins to assume disquieting proportions. Hence, the question of ratification of the Hague convention is now the order of the day. But this agreement must be carefully studied and first of all it is essential to ascertain what are the legitimate needs of Switzerland as regards the products envisaged by the Convention. Therefore, in order to ascertain approximately this point, The Federal Service of Public Hygiene has addressed a circular to pharmacists, asking what amounts of each of these products each pharmacist annually employs, viz., opium, morphine, heroine, dionine and cocaine (ecgonine). The replies are to be regarded as strictly confidential.

Kala Azar and Bedbugs.—As the result of prolonged investigation into the causes of kala azar (Assam fever), Mrs. Adie has discovered a parasite in the salivary glands of the bedbug. The parasite is probably a stage of the Leishman-Donovan body which causes kala azar. The idea that this disease is carried by bedbugs was put forward some considerable time ago, particularly by Sir Leonard Rogers, the distinguished ex-medical officer of Calcutta, who has done so much pioneer work in connection with kala azar. Mrs. Adie is the widow of a physician, who, it appears, was greatly interested in the subject and since her husband's demise she has continued the research work herself at Delhi. Kala azar was formerly one of the most lethal diseases of India and entire villages were frequently ravaged by it. However, Rogers' work showed that if the village was removed from one site to another the disease was frequently much reduced in extent. Mrs. Adie believes that her parasite represents a phase in the life history of the Leishman-Donovan body and if she is correct, then the chain of evidence is complete and the bedbug stands convicted. So enormously numerous is this parasite in India that its destruction is said to lie outside of the range of possible measures, but Rogers believes that the best method of prevention is the use of antimony. Provided there are no infected persons for the bugs to bite, there can be no spread of the disease.

A Culture Medium for Rickettsia.—It is now believed that Kuczynski has finally succeeded in growing *Rickettsia prowazeki*. This observer laid stress on the fact that this Rickettsia seems to be an obligatory intracellular organism, as well when it lives in the house as in its cycle in man. Its mode of life is thus exclusively anaerobic and in a medium composed of elements different from those of the ordinary blood plasma. The suitable culture medium which he finally devised was one in which the blood plasma is diluted and modified so as to resemble in its composition the human tissue lymph.

To avoid accumulation of metabolic products that he considers to be very harmful to the organism in question he used a method of Metchnikoff, which consists of growing the culture in collodium bags implanted in the abdominal cavity of guinea pigs. By this method in repeated experiments he cultivated the Rickettsia from the brain tissue of infected guinea pigs; the organism grew luxuriously and, he claims, in pure culture after recultivation. Guinea-pigs inoculated with these Rickettsia cultures developed the well-known types of pyrexia characteristic of experimental typhus, and were immune from further inoculation with ordinary typhus virus. If these findings are confirmed, then, as Kuczynski himself says, by obtaining the organism in pure culture from infected guinea pigs and reproducing the disease with this culture, the etiological chain for typhus fever will be closed. It is possible that the defenders of the theory of filtrable virus will consider the matter not yet settled, since the invisible virus may have grown at the same time in the supposedly pure culture of Rickettsia. But a similar objection might also be raised against recognized pathogenic organisms of many other diseases.

Shock.—Prof. Arthus of Lausanne, in his book: *De l'Anaphylaxie à l'Immunité*, recently published, says that "it is possible to verify that the production of certain precipitates in the blood does not give rise to accidents having the character of seroanaphylactic accidents." As a proof of this he shows the innocuousness of intravenous injection of an emulsion of white beeswax, and nevertheless, this emulsion precipitates in presence of blood serum.

This fact might at first appear to invalidate the physical theory of shock, but when examined more closely it will be found that Arthus resorted only to intravenous injections. Now, Lumière and Couturier, of Lyons, have shown that many insoluble substances do not produce shock when injected intravenously or into the right heart, but on the contrary, invariably provoke anaphylactoid accidents when injected into the left heart. Ligature of the carotids completely prevents the occurrence of these accidents while, on the contrary, an injection into the carotids produces effects of maximum intensity.

All the investigations of Lumière and Couturier tend to prove that shock does not ensue unless the precipitates or floccular substances suddenly reach the vessels of the nervous centers. The passage of these precipitates into the pulmonary or peripheral capillary circulation arrests or delays their mechanical action on the endothelium of these vessels and this is exactly what takes place when an emulsion of wax is injected into the marginal vein of a rabbit's ear. The relatively large globular wax elements which form by the mixture of the emulsion with the serum, are retained in the capillaries and cannot exercise a sudden central action which is essential for the production of an anaphylactoid crisis.

In order to confirm these views, Lumière and Couturier repeated the incomplete experiments of Arthus, employing an emulsion of white wax according to the latter's technique. An injection of 1 c.c. into the right heart of guinea pigs gave rise to no shock, but when injected into the left heart a characteristic crisis ensued, with all symptoms of shock. According to the dose the accidents are slight or end in death. After ligature of both carotids the intracardiac injections remain with-

out effect. If five centigrams of sodium hyposulphite are dissolved in 1 c.c. of the wax emulsion the mixture becomes inactive, although the addition of this salt has a pronounced tendency to determine the reunion and precipitation of the dispersed wax elements. A non-lethal dose of wax emulsion injected into the left heart vaccinates animals for about twenty-four hours against barium shock or even against true anaphylactic shock in sensibilized guinea pigs. Inversely, animals having survived a paralethal dose of barium sulphate become insensible for twenty-four hours to an intracardiac injection of Arthus' emulsion. The latter's experiments, completed by those of Lumière and Couturier, far from invalidating the conceptions previously put forth by the latter two observers confirm, on the contrary, their views and constitute another argument in favor of the physical theory of shock.

1. The Theory of Psychoanalysis. John F. W. Meagher.
2. Achylia Gastrica. Louis Fischbein.
3. The Extraction of Non-Magnetic Foreign Bodies from the Anterior Chamber of the Eye. William F. O'Reilly.

2. Achylia Gastrica.—Louis Fischbein, in a careful study of thirty cases of primary *achylia*, found gastric hypermotility in every instance. After considerable straining and retching on the part of the patient, not more than 10 to 15 c.c. of gastric contents could be obtained, consisting of a thick, practically neutral liquid with an admixture of mucus from the throat, in which were suspended a few poorly digested crumbs of bread used in the test meal. Achylia is not only a disturbance in secretion, but a disturbance in motility as well. Primary achylia, in the sense in which the essayist uses the term, is found almost exclusively in neurotics. It occurs more often in men than in women, and is more common in young adults and in the middle-aged than in the elderly. Neither is achylia due to primary cell atrophy in consequence of some local infection, as maintained by Bassler, as his observations were made upon pieces of gastric mucous membrane obtained in vivo, which are not indication of any pathological changes in the stomach. Besides, primary cell atrophy, even if it does exist, need not involve all the secreting cells, and thus give rise to achylia. Achylia is, like hyperacidity and hypersecretion, either a symptom or a part and parcel of a general neurosis. Practically all the patients in this series were pronounced neurotics, the majority of them being in the prime of life and in good physical condition, with no history of antecedent infection, intoxication or other illness, to which their gastric disturbances could be attributed. In some the local as well as the general symptoms disappeared under treatment; in others, the local symptoms disappeared, while the general symptoms persisted. Some, after getting rid of their digestive disturbances, complained of headache, dizziness, or a feeling of faintness, so that there could be no doubt as to the nervous nature of the affection. Further, experiments have shown that emotional states are followed by actual physiological and chemical changes; but why these changes should, in some cases, give rise to a hypersecretion or hyperacidity, and in others to anachlorhydria or achylia, is not known and can only be surmised in analogy with nervous disturbances elsewhere. The treatment of achylia is general, dietetic and medicinal. The general treatment comprises a variety of methods, of which psychotherapy is the most important. A mixed diet is employed from which those foods alone are excluded which, by their chemical or mechanical action, might cause irritation and distention of the stomach. Dilute hydrochloric acid, which has been highly recommended by almost all authorities as the drug *par excellence* in achylia, has been found, in the writer's experience, to be not only of no benefit whatever, but, in some cases, even to aggravate the dyspeptic symptoms; neither has he seen any benefit from nux vomica, tr. cinchonæ comp., and the other so-called stomachics. On the other hand, drugs like the bromides, chloral hydrate, extract of valerian, and tr. opii, have been found of decided benefit.

3. The Extraction of Non-Magnetic Foreign Bodies from the Anterior Chamber of the Eye.—William F. O'Reilly reminds us that text-books advise the removal of foreign bodies in the anterior chamber and iris by the use of forceps inserted through a keratotomy wound lying close down to the iriditic angle, eliminating a posterior lip. To a keratotomy no exception can be taken, but to the forceps, no matter how ingeniously constructed or deftly manipulated, the exceptions are obvious. To overcome the embarrassments and complications that may arise in the use of forceps the following method is recommended: A two-inch strand of horse hair is looped and the free ends inserted into an ordinary broach holder. The loop of hair is sized and moulded and bent to suit the individual case. The usual low non-posterior lip keratotomy is made nearest the foreign body. The incision should be small, just enabling the loop to enter the chamber and pass over the foreign body. The distal end of the loop is depressed and the foreign body drawn toward the corneal opening. Several engagements of the body by the loop may be necessary before the body reaches the chamber angle. This instrument may be made and remade to suit the case and the conditions that arise in the extraction of the foreign body. The procedure is carried out under cocaine anesthesia, and the usual postoperative measures are used.

1. The Technique of Prostatectomy and Its Relation to Mortality: Report of 165 Consecutive Cases of Perineal Prostatectomy Without a Death.—Hugh Hampton Young writes this article for the purpose of showing that by means of the perineal route just as radical and satisfactory removal of the entire adenomatous prostate in one piece can be accomplished through the perineum as by the suprapubic route, with, however, complete conservation of important anatomic structures—vesical sphincter, ejaculatory ducts, etc. By means of the great natural advantages of the lower operation, namely, ability to do an open operation through visual inspection, to arrest hemorrhage and to apply sufficient packing for complete hemostasis, and with dependent drainage, and avoidance of sepsis, and the inconvenience of distention of the bowels which so frequently follow suprapubic operation, a remakably low mortality can be secured and prostatectomy brought within the ranks of those modern major procedures which are practically free from danger. In performing the operation to which Young gives preference, the capsule and urethra are opened by an incision beginning along the left side of the tractor (introduced through a median urethrotomy wound), where it enters the prostatic urethra, and from that point continues backward and slightly outward near the pos-

terior limit of the prostate. The whole prostatic urethra is thus widely opened, and investigation will show the verumontanum well preserved along the floor of the urethra to the right. Incision is then made along the mucous membrane covering the inner surface of the right lateral lobe, and enucleation of the lateral lobes carried out by means of the blunt dissector and the index finger. The mucous membrane covering the middle lobe is then divided transversely, the ejaculatory ducts and verumontanum being pushed backward and guarded by the index finger, which is inserted along the floor of the urethra until it reaches the middle lobe, the incision then being made with the scalpel on the finger nail through the mucous membrane covering the median portion of the prostate, after which the finger is pushed backward beneath the middle lobe, thus freeing it from the proximity of the ejaculatory ducts posteriorly. Enucleation of the lateral and median lobes is then completed, until the entire adenomatous prostate is drawn forward and gradually separated from its attachment to the vesical and urethral mucous membrane, which usually strips away without difficulty, leaving the interior surfaces of the lateral and median portions of the prostate completely free from mucous membrane.

5. Potential Cardiac Disease and Prevention of Organic Heart Disease in Children: A Study of Sixty-five Consecutive Cases Under Continuous Observation for an Average Period of Four and One-Half Years.—William St. Lawrence states that of these sixty-five potential cardiacs forty-nine, or 75 per cent., remained free from evidence of cardiac disease during the time they were under observation. Of twenty-five patients with acute rheumatic fever in the series, none contracted a lesion in the heart. Of nine patients with myositis, bone and joint pains (growing pains) and sore throat, none contracted a lesion in the heart. Sixteen patients (25 per cent.) contracted a cardiac lesion while under observation. In every case in which a cardiac lesion developed, the clinical picture was dominated by chorea in severe form. No patient contracted a lesion in the absence of this manifestation. Of forty-one patients with chorea in the series sixteen (39 per cent.) contracted a lesion in the heart. Measures of value in preventing disease of the heart are of the greatest benefit when directed against acute rheumatic fever and myositis, bone and joint pains (growing pains) and sore throat. Such measures have little if any value when directed against chorea. In untreated potential cases, acute rheumatic fever is the most important factor concerning disease in the heart. In potential cases under management, chorea is the most important factor concerning disease in the heart. With the exception of mitral stenosis, cardiac lesions practically always occur during the active phase of a rheumatic manifestation or a period of pyrexia. In the absence of an active phase, the physical signs in the heart remained unchanged. Evidence of mitral stenosis may not appear for a year or more after the cessation of the rheumatic manifestations. It is therefore impossible to state at the conclusion of an attack of acute rheumatic fever or chorea that the heart was unaffected by these conditions. Heart rate may have a marked effect on the physical signs of mitral stenosis, as shown by a graphic record.

6. Carcinoma of the Spleen: Its Microscopic Frequency: A Possible Etiologic Factor.—S. W. Sappington reports a case of carcinoma of the spleen, secondary to cancer of the breast, and part of a general microscopic carcinomatosis. The rarity of cancer of the spleen is genuine, but there is evidence to show that there is actually no local immunity, and that microscopical examination may add considerably to the number of reported cases. In this case massage was probably an etiological factor, an evidence of the danger of tumor manipulation.

9. Sequels of Acute Epidemic Encephalitis: A Study of Ninety-two Cases from One to Three Years After Recovery.—Morris Grossman states that only ten of the ninety-two patients examined in this series were free from symptoms and showed no residual signs when observed from one to three years after the acute illness. Fourteen others had recovered, within this time, sufficiently to allow them to return to their work. These patients, however, still showed residual signs of their previous illness and complained of various forms of psychic disturbances, such as insomnia, irritability, poor memory, and fear neuroses. Sixty-two patients showed a serious, more or less progressive involvement of the central nervous system which was evidenced by disturbances in the motor psychic or autonomic functions. Of these sixty-two patients, forty-two showed a clinical syndrome which closely resembled that seen in paralysis agitans. On account of the rapid development of the syndrome, their emotional responses were more active than those of the average patient with paralysis agitans. They smiled more readily and seemed to overcome their facial immobility more completely and more easily. Their mental reactions were likewise more prompt. Almost 70 per cent. of these patients were below thirty years of age. A strikingly large number of them also showed pupillary changes and residual signs pointing to cranial nerve involvement; this is an unusual finding in true paralysis agitans. Another outstanding feature that was noted in the re-examination of these patients was the strikingly large number who showed increase in the activity of the abdominal reflexes.

6. The "Cold Plague" of the War of 1812-14. William Renwick Riddell.

3. The Surgical Treatment of Exophthalmic Goiter.—W. H. C. Romanis bases this paper on a series of 250 cases of the diseases, of all types of severity, upon which he has operated, many with pulse rates of over 180 and some with auricular fibrillation and other gross disorganizations of the heart. Only six, or 2.4 per cent., have succumbed. Nearly all the operations were performed under local anesthesia and twilight sleep, with a few exceptions in which a little open ether was given. The writer feels that the performance of the operation under local anesthesia has largely contributed to the low mortality. Stress is laid on the advantage of giving preliminary injections of morphine and hyoscine. It is strongly urged that removal of one thyroid lobe (hemithyroidectomy) is hardly ever sufficient to completely cure a case of Graves' disease, and that if a permanent cure is aimed at it will be necessary to remove one lobe, the isthmus, and a sixth, a third, or even a half of the opposite lobe, according to circumstances. It is usually feasible to do this at one operation, but occasionally—where the gland is abnormally adherent or where the patient is desperately ill—it has to be done in two separate stages, one lobe being removed at the first operation, and later a portion of the other lobe is excised. Following the operation a long stay in bed and four months of very easy life are essential parts of the treatment. As a rule after three or four months the writer finds that patients who have had an adequate amount of thyroid gland tissue removed feel well, eat well, sleep well, and can do their day's work, though it is not advisable for them to take up their normal life as soon as this. The gain in weight following operation is nearly always marked. In this series only two or three patients after operation have shown a slight fall in the basal metabolism below normal, to amounts varying between —5 and —10 per cent., and these patients have not up to the present time shown any signs clinically of hypothyroidism.

4. The Etiology of Gout.—Llewellyn Jones Llewellyn holds that gout is purely hereditary. A tendency to cellular sensitization is the pathological groundwork of the disorder—viz., latent gout. The gout is evoked by the corresponding protein or antigen, whether animal, vegetable, bacterial or other. It exerts its effect through the medium of vascular endothelial poisoning, with tonus of unstriped muscle, especially the bronchioles. The same phenomenon finds its clinical ex-

pression in the regular and so-called irregular manifestations of gout. May not skin protein tests if applied to the gouty yield as rich a harvest of information as has already been gleaned in asthma?

5. Estimation of Physical Fitness in Terms of the Respiratory Movements of the Several Regions of the Chest.—Alfred A. Mumford describes repiratory tests suitable for testing the fitness of school children. These tests are arranged in three categories: (1) Tests originating in the measurement of respiratory range or total volume of air expired in relation to the body surface. (2) Tests based on the measurement of the force of inspiration and expiration—that is measurement of the force of those voluntary and involuntary muscles which are impressed into the service of vigorous respiratory action. The movements may be momentary or sustained, and are measured by an ordinary U-tube manometer, the first being calculated by the height and the second by the length of time during which the breath can be held against a slight resistance. This power grows rapidly during adolescence. This is a useful test of fatigue and overwork when once the optimum standard of a boy has been fixed. (3) Tests based on the completeness with which the several regions of the thorax display their functional activity. This test depends on clinical examination and measurement of the movements of special regions. The regional method requires special procedures and special apparatus. By these methods it has been shown that the mammary and midsternal regions move most freely in subjects with well developed pectoral muscles—singers, swimmers, long distance runners and gymnasts. The movements of the submammary regions, and still more the postero-lateral regions, covering the tenth to twelfth ribs, afford the most complete indication of innate bodily vigor. It is rare to find great persistence and continuousness in effort among boys, when the movements of this region are limited. There may be considerable development of strength in the shoulders and arms with restricted lower costal breathing, owing to tonic contraction of abdominal muscles, but any blow given by the arm will be a sudden effort rather than a sustained one. Movement is greatly restricted in children with hollow backs or weak spinal muscles.

3. Rickets: A Theory of the Metabolic Disturbances and of Its Association with Tetany.—D. Nöel Paton observes that recent work is pointing more and more to the primary involvement of phosphorus rather than calcium in the perverted metabolism of rickets. He reviews evidence which seems to point to: (1) The independent carriage of at least part of the calcium and of the phosphorus in the blood to the growing bone and and to their combination in situ. (2) A limitation in the supply of phosphorus or phosphoric acid, or a supply in unsuitable form as a primary disturbance in the metabolism of rickets. (3) The important part played by phospholipin, especially of lecithin, in the metabolism of phosphorus in the body on its way to the formation of calcium phosphate in the bone. The possibility is suggested that some modification in the normal metabolism of lecithin may be the essential disturbance in rickets. This faulty metabolism may in some cases be accompanied by an increased conversion of cholin into guanidin compounds, thus explaining the association of tetanus with rickets, since Paton, Findlay, and others have shown that methyl guanidin produces the same symptoms as those of tetania parathyreopriva. The fate of methyl guanidin in the body is not fully known, but probably it is not excreted as such. This suggests that it may first be linked to acetic acid to form creatine, which is an inert substance, and that thus the active guanidin may be detoxicated.

5. Clinical Aspects of Abdominal Tuberculosis.—John Morley sums up the indications for operation in the various types of abdominal tuberculosis, as follows: Pain, when it occurs in recurrent, well-defined, colicky attacks, especially if they return with periodicity and sharp intensity, signifies a mechanical interference with intestinal peristalsis, and this can only be relieved by operative measures. Glandular masses in the mesentery, if not too extensive, and if they do not yield rapidly to constitutional treatment, should be excised, and this is particularly urgent when they are associated with colicky attacks of pain. Palpable masses in the ileocecal region, associated with signs of chronic intestinal obstruction, are an emphatic indication for laparotomy and resection of the tuberculous ileocecal region should such be found. The ascitic form of tuberculous peritonitis is essentially a disease for surgical treatment. The operation is free from danger, and its beneficial results are usually dramatic. The utmost care in medical and constitutional treatment is of great importance in the cure, but operation is almost equally essential. In the plastic type of tuberculous peritonitis, if the trouble does not yield to the ordinary medical measures, operation may be undertaken with a fair degree of safety, provided that no extensive attempt is made to separate adhesions; and the author says that there is some ground for hoping that even apparently desperate cases may make a complete recovery.

7. Pertussis with a Leucocytosis of 176,000.—Geoffrey Bourne and J. M. Scott report this case because no other white blood count of such a high figure has come to their notice, excluding those found in leucemia. The patient was a female child of 1 year 9 months, who had been subject to fits of coughing of gradually increasing severity and duration for twelve days before coming under observation. The first blood counts, taken on the sixteenth day of the disease, showed 176,000 white cells per cubic millimeter, of which 116,000 were lymphocytes. From this time the total leucocyte count fell and with it the lymphocyte count. The case seems to show that the leucocytosis is high at the end of the paroxysmal stage and that a fall in the count is of good prognostic significance since with the fall in the leucocyte count the clinical improvement was progressive. It is also of interest that the excessive lymphocytosis—presumable a manifestation of active pertussis—was present sixteen days after the onset of the disease.

Hygiea.

February 15, 1922, lxxxiv, 3.

Case of Congenital Defect of Radius and Ulna.—This case, reported by Sven Johansson, is of marked interest because probably the first of its kind to go on record. The patient when first seen was a boy aged one year. The humerus at the juncture of the third and fourth quarters was bent at a right angle, and was without an epiphysis. The skeleton of the hand is normally developed. A congenital cutaneous scar at the site of the angulation points to the action of intrauterine pressure in causing the defect. An osteotomy performed on the humerus has given the patient an enhanced use of the limb.

Os Vesalianum Pedis.—The same author also reports a find which he regards as a Vesalian bone in the foot. It occurred in the distal row of tarsal bones between metatarsal V and the os cuboides on the left side. Its configuration was cuboidal, and it measured 22 by 15 cm. There was also a small os peroneum and the anomalies were bilateral, though smaller on the right foot. Clinically the supernumerary bone was seated just back of the distal end of the fifth metatarsal, from which situation it was exsected. It is not to be confused with an epiphysis of the tuberosity of the metatarsal. Vesalius himself included this bone among the supernumerary structures. Many anatomists have insisted that this bone is usually found fused with the metatarsal, constituting an epiphysis of that bone, but the author of this article says that, as a result of the radiogram and operation, he is able to prove that his find is not of the same type.

Book Reviews.

THE TREATMENT OF ORDINARY DISEASES. Notes from the Record Book of an Old Practitioner. By BEVERLEY ROBINSON, M.D. (Paris), Emeritus Clinical Professor of Medicine at University and Bellevue Hospital Medical College, New York; Consulting Physician to City and St. Luke's Hospitals; Honorary Member Association of American Physicians. New York: American Medical Publishing Company, 1921.

IT is a great service to his profession that Dr. Robinson has rendered in jotting down these therapeutic notes for the benefit of the younger generation of physicians. In the modern running after the science of medicine, the art of curing has been rather neglected, and we sadly need the reminder that this book gives us that, while it is essential to find out the cause of disease, if possible, it is malpractice to abstain from all therapeutic effort until such cause can be discovered. Thousands of old-fashioned country practitioners cured —yes, *cured*, pneumonia (in spite of Osler's dictum that it is a self-limited disease and cannot be cured)— long before Types I, II, III, and IV, and the other nondescript germs were seen and classified; quinine cured malaria long before the plasmodium appeared to view; the progress of syphilis was arrested by mercury before Schaudinn's day and before the manufacture of silly salvarsan (or is it silver salvarsan?). In this little book Dr. Robinson, a revered practitioner of the old school, perhaps a little bit too scornful of the modern methods—for with all their shortcomings the laboratories, when kept in their proper place, are useful—tells how he treated pneumonia, common colds, typhoid fever, whooping cough, malaria, syphilis, rheumatism, gout, headache, tuberculosis, anemia, and a host of the other ills which so often afflict erring humanity. One need not follow his methods to the letter, for many of the new things are really most useful, but the reader will glean from these pages many valuable suggestions that will help him enormously in his mission of healing.

PRACTICAL ORGANOTHERAPY. The Internal Secretions in General Practice. By HENRY R. HARROWER, M.D., F.R.S.M. (Lond.). Third Edition. Glendale, Calif.: The Harrower Laboratory, 1922.

THERE is a great deal of valuable information regarding the morbid states dependent upon dysfunction of the endocrine glands in this well written book—so much, indeed, that it is well worth the while of every physician who would keep up to the times to get the book and read it through. And this despite the caution which leads one to look with doubt upon the merchant's praise of his own wares. The author of this book is frankly a manufacturer of endocrine products and his pages are dotted with references to, and recommendations to use, the various Harrower products. But no educated physician with a brain of sufficient dimension to enable him to treat disease ever uses ready made preparations except in the individual instances where he finds the combination suitable. In other cases he writes his own prescription and trusts to the pharmacist to fill it correctly—which, to his credit be it said, the pharmacist usually does. In the same way the reader of Dr. Harrower's book must exercise his right of discrimination—get what knowledge he can (and he can get a good deal) from these pages and then prescribe as he thinks best, using whatever make of gland extracts or nucleoproteins he may prefer, or using none, giving gland-stimulating drugs in place of the gland substance or extract. If a man is so wedded to the use of ready made preparations that he has forgotten how to write a prescription, he is unfit to practise medicine and will waste his time reading this book. His job is waiting for him in the coal mine or the stoke hole of a steamship.

THE LIFE OF JACOB HENLE. By VICTOR ROBINSON, M.D. Price $3.00. Medical Life Company. New York. 1921.

ANY addition to the literature of historical medicine is welcome if it be well and carefully done. If it be biography and the author has a true enthusiasm for his subject then the result is all the more welcome for the pages show forth not a dry compilation of some long dead scientist, but a living picture of a man who worked in medicine in the earlier days of our profession. Henle occupied a position of importance in the scientific world in the nineteenth century, but little has been known about the man because of the paucity of writings on the subject in the English language. Robinson has spent much time on his subject and is filled with enthusiasm for his hero. The book is not large and is interesting reading. It gives us not only a vivid picture of Henle himself, but a fair idea of general conditions of the time. If any should object that the importance of the subject of the sketch has been overemphasized one can say that overemphasis is preferable to omission of such work, but that we are not sure but that the author has not established good reason for his enthusiasm.

THE ORGANS OF INTERNAL SECRETION, THEIR DISEASES AND THERAPEUTIC APPLICATION. A book for General Practitioners. By IVO GEIKIE COBB, M.D., M.R.C.S., Neurologist, Ministry of Pensions; Late Assistant to Out-Patient Physician, the Middlesex Hospital; Temporary Captain, R.A.M.C.; Neurologist, Brinnington Section, Second Western General Hospital. Third Edition. Price $3.50. New York: William Wood & Co., 1921.

THE scope of this work is explained on the title page. It is intended for the general practitioner, and it approaches the study of the internal secretions from the viewpoint of their diseases and therapeutic applications. Hence detailed studies of the anatomy and histology of these structures, and elaborate accounts of laboratory research are not to be found here. In place of these features the author lays before hs readers the important points which the endocrine glands play in health, how they are affected by disease, and the conditions in which they may be used as therapeutic agents. The fact that a third edition is called for within a few years of its appearance is evidence that the book is of practical use. This new edition contains two or three new chapters, and much revision of the older material. The bibliography is of value, and will doubtless be utilized by many readers of this volume who will be desirous of enlarging their knowledge of the endocrine glands. In each of the three editions there has been a reference to Beebe's book on the Ductless Glands; but we have been unable to find the book in the medical libraries.

ACUTE EPIDEMIC ENCEPHALITIS (Lethargic Encephalitis). An Investigation by the Association for Research in Nervous and Mental Diseases. Report of the papers and discussions at the meeting of the Association; New York City, December 28th and 29th, 1920. Price, $2.50. New York: Paul B. Hoeber, 1921.

IN 1920 the Association for Research in Nervous and Mental Diseases was formed to meet once a year and hold a symposium on some appropriate subject. Epidemic encephalitis was chosen for the first meeting and this book represents the result. Care has been taken to avoid duplication by omitting the overlapping parts of papers and discussions. An interesting feature is the verbatim report of the written questions submitted to each speaker, with his replies. The history of the disease, its nature, general and special symptomatology, differential diagnosis, and pathology are discussed at considerable length. The latest reports are given of laboratory workers who have arrived at the discovery of a minute, filtrable organism, which is probably the cause, although the association, with commendable conservatism, refuses to endorse this, for the present, anyway. At the meeting itself there was considerable discussion of the treatment, but for some reason this is not embodied in the present volume. Although over a year has elapsed since the association met, this book represents pretty accurately the present state of our knowledge about epidemic encephalitis. The somewhat bewildering impression one gets from reading the reports of these investigators is not due to any lack of clinical acumen or energy of research, but rather to the bewildering multiplicity of symptoms in this disease, the obscure epidemiology, the lack of prognostic criteria, and the absence of effective therapy. After considering each phase of the subject the association as a whole has summarized its conclusions. If it has leaned to conservatism in so doing, this is perhaps the safest course in a disease so new to modern science as this one.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 9, 1922.

DR. MARSHALL PEASE, JR., IN THE CHAIR.

Reeducation Treatment of Confirmed Stammerers.—Dr. L. PIERCE CLARK. (See page 609.)

Dr. SMITH ELY JELLIFFE stated that in a moment of weakness he had acquiesced in Dr. Clark's request to discuss this paper. According to the Chairman he had five minutes for the discussion. It was therefore with temerity that he undertook it. To try to discuss the problem of influencing the expressive side of a personality in five minutes did not amount to anything; at the same time he would begin and try to say something about what he had found was wrong with some stutterers. Personally, he did not enjoy treating stutterers, and nearly always sent them to someone else, but he was very much interested in putting his finger upon certain fundamental defects in the personality make-up of stammerers. He was interested in the character defect which formed the basis of this disorder. In his attempts at an analysis of the mmm, ttt, sss, or other types of stutterers he thought the particular sound difficulties meant something often quite definite. To convey just what he meant Dr. Jelliffe drew a circular diagram and said one could conceive of the fetus, which in nine months had gone through the evolution of one hundred million years. This might be represented as the center of an enlarging circle which he divided into segments each representing different organ strivings of the individual. At birth these segments must come into harmonious relation with each other. The first segment in the circle he indicated as the respiratory system. The first cry started the processes of life on three levels, in the terms of Hughlings Jackson. The first was a biochemical requirement; the need for oxygen satisfaction, the second was physiological respiration, and finally there was a third, the cry which was the symbol. In so far as the demand for oxygen was concerned in the new born it was met by a cry. Finding that the cry granted the satisfaction of the oxygen craving, the infant endeavored to meet other cravings by the same symbol. He cried when he felt something. It might be noted that 100 per cent. of the infant's energy went into the first cry. A second segment in the circle represented the need of the infant for food. Having learned that a cry led to the satisfaction of his first demands, he cried for food. Here he first learned that he could not "holler" and "swallow" at the same time. That was the first fifty-fifty struggle the child met with in life. The result was a *displacement* of interest in order to get from the cry to the swallowing. The mmm type of stutterers had never actually learned the first lesson that they could not cry and swallow at the same time. They "want their cake and eat it too." It was very difficult to cure the mmm type of stutterers. The struggle started so far back in infancy. In his study of neurotic conditions he had found that the amount of compulsion that lay back of the symptoms was in direct proportion to the age at which the fixation had occurred. If it began at an early age it had almost the whole force of the personality behind it. Continuing his chart, Dr. Jelliffe spoke of the next necessary type of craving that the child had to displace his energy. One hundred per cent. of his energy now went to the bladder. The infant found that if he wanted to urinate, he had to stop, practically, at least, crying and swallowing. Another necessary early satisfaction was the function of defecation. These four different functions he had found distinctly valuable in classifying different types of stutterers. With the mmm type of stutterers the inability to cry and swallow at the same time was a manifest mechanism; in the sss and ttt type urinary fixations were playing a preponderant rôle. The bbb type, those who blew or burst their words out, were those in whom fecal phantasies were largely responsible. In other words, certain amounts of displacement of initial craving satisfactions were coming out in the defect shown in stuttering. In the group of stutterers in whom the disorder occurred at their early level fixations it took a long time to get well; they belonged to the compulsive or even the epileptiform groups. They were occurring in the organ erotic phase of psychological development. If the speech defect were later, at from six to ten years of age, the narcissic or exhibitionistic level, which level in general represented the effort of the child to call the attention of his environment to *his* various individualistic type of performances, the prognosis was by no means so bad. These patients were often quite readily cured. Then there was another group in which the stuttering developed at puberty or later, under some special stress or strain. Cases of shell shock which developed at puberty or later, under some special stress or strain, which developed speech defects were illustrative of the latter group, and most of these could be readily and successfully treated. In cases in which the stuttering developed at a deep level, prognosis must be given at least with a great deal of caution, and for himself, Dr. Jelliffe said he treated such cases reluctantly, feeling that unless they had a high grade of real intelligence, not book learning, the outcome was quite unpredictable.

Mrs. E. W. SCRIPTURE said that after listening to two such eminent authorities she hesitated to say a word, since all she could speak of was the practical work. In her experience she had met just what Dr. Clark and Dr. Jelliffe had spoken of. Those cases of stuttering which had their origin at the lowest level were very difficult to handle. The three stages at which most cases of stuttering had their origin were mostly the first initial ones, at the first school age, and at puberty. It was of interest to note that the many statistics gathered all showed that boys were much more afflicted with speech disorders than girls. The girl was proverbially a smooth talker. It was rarely possible for a school teacher to undertake the cure of a stutterer without the aid of a neurologist and a psychologist; but the class exercises in muscle training which engendered confidence in the individual was of inestimable value. The cure of stuttering was, as Dr. Clark had so clearly shown, a matter of reeducation—an adjustment to environment which could mostly be secured by individual analysis and maintained through thorough and constant training. It was important to make a distinction between stammering and stuttering. The German *Stammeln* meant to stammer or lisp while *Stottern* meant to stutter. It was important to make this distinction because to lisp was one thing and to stutter was another. We might define stuttering as difficult speech—stumbling, hesitating, repeating and restraining, and lisping an organic disturbance, as mispronunciation. The *more* the lisper thought of his speech the better; the *less* the stutterer thought of his speech the better. Lisping was a mechanical defect which could quite easily be corrected, but stuttering involved a personality defect and required long patient individual work to overcome it.

Dr. CLARK, in closing the discussion, stated that it was a singular thing in these cases that mere analysis of the fault where it was a constitutional defect was not sufficient to relieve the condition. In addition to the supportive reeducation by analysis there must be a very distinct understanding of the psychological development of the instinctive life. The reeducational feature was the one he particularly wished to emphasize, because in both the literature and the practical handling of these cases we had been led to suppose that a cure might be effected along the way of approach to the initial fault. In effect a cure required both methods of approach, and it was only by such a complete synthesis that the best results were attained.

Some Diagnostic Points in Scarlet Fever. (An Analysis of 1,500 Cases of Scarlet Fever.)—Dr. HAROLD RUCKMAN MIXSELL presented this paper which included the results of their personal experience with 1500 cases of scarlet fever in the wards of Willard Parker Hospital during the past three years. He said he would not dwell on the better-known diagnostic points of scarlet fever but rather devote his time didactically to the less well-known signs, and briefly to touch upon certain points which were overlooked, not only on account of their evanescent character, but also

on account of their relative unfamiliarity to the average practitioner, who was only seeing occasional cases of this disease. Signs might arbitrarily be divided into two groups: (1) the more common signs; (2) the special signs. These signs might be grouped under the head of four states, namely: (1) The preeruptive; (2) the eruptive; (3) the posteruptive; (4) the stage of desquammation. The more common symptoms of the preeruptive stage were high fever, prostration, thirst; angina, especially in the submaxillary, postcervical and inguinal regions; the face was puffy and red; there was a rapid pulse, markedly increased out of all proportion to the temperature; the tongue was coated and vomiting might or might not occur; headache and lassitude, sore throat, with pain on swallowing. Usually there was an epidemic in progress or there had been exposure in isolated cases. In the eruptive stage, in addition to the above symptoms, respirations were increased; the strawberry tongue, dark red at the tip, the redness gradually extending backwards with enlarged papillæ (this was also seen in measles and diphtheria); erythematous rash, punctate and dull red-brown in color, appearing in twenty-four hours on the forehead and back of the neck. It rapidly spread down the trunk as far as the groin, with strips running down the inner side of the thigh, and backwards as far as the hip. It finally spread to the extremities. The rash usually became confluent and did not appear to be made up of single puncta. A delayed rash was not rare. Eight or ten days might elapse before its appearance. In the posteruptive stage there was a faded rash; the tongue was glazed with the papillæ still enlarged; the skin was dry and shrunken, a dirty brownish-yellow in color, with a distinct pigmentation on pressure, not as intense as in measles nor as long-lasting; there were sudinima, miliary vesicles and pustules; the subjective symptoms gradually cleared up. The temperature fell by lysis, a very characteristic point in the differential diagnosis of scarlet fever and measles. The fourth stage was that of desquammation, the character of which was typical. On the face there usually appeared a fine dusky desquammation; on the neck, chest, and trunk (middle of second week), the desquammation was flaky and the skin sometimes peeled in large strips. The palms of the hands and soles of the feet were the last to be involved. The amount of desquammation normally bore a definite relationship to the severity of the antecedent rash. The skin had a papery feel and resembled the skin of a very old person. *Special symptoms* not ordinarily recognized were during the eruptive stage: The mucous membrane of the cheek and gums was reddened and thickened; the dorsum of the tongue was dark red in color, and barely coated; the paratonsillar lymph nodes (at the angle of the jaw) were enlarged and tender to the touch; the mucous membrane of the soft palate and pharynx was markedly reddened, the redness being sharply bounded at the hard palate; the uvula might be red and edematous. During the eruptive stage there were fine puncta on the tonsils and palate. The lips were much redder than usual. The rash appeared on the temple, the cheeks were profusely red, the discoloration being confluent, and spreading over the bridge of the nose. The tip of the nose, the upper lip, and the chin were pale, presenting a triangular section of the skin, the base downwards. This was called circumoral, or perioral pallor *and was very diagnostic.* There was marked involvement of the flexor surfaces of the joints of the extremities, especially of the anticubital and popliteal spaces. The rash of scarlet fever was always generalized. Pressure of the finger on the skin would obliterate the rash; stretching the skin with a fingernail would cause a red line, with an area of distinct pallor on either side. This was not seen in all cases. Scarlet fever was often hard to diagnose in negroes. A point to be remembered was that *strong* pressure on the skin, especially on the soft parts of the upper arm or abdomen, would sometimes reveal the typical scarlet rash in the pallor which resulted. Occasionally there appeared small papules filled with serum or pus. In the posteruptive stage, purpura (simplex) was sometimes seen, and was probably caused by sepsis. Very slight pressure would sometimes cause numerous petechial hemorrhages. However, they were not diagnostic of scarlet fever alone. During the stage of desquammation pinholing, that was large flakes of desquammation with a perforated center, determined this point of desquammation. Peeling from the hands, feet, fingers, and toes sometimes resulted in the epidermis coming off entirely in a cast, en masse. Finger desquammation was pathognomonic of scarlet fever. The beefy tongue was the earliest manifestation of desquammation, starting on the fourth and fifth days of the disease. Where there was only a little desquammation, the heels and the anterior surfaces of the fingers and toes usually showed desquammation. This or the development of a late nephritis might clinch a diagnosis in cases in which the rash and other signs had been atypical. Second desquammation was a rare feature of scarlet fever and might appear from two to six weeks after the first desquammation. There was extreme sensitiveness of the skin to heat and cold; this was not usually described in the text-books. The hands and feet after desquammation were sometimes left soft, moist and clammy. The blood examination usually showed leucocytosis of 15,000 to 45,000, the increase being in polymorphoneutrophiles. This usually disappeared about the end of the second week. The eosinophiles might sometimes be diminished, although this was not constant. The amount of urine diminished during the preeruptive and eruptive stages, returning to normal during the posteruptive stage, and increased almost to polyuria during the stage of desquammation. Normally there might appear during the eruptive stage a small amount of albumin, a few casts and red blood cells. This was the result of high fever and must not be confused with postscarlatinal nephritis. Real kidney involvement usually occurred from four to six weeks after the onset. A detailed analysis of the 1500 cases was given. In these 1500 cases there were charted 82 different symptoms on admission, with 27 conditions not primarily caused by the scarlet fever. There were charted in these cases 92 various symptoms during the course of the disease, with 9 other conditions not directly due to the scarlet fever. The most common causes of death in the 1500 cases were toxemia, cardiac involvement, pulmonary involvement, renal involvement, and otitis. Relapses were unusual and occurred in fever hospital wards where there was a constant addition of new cases which kept the ward surcharged with infection. Dr. Mixsell said he had seen one well-authenticated second attack of scarlet fever in the last three years. It was evident that scarlet fever was a many-sided disease. This would be recognized by keeping in number of the large number of symptoms, sequels, and complications charted in this paper.

Dr. ROWLAND G. FREEMAN said he did not know what experience most of his hearers had had with scarlet fever, but in describing typical cases of scarlet fever to students it had occurred to him that it had been a long time since he had seen such typical cases. He thought that scarlet fever at the present time was running a rather mild course. Not all cases had high temperature, very red throat, and enlarged cervical lymph nodes. The temperature was not always high; usually the throat was red and the cervical lymph nodes were enlarged, but the rash found was not typical and not well developed. Some of these atypical cases were very difficult to diagnose. He had seen one case in which the rash came out only on the flexor surfaces of the limbs. A man of large experience said it could not be scarlet fever, as the scarlet rash always stayed out twenty-four hours, and the rash in this case had not done so. Later this child desquammated. Dr. Freeman expressed the opinion that the real diagnosis of scarlet fever rested on a characteristic desquammation. Scarlet fever did some very peculiar things. There was usually a high temperature by the second day of the rash, and the temperature then subsided; but he had seen cases in which it remained high up to the fifth day, the rash spreading and the temperature becoming higher each day. That condition was apt to alarm one, as it suggested complications. The temperature would then come to normal without any complications at all. In some cases after the first rise of temperature had subsided there would be another rise in temperature and another rash and another enlargement of the cervical lymph nodes. In his experience, Dr. Freeman said the dates for the appearance of nephritis were not exactly as Dr. Mixsell had given them. He thought they were from the seventeenth to the twenty-first day. If a child had not developed nephritis by that time, one could al-

low him to get up without expectation of trouble. Dr. Freeman recalled a small epidemic of scarlet fever at the Foundling Hospital during which there were 10 cases, and none with a temperature over 101°, and some went on to chronic joint disease and heart disease and all sorts of complications. During another epidemic at the Foundling Hospital in March, which occurred at the same time as an epidemic of measles, there was one child with a denuded neck, the result of the breaking down of the cervical lymph nodes. Measles then began to crop out, and there were many complications and the loss of many of the children. He persuaded the sister in charge to put these very sick children on an enclosed porch. Those case put on the porch were all either in the middle of or recovering from scarlet fever. After these children were put on the porch there was no more mortality, and even the child with the badly denuded neck made a good recovery, and th denuded area healed completely.

Dr. William P. Northrup stated that at the Foundling Hospital, in conjunction with Dr. O'Dwyer, they had seen all sorts of irregularities presented by scarlet fever. Granting there were many essential signs, Dr. O'Dwyer had canvassed the field very thoroughly, and they had come to the conclusion that sore throat was so characteristic that scarlet fever seldom ran its course without the burning sore throat. They had observed the symptoms during an epidemic, and each patient stated that he or she had the hot, burning sore throat; some complained of headache and some vomited. There was no one symptom absolutely characteristic, but for purposes of help at the bedside the red throat was perhaps as good as anyone.

Dr. Philip Moen Stimson stated that at the Willard Parker Hospital last winter there had been a great many cases of arthritis complicating scarlet fever; this year there were practically no arthritis cases. There was one feature that the resident physician on the service a year ago brought out by which she had been able to predict the cases which would have joint manifestations. About half the cases that developed arthritis showed during the twenty-four-hour period before the first appearance of the joint inflammation a rather characteristic eruption of from five to thirty or more small reddish-brown spots on the body or extremities. Another point that had been of value in the diagnosis of scarlet fever, and that was applied with the British soldiers, was that one always found the rash first on those portions of the body which were warmest or under pressure, as under the straps, under the arms, in the groin. The value of this point was so well recognized that the doctors were instructed to inspect these areas in suspected cases.

Dr. William St. Lawrence stated that there was considerable dispute among men interested in this subject as to the importance of scarlet fever as a cause of cardiac disease in children. Some workers thought that it had little bearing on this problem, while others believed that scarlet fever was an important etiological factor. Still others believed the heart was more likely to show involvement if arthritis was present during the attack of scarlet fever. For this reason he would like to know Dr. Mixsell's experience on this point. Were the cases which he reported examined on admission and during the course of the disease? Was cardiac disease absolutely excluded at the onset of the attack of scarlet fever, and upon what facts and according to what standards was the heart considered to be the site of new disease?

Dr. Mixsell, in reply to Dr. St. Lawrence's question, said he thought there was no standard for the heart cases. The findings on admission were simply filled in on the charts. Most of the cases considered in this study Dr. Mixsell said he had not seen himself. He agreed with Dr. Freeman at to the atypical course of scarlet fever. As they saw the disease at the Willard Parker Hospital, all the signs were evanescent and disappeared rapidly. The only way one could be sure of the diagnosis was by finding desquammation or nephritis. He also agreed with Dr. Freeman that the primary symptoms might disappear, and then there might be a recurrence with all the signs and symptoms of the disease. One found nephritis at the beginning of desquammation, which might be from five to twenty-one days from the onset. In making the essential diagnosis, Dr. Mixsell said he agreed with Dr. Northrup in regard to the sore throat. When one found the strawberry or raspberry throat which desquammated and looked quite beefy, one could almost prognosticate the stage of the disease, and certainly could make a diagnosis. The rash, it was true, appeared first in the warm areas due to skin apposition, the usual sites being in the axillary, popliteal and gluteal regions.

Results of Active Immunization with Diphtheria Toxin-Antitoxin in the Public Schools of New York City.—Dr. Abraham Zingher made this presentation, which was illustrated by lantern slides showing the statistics collected in his work in the public schools of the city, in other schools and in institutions. He called attention to the fact that there had been a large increase in diphtheria in 1921, from 50 to 200 per cent. in almost every state in the country. That had perhaps stimulated health officers to take an interest in the newer methods for the control of diphtheria, which where the Schick test and immunization with toxin-antitoxin. In the second place the results obtained during the past eight years by these methods had been very favorable, having shown that 85 to 100 per cent. of non-immune children became immune to diphtheria after the first series of toxin-antitoxin injections. When it came to the work in the schools they had met with great variations in the results of immunizing injections with the same strength and preparation of toxin-antitoxin. In retesting children who had had one series of injections the discrepancies varied all the way from 75 to 80 per cent. of successful immunizations in some schools to 25 to 30 per cent. in other schools. It was found that the percentage of those becoming immune after receiving one series of injections of toxin-antitoxin was in inverse proportion to the percentage of positive reactions following the original Schick test. Where the number of positive Schick tests was high the number of children becoming immune after one series of injections was low. The reverse was likewise true. It was found that the children in the schools in the poorer sections of the city gave fewer positive reactions to the Schick test and responded to the toxin-antitoxin injections with a higher percentage of immunes than the children in the better sections of the city among the well-to-do. They had obtained as high as 60 to 70 per cent. of positive Schick reactions with the original test in schools located in certain sections among the better classes, while in schools in crowded sections of the city only 15 to 20 per cent. gave positive Schick tests. The explanation was that the children in the poorer sections were often exposed to mild doses of diphtheria organisms which brought about a certain degree of natural immunity. Among the children of the better classes this exposure was not present, because they were segregated and isolated, and they therefore remained susceptible. It was evident that the toxin-antitoxin brought about a better response in the children in whom antibodies had been stimulated by previous exposure. Even if they still gave a positive Schick reaction they responded readily to the immunizing doses of toxin-antitoxin. Dr. Zingher stated that he had seen no harmful effects from the Schick tests and the toxin-antitoxin injections. In some children there was a little fever and a sore arm, but their reactions rapidly cleared up. He had thus far tested over 100,000 children and expected soon to finish testing the children in every school in Manhattan and the Bronx. Among all these tests and injections he had not seen one case of infection. In closing, Dr. Zingher made a strong plea for the active immunization of all children of the preschool age. In order to bring about an immune child population it was necessary to begin early and to immunize all children from one to five years of age, inasmuch as 85 per cent. of the cases of diphtheria occurred among this group. The injection of toxin-antitoxin in the newborn brought about very little immunity, as at this time the infant was protected by the antibodies it had brought over from the mother. The injections were effective, however, after the child reached the age of six months.

Dr. Everett W. Gould stated that these reports which Dr. Zingher had made regarding the Schick tests and toxin-antitoxin immunization in the public and private schools were most interesting and valuable, for it was only from the results of thousands of

cases that it would be possible to formulate the position which the practising physician should take in respect to the use of this method of controlling diphtheria. He felt that Dr. Zingher was probably not yet ready to state what the Board of Health would recommend as the universal practice of the medical profession on this subject, and it would be too much to expect him to state the details of such a far-reaching problem. But he felt quite sure that the goal for which they were striving was that every child should be required to be vaccinated against diphtheria just as it was now required to be vaccinated against smallpox. Before that time would come it would be necessary to educate both the physician and the public. In order to accumulate definite data on the subject it was important that every one who had access to material should use it as scientifically as possible. To-day, Dr. Gould said he thought there was no one who had done scientific work who doubted that the Schick test when properly done and properly interpreted was a reliable measure of sufficient antitoxin to protect the individual against diphtheria. If now we had a method by which an active and persistent immunity could be aroused in an individual, we should encourage any work which would ultimately determine the details of this method. There naturally would be much discussion and differences of opinion in regard to the size of dose, the strength of the toxin, and the length of time the immunity would last. There was also the question as to the time when it should be given. It was useless to give the immunizing injections during the first six or eight months of life because the child was passively immunized during that time by the antibodies it had inherited from the mother. If one waited until the child was in school there were a good many bad reactions which reflected on the teacher and the doctor and brought the procedure into disfavor. Furthermore, it was important that the immunizing injections be given in that period of life when the child was most susceptible, namely, from two to six years. The Board of Health could not easily compel the giving of toxin-antitoxin to every child two years of age, but they could compel every child to show a certificate that he had a negative Schick before he could enter school just as they compelled every child to show a certificate of vaccination against smallpox, and this would have an influence in having children vaccinated against diphtheria at an early date. The public would be willing to do this when they saw that the incidence of diphtheria was actually diminishhed by this procedure. It was a difficult problem and could not be worked out in a few years. Even more important than the statistics which had been shown this evening would be the statistics in regard to the incidence of diphtheria in schools in which the children had been immunized. It was hoped that these reports would be much more convincing to the public and the profession and lead to a hearty cooperation on the part of all.

Oxygen Therapy in Premature Infants with Cyanosis.—Dr. HARRY BAKWIN read this paper, in which he said that cyanosis was a frequent symptom in premature infants. It might be associated with a number of different conditions, such as cerebral hemorrhage, bronchopneumonia, sepsis, etc. Not infrequently, no organic basis was found for the cyanosis, except, perhaps, a few atalectatic patches in the lungs. Usually, a diagnosis during life was impossible. Whatever the cause, however, cyanosis was an extremely grave symptom and required immediate treatment. The method of administration of oxygen was of the greatest importance. The funnel method which was so widely used was useless. The widespread use of this ineffective method of oxygen administration had done much to discredit oxygen therapy. At the New York Nursery and Child's Hospital oxygen was given by means of a rubber tube about one-quarter of an inch in diameter, with a hole in the end of the tube. The tube was inserted into the infant's mouth and held in position with a glass collar, which fitted snugly over the tube. The collar was held in place with tape, which passed through perforations in the end of the collar and was tied back of the head. Dr. Bakwin demonstrated this collar, showing that it was a simple device which eliminated the need of a nurse in constant attendance during the oxygen administration. The results of oxygen administration in two infants with severe cyanosis were reported. In both these infants the cyanosis entirely disappeared, the babies becoming rosy pink in color, the pulse markedly improved, and the oxygen unsaturation of the blood, which was very high in both instances, falling to normal. One of the two infants thus treated was five months of age, and seemed in every respect a normal baby.

Dr. L. C. SCHROEDER said he did not know any finer test of a man's fitness as a pediatrist than his ability to offer an explanation of cyanosis in prematures and to outline a rational treatment for it. The reason pediatrists knew so little about premature infants was because in their initial training in pediatrics they had little opportunity to see the new born, and as a corollary it followed that there had been little work attempted such as Dr. Bakwin had done. Much time was spent in talking of lowering the mortality from various causes in infancy, and much had been done in a preventive way while little was being done where it was most needed. Since Haldane's work had been published showing that when oxygen was given by funnel 98 per cent. of it was lost in the air, it was not being given in that way. The glass collar which Dr. Bakwin had devised kept the child from closing his teeth on the tube and shutting off the oxygen. An oxygen tent had been suggested as a means of administering oxygen, but Dr. Schroeder thought the problem would not be solved until some one devised an oxygen chamber. The work of Meltzer and Haldane suggested that it was time for some of us to see if we could not place oxygen therapy on a sound basis because oxygen was certainly a tremendous help in certain conditions. We must remember that anoxemia had a distinct effect on all the bodily structure, especially the brain, often leading to permanent damage. That being true, how great must be the effect of a lack of oxygen on the tissues and brain of a four-pound baby and how little chance he had of surviving unless cyanosis was relieved!

"Thinking About Nothing."—According to Gueniot certain individuals are capable of such abstraction that they can think without object or content. Denonvilliers claimed many years ago that ability to think in blank was a sovereign remedy for obsessions, neurasthenia, and other mental states. Alexander Dumas, Sr., had the same faculty. Gueniot strives to make his neurasthenics cultivate this habit.—*Le Progrès Médical.*

Swimming Tank Conjunctivitis.—Paris has as a rule been free from this affection, only an occasional case or two being reported at long intervals, but recently eight cases were traced to one tank. The affection was first heard of in Berlin in 1899. The bacteriology and the inoculation tests were negative. Trachoma, ordinary follicular and Parinaud's conjunctivitis can readily be excluded, and the condition is entirely benign.—*La Presse Médicale.*

Carcinoma a General Disease.—Sauerbruch, the distinguished surgeon, states that at the present time we are headed toward the old humoral or constitutional theory of the nature of cancer. The local manifestations are but local manifestations of a general disease. The doctrine of Virchow that the constitutional manifestations of cancer are invariably secondary is being abandoned.—*Wiener klinische Wochenschrift.*

Jennerian Vaccination of Leucemic Subjects.—Ramond, Jacquelin and Borrien state that vaccination is very seldom contraindicated even for the time being and is tolerated alike by subjects with high fever and those in advanced cachexia. There is one class of patient, however, who must be approached with great caution. This is the leucemic and especially the victim of chronic lymphadenia. In one case lymphademic leucemia a powerful reaction was set up which seems to have been entirely local and painless. The subject died in about twelve days, and although he was at the time a victim of incurable disease this result was regrettable. In lymphadenia without leucemia there was no reaction, but the original affection grew worse. The rationale of such accidents is that vaccine naturally gives rise to a leucemic reaction and hence must be contraindicated in all leucemic patients.—*Le Bulletin Médical.*

Medical History.

CRITICAL AND DESULTORY REMARKS IN THE LIGHT OF THE HISTORY OF ANCIENT MEDICINE.*

By JONATHAN WRIGHT, M.D.,
PLEASANTVILLE, NEW YORK.

IX

On the whole there has been no one department of medical research which has offered so much that is suggestive and to the intelligence of the world at large so much that is acceptable to it as psychology. Medical psychology has inevitably linked itself to sociology in such a way it has attracted to medicine in general, in a very considerable degree, that sympathy of the public which has largely grown cold to what bacteriology has of late had to offer, once taken up by the curious with such avidity. Singular to say, the interest of the public in serology, probably presenting the most promising, certainly the most astonishing, of the recent advances in medical science, has been very meager indeed. Sneer at it as we may, this is a subject which should be very seriously considered by medical men, the public interest in and the public sympathy for scientific work in medicine. Public health, which has such claims on the public and which has striven so earnestly to enlist public sympathy, has alienated a very important if not a very numerous element in the public, by the methods of publicity it has adopted. There can be no doubt of this. All over the world is seen the revolt against the modern publicity given not only to things which have not been digested, not only against the flaming publicity demanded for diplomacy, where there is plausible excuse in the trend of democracy, but resentment against the impertinence with which professional exploiters and people of bad taste, without any excuse, drag modest men and women into undesired notoriety. I hesitate to say there has not been gained thereby for many causes more than has been lost, but science and medicine especially, because it tries to be a science, should not be placed among these. If it is a fact that more has been gained than lost by this policy in numbers, the question still remains for medicine if more has been gained in weight, if quantity can in practice replace quality. This seems to parallel the problem of modern democracies. Can the loss of the talent of the few be made good for politics by raising the average intelligence of the many? They may be parallel problems, but they are not identical and the answer to them is not the same. Public health agencies have, however, in instructing the public, not only adopted the ways of some branches of commercial life, most offensive to modest and earnest and high thinking men, but they have based much of that instruction upon theories, which, if often of great professional interest for moderate lengths of time, do not warrant the positive assertions made in flaming posters and in folders sent through the mails, written in wretched taste. A certain number of the practices based on these theories of the hour urged, nay forced on the public, have been manifestly inefficient, and with the crumbling of the theories on which they have been based they have had to be abandoned and the public, without the assistance of the attractive nurse on the posters, has silently taken note of it. A large portion of the public takes no account of the general fallibility of human judgment and even among the unthinking, medical stock has gone down and a considerable percentage of indifference has been added to the disapproval of other classes in the mental make-up of the public. The taxpayer as well as the charity giver has been moved by such methods to contribute money to endeavors whose demonstrated futility has none the less powerful influence upon them because they are silent as to their own lack of self-restraint in giving way to such influences.

*See Medical Record, November 26, 1921, and February 4, 1922.

X

However, whatever may have been the cause of the manifest decay of public interest in some forms of altruistic effort in which the medical man has been an important factor, psychology seems surely stepping in to fill up the gaps and some of the aspects of the phenomenon are sufficiently interesting to warrant passing notice, quite independent of the importance to the medical profession of its maintaining the tie of interest and sympathy which binds it to the rest of the body politic, but that in itself is not devoid of interest on our way to enter the affiliations modern thought has with ancient ways of thinking and ancient influences on action. In psychology there is, in its very name, the immutable nature of the human soul, a bond of human sympathy not only with ancient thought but with contemporary thought and feeling in that part of the public, usually unresponsive to medical science. That link of interest has been ready at hand, deep seated in the ineradicable tendency of man to stand with greater interest before that part of the great unknown which has to do with his survival after death. Repugnant as it seems to be to a large number of materialistic men in science to touch upon matters so immediately running into metaphysics, they will find with advancing years that if they expect to keep up the present flow of ducats to their leaky lockers or to excite the movement of new streams to their own realms of research, they will have to take note of this ever underlying current in men's minds, which at certain epochs in the pulsation of the world thought as well as of world emotion comes to the surface. The fact that it has been, now for a long period of time, largely suppressed in the minds of scientific men, and the fact that it has most lain on the surface of uncultivated minds, should not mislead us and would not mislead us but for a sort of foolish caste arrogance which a few scientific men seem to cherish as their most precious inheritance of past generations of science, in which boldness and originality of thought once encountered a similar tenacity of ancient but outworn belief. It is now the sign neither of boldness nor of originality of mind. For the most part it is the mark of crass ignorance and superficiality of thought.

As a matter of fact it is among the biologists, obfuscated and perplexed by the complexity of the processes and forms of living things that we find chiefly that stubbornness to accept no explanation but the physical one. The metaphysical tendencies we find chiefly among the physicists and the psy-

chologists. We find Lodge and Crookes in territories close bordering on the beyond, peering into domains that are taboo to the man with one eye glued to the eyepiece of his microscope and the other eye not functioning. The cloud in his tubes is matter of such interest to the serologist he cannot see beyond the mist, even if he should look. The stark simplicity of the electron in close proximity to that vast field beyond sense is not for such troubled ones.

XII

My understanding of embryology is weak, but I believe it is said the brain is developed at a later stage than the organs of sense from the same external blastodermic layer. If we are to suppose, as so many evolutionists, following Haeckel, were disposed to do a generation ago, that on the whole the evolution of the individual *in utero* and in immaturity afterwards is an epitome of the evolution of the species, if we take these old discussions from the shelf, where they have lain for so many years, but which may yet formulate some adumbration of the truth, we see that there is a biological basis of fact behind the declaration of the physiologist that the mind of man is an epiphenomenon. This may be so, we will assume it is so, but if so then we see the reason of our difficulties, when as mystics we wrestle with the materialist. How can an organ developed from the same origin as the organs of sense and in an evolutionary, if not a teleological, destiny evolved for organs of sense, trained by them and for them at least, how can such an organ function beyond sense?

Now let us go back to the ancients, whom this time we have approached from a great distance and mention Euclid if only as a hint of what further excursion into the present we still have to make. After all, he is the most familiar figure in that distant past whom we associate with the start of the mathematical globe and less perfect geometric figures rolling down the galleries of the ages. For all this time we have been little troubled with the troubles of the more ancient Greeks, but they must have been a sore trial to Euclid of Alexandria 300 B. C., starting in to clear up for the new world Alexander had made, just as we are trying to clear the way for the materialism following in the wake of a triumphant plutocracy. It has been thought all these long ages he had cleared up the difficulties Socrates talked of with Euclid of Megara a hundred years before. For many generations of men, down to our own time indeed, it was apparent how his figures and blackboard diagrams gradually in the mind of youth assumed the forms which our senses assured us were correct. The logarithms of the calculus patched out our senses apparently, but now comes along Einstein and shows us we only need some millions of miles of perspective beyond our senses to convince us our senses had the gift of the brain from the gods for local use only. Lodge, who, perhaps from the force of believing in an ether, inconceivable by the brain of man, also points toward something I for my part and most of the men I associate with cannot see at all. But men of science are a small part and, except remotely, a very insignificant and a very unnoticed part of the public, who in the mass have always believed in something of the kind or something that stands for it in the argument. Now comes along Bergson with his mysticism—a mere aberrant by-product of Lodge and Maxwell and Poincaré and the psychologists who scoff at him and they also all tell us tales of the unconscious, not allowing us to call it the subconscious; is it because they, too, have a doubt it has anything to do with consciousness? For Bergson goes further and links it up with something outside of and beyond man and we men of science lose track of him altogether, but not of Einstein, neither we nor the public. Now I cannot help yoking all this up with the difficulties of the neovitalists in biology. They flee to-day very much as Aristotle did to an *entelechy* in the shape of a germ plasm whose nature it is as impossible for the mind of man to grasp as the ether of the physicist or as the non-existence of space or time in which we live and work and have our holidays.

I must add a word here to escape the reminder, to which I lay myself open from those physicists who seem to have a rather insufficient knowledge of ancient philosophy, that the relativity of Protagoras has nothing at all to do with the relativity of Einstein. From their point of view, of which I in my turn may also have insufficient knowledge, they may be correct and I do not even feel capable of maintaining that from the standpoint of the philosopher they may not have a good case. My concern here is primarily an exposition of the currents of popular thought, mistaken or otherwise, and the phenomena which have set them moving toward an era of mysticism in which we bid fair soon to be immersed. I am not presumptuous enough to declare how far that current will carry us or how long it will bear us on its crest, but the tendency is unmistakable. The right or wrong of it, the true or false of it is not for me. It can properly be left to those coteries of science, which settle all things by joint resolutions of committee from time to time, when they think the public is really going too far astray, as they once attempted to do for the tubercle bacillus question, by Public Health posters, while at the same time emphasizing the necessity for keeping the mind open to doubt and skepticism. With these gentlemen it seems to be important what you doubt and they seem to take for their province the making clear what their fellow men are to be skeptical about.

XIII

In our difficulties then with the germ plasm we get into touch with Aristotle[1] and with Hippocrates and his dynamism,[2] to which in despair he attributes all phenomena he cannot otherwise account for, a dynamism which has very much the aspect of the devils of primitive man. It is refined a little, as was Socrates' dæmon, around which Plato has thrown the glamor of his prose,[4] but for all that all of them are to be tied up in the same bunch with the modern germ plasm and placed on the same shelf with Bergson's mysticism and Einstein's physics and the spiritualism of Lodge and Crookes. It is plain that all these things, which it has taken me such a long time to collect, belong in the same category with the devils of disease of primitive man. This is the deep root from which springs the interest the people take in psychology and we see how respectable are its affiliations. It is wrapped up with the deepest thought and the strongest aspirations of

the ages. The most forward men of ancient times, of modern times as well, leave names or have names which cluster around it in the history of thought. It is not for me, a mere materialist, to treat of such a subject in a spirit either of contempt or of ridicule. Scientific men, most of them, try to avoid it, say it is not adapted to the experimental method. What was that definition of the true scope of science, something susceptible of being tested by experiment, or observed by the senses? Some of the presidential addresses before their sections can perhaps be rescued from the dust bins. It is to be hoped that the history of scientific thought, written in another generation or two, will deal gently with them. However desultory the remarks and however presumptuous the criticism, it is in the light of ancient history these modern problems should be judged. The light is more illuminating than the remarks of the presidential specialist on general subjects.

As we look back across the ages at the course of philosophy, of which medicine, in its guiding principles, is the specialty Celsus said Hippocrates made, we perceive that the psychologists are linking us up, despite their earnest declarations they are materialists too, with something the public cherishes and has always cherished. The reasons for the persistence of religious feeling are not any too satisfactorily demonstrated to us as materialists. The rise of the fear of death and the anxiety for the future is not all explained by the evolutionary doctrine that without them neither man nor any other animal would survive. All men do not fear death. Many savage races are indifferent to it, some taking their own lives in sport or from some passing whim.[6] However the evolutionary answer on the whole stands good. For my part, "que sçais-je?", but if I were in the prophet business I should say we were in for a decade or two of a steady drift toward mysticism which has already contaminated the very portals of the temple of science itself.

Now at the house of Euclid of Megara occurred, in the imagination of Plato, that wonderful discourse[5] Socrates carried on with Theætetus and Theodorus about this very matter, which Einstein has introduced anew, straight out of the figures of Euclid of Alexandria and Newton of Cambridge. I do not mean the relativity of time and space and the horrible equations of pure mathematics which prove that Euclid and Newton were a little local in their laws for these, nor to the more interesting observations of phenomena which demonstrate the fact. I refer to the relativity of knowledge itself. Cyrene was the forerunner of Alexandria at a distant spot along the coast land of Africa and Socrates had his eye on a geometrician from there by the name of Theodorus who was having some success with the Athenian students. "I see that a great many of them follow you, in which they are quite right," is the bantering remark of Socrates, "considering your eminence in geometry. I should like to know if you have met with any one who is good for anything?" By this inquiry he finds that Theætetus, a model youth, has been indoctrinated by Protagoras with the very disturbing philosophy which underlies the demonstrations of Einstein "that man is the measure of all things." Thereupon, with evident joy in his soul Socrates girds himself to the task: "I am about to speak to you of an illustrious philosophy, in which all things are said to be relative." But why go on? Pick up the newspapers and magazines on the morrow of Einstein's appearance before the general public. If you will take the trouble to compare the gist of their news, you will find in it the superficies through which Socrates plunged, only not half as well set forth as it is by Plato, and he broaches the more intricate details when he declares "there are plenty of proofs which show that motion is the source of that which is to be and becomes," that is, reality, "for fire and warmth, which are supposed to be the parent and nurse of all things are born of friction, which is a kind of motion." It would not be candid to allow the reader to expect to find in this dialogue of Plato everything as familiar to us as this, but unless he belongs to the inner shrine of the mathematical temple he will have less difficulty with Plato and Socrates than with Lodge and Einstein. At any rate he will find even the popular discourse of Einstein and his ilk illuminated in the light of the history of ancient philosophy.

XIV.

It has been my aim in this series of papers in the MEDICAL RECORD, incited by a browsing in the history of ancient philosophy and of medicine in particular, to assist, so far as my limitations allow, in the task of building a bridge across the ages that we may sharpen our wits in a world of intelligence, inferior to our own, it is true, but in an era in which lived a people vastly more alert in their mental processes, more acute yet more pliable in the fiber of their thought. In some of the former sections we have mingled much with Cicero and Celsus and found a lesson or two in the forms on which they modelled what they had from Plato and Hippocrates and the epoch which was already in the time of Cæsar ancient history, but as we pass from the glory of Athens to the glory of Rome we can not fail to take note, and if we expect to know the history of the evolution of medicine it is vital we do take note, that we have left behind us the essential superiority of intellect which strikes every student of Plato and Hippocrates, of Aeschylus and Euripides. If we were to continue the thread of thought we took up in the discourse of Socrates with Theætetus where we might expect to find it in Cicero we would soon perceive what a feeble follower in philosophy he was of Aristotle and Plato, and in Celsus how limited is the sweep of his intellect, how it lacks, even as far as it goes, incisiveness as compared with that of Hippocrates. Like some of us modern specialists, when called on to deal with the deeper and wider problems of the ages, when he is spread out over a wider area we find the material in Cicero hardly suffices for the thinnest sort of veneer. What we have done in our little cubby holes of specialties in science is the only thing which saves us from ridicule when we stray beyond them. We have every reason to be thankful for the kindness which has gathered around our modest endeavors in time past in narrower fields. Cicero was not a shining light of philosophy, but was, nevertheless, a keen observer and a matchless delineator of what he heard and read.

XV.

The psychologists with whom we began, have had much to say which is illuminating and suggestive about the subliminal burying of physical pain and the same can be said of mental pain and the sorrows of the soul. The use of this stern discipline is what makes character. It is a cure, a mind cure if you will, which differentiates the weakling from the strong man. It grows in efficiency with use. It excites awe and admiration when we see a man triumphant over the ills of all kinds which overwhelm others. The establishing of habit is taken for will power. It is the basis of the cult of the stoics, to which sect so many of the ancients were the avowed or the pretended adherents. A man's preoccupations allow him to exercise a certain empire over that brain organ developed, as we have seen, from the blastodermic layer of the senses, the external one, the one in contact with the environment. It seems a sort of lifting one's self by one's boot straps, but it works. It allows him to bury his pain, world pain or belly pain, in his subconsciousness. The martyr sings hymns and clings smiling to his beatitudes in the midst of flames, the true believer walks serene over red hot ploughshares with bare feet, the vilest wretch who ever breathed, with thoughts of the censure or the admiration of the gang after he is gone, he knows not or cares not where, since he has to go, jokes with his jailer on the way to the electric chair. The martyr, the hero, the patriot dying for his country has in this line no preeminence over the thug and the worst of villains who have perished with the universal consent of society. Is not this a miracle? What is this noble, stoic faculty which conquers sense and bends its own organ to its will? Can the psychologist tell us? The moralist has not succeeded very well. Now this is what psychology is going to do for many things far beyond the domain of medicine. It is going to explain to us the secret of the stoic, the faculty by the exercise of which he dominated the whole religious thought of the world before the advent of Christianity, itself a certain ecstacy, which in its way too conquers sense and still rules the world. We see, therefore, the science of psychology astride of the ancient world and the new world alike, with one foot in the stoicism of Zeno of Citium and the other in the modern fripperies of Mrs. Eddy. We see it then reaching far out beyond conventional hypnosis, throwing a light on much of ancient history and as much at least on modern sociology.

I think I have made it quite plain that psychology has not only found a hitherto unoccupied field of usefulness in the world. It is seen to be the cement which binds society together, which explains one problem of one section of the world to another. It is unfortunate but perhaps unavoidable that it joins hands, frequently soils its hands, with various interests which are repugnant not only to decency but to common sense, but the evidence of the hold it is securing on the attention and the sympathy of the public is one which science and medical science in particular has every reason to view with satisfaction. As it reaches all the ramifications of medical interests, is intimately wound up with the problems of all its specialties, so we find it opening up vistas that let in a light to us from the remotest epochs in the history of the evolution of medical thought and achievement.

MOLIÈRE AND THE PRACTICE OF MEDICINE IN THE TIME OF LOUIS XIV.

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CAL.

This is the tercentenary of a man who, though not of the profession, has been of inestimable value to us by holding up for our inspection the faults and extravagancies into which we are too apt to fall. He lived at a time and in a city in which those faults were exaggerated, and he had the genius to fix them in undying literature. This man was the great French dramatist Molière.

Recently I attended a good rendition of "Le Malade Imaginaire," a play filled with medical allusions, for Molière, both through his acquaintances and from natural inclination, was deeply interested in medicine; in fact under Gassendi he studied philosophy, which then consisted largely of physiology. His first play was on a medical subject, as was also his last. Before all his medical friends, and there were a considerable number, there was Mauvillain, his own physician. According to Molière, Mauvillain promised him before a notary thirty more years of life if he could obtain from him a certain favor from the king. Molière said this was even more than he required, it would be enough if he solemnly engaged not to kill him.

Molière was one of the few in medicine who, with a clear vision of the weaknesses and follies of mankind, had that abiding charity which prevents them from growing bitter. On the contrary, he had an infinite wit, kindliness and gaiety of spirit which enabled him to expose entertainingly ridiculous bombast and pretentiousness, a task always congenial to the Gallic mind.

The whole play is so full of medical allusions as to constitute an invaluable and vivid description of medical practice in the time of Louis XIV. It shows the profession's uncritical assumptions, its trivialities about the pulse, its liver lore, its pedantry, its arrogance, its willful ignorance of science, and its lavish employment of purgatives, enemas, and phlebotomy.

Its ignorance of science was not altogether a fault, as there was very little of that sort of knowledge then available, but what there was to be known was not welcomed by those in power, but, on the contrary, was vigorously resisted, and this furnished Molière with many an opportunity for a sharp stab.

This resistance was not, as might be imagined, that of stupidity, but of a very active intelligence, and how vigorous it was may be gathered from the fact that the University of Paris successfully opposed the teaching of the circulation of the blood

for more than half a century after the appearance of Harvey's treatise, "De Motu Cordis," in 1628.[1]

That the members of the faculty were men distinguished, and rightly so, for their learning is shown by the fact that Riolan, one of the most distinguished of them, was the only opponent whom Harvey took the trouble to answer. In explanation of this, however, it must be said that Harvey was not of a controversial nature.[2]

The scientific innovators were jestingly called "circulateurs," a common name for "quacks," and this, as will be seen later, is referred to in this play.

Molière did not limit himself to criticism of the physician; the patient is also severely dealt with, and the chief character in "Le Malade Imaginaire" is, as the title indicates, the patient; and I suppose no one but a physician can fully appreciate this hypochondriac, with his craving for sympathy, his exclusive attention to himself and his own ills, and his childlike outbursts of temper. How bitterly he complains when forced to attend to an incident in his family that he had not "the leisure to think of his own illness!"

The introductory scene is well worth medical study. It introduces the hypochondriac, seated in his chamber garment before a table, perusing his drug bill. He is indeed a very lively invalid. Attached to the back of his chair is the long cane with the red top which we are so used to seeing in pictures of the Grand Monarche. He cannot leave the room without the assistance of this cane, but he does not always use it as an aid to his steps, which on occasion are very lively steps indeed, but also for threatening and corporeally punishing the servants.

The druggist has described each item of his bill, and set opposite each its cost. It is a most minutely itemized account.

First on the list was "a little sinuative enema, preparative and emollient, to soothe, moisten, and refresh the bowels of the gentleman." On reading this the patient remarked that it was a pleasure indeed to have the apothecary draw up his bill in such polite terms, but that civility alone was not enough. One should be reasonable and not skin the public. With that he said that "when a druggist writes down twenty sols, he really means ten," and so he cut down this item 50 per cent. In pursuing further his criticism of the bill he noted a "good detergent clyster composed of double catholicon, rhubarb, honey of roses, et cetera, to sweep, wash out, and clean the lower bowel of monsieur." And, by the way, it may be remarked that the term catholicon is our familiar word catholic, which means universal (Greek *catholicos*); a universal clyster to clear out *all* the humors. This he cut down 60 per cent. There was also set down in the bill, as having been furnished on the same day, "a julip for the liver both soporific and somniferant." This the grateful patient did not object to, for, as he explained, it really soothed him to sleep. And that in this instance he paid in full is worthy of our attention.

The next item was "a corroborative, *i. e.* a strengthening (Latin *corroborare*) purgative composed of fresh cassia, Levantine senna, et cetera, compounded according to the prescription of Dr. Purgon, to expel and evacuate the bile of the gentleman." The cost of this elicited the remark that "It is no time for joking, and it is necessary to live with as well as by one's customers." On the same day he had an anodyne and astringent potion, to sooth the nerves as we would say. On the twenty-sixth of the month there was set down "a carminative clyster to expel flatus; this was to be repeated in the evening." The next day he received "a good compound medicine to hasten, set going, and expel the bad humors." Then came a draft made of whey, clarified and sweetened, to soothe, temper, and refresh the blood. And besides, on the same day, for we have now come to the twenty-eighth day of the month, there was delivered "a preservative cordial containing twelve grains of bezoar, syrup of lemon, pomegranates, and other things according to prescription." On observing the price the sick man exclaimed, "Easy, my friend, if you please; if you act in this way no one will wish to be sick," and with that he cut a good slash from the price.

On finishing his perusal of the bill and adding it up he found that he had taken eight bottles of medicine and twelve enemas during the month, and he was not astonished to find that he was not quite so well as during the previous month, when he took twelve bottles of medicine and twenty enemas. He said he would have to see his physician, Dr. Purgon, about this so that it might be better arranged.

At this point Toinette, his chambermaid, enters and, after passing a few remarks, none of which were pet names, Argan arises from his chair, which was indeed a chaise percée, and asks Toinette to remove it, and at the same time inquires if she thinks the stool a good bilious one. Toinette retorts that she does not mix in such affairs; that the apothecary might stick his nose into that since he had the profit. She further remarks that both the physician and the druggist have a gay time with him; that in him they have a good milch cow, and that she would like to ask them what malady he has, indeed, to require so much medicine.

All the functions of the body, when carried out physiologically, give rise to pleasurable feelings, but the hypochondriac wished to get altogether too much entertainment out of his alvine discharges. In two instances in the play he leaves the room hurriedly, as Marcellus in Hamlet would say, "to seek a more removed ground," and on his return he reseats himself in his chair with a wonderful expression of contentment and accomplishment on his face.

The hypochondriac was in mental servitude to his physicians. He dismissed Toinette's criticisms of them by calling her a dunce who had no right to criticize the rules and regulations of the faculty. He was equally opposed to his brother's criticisms. In the minutest details the doctors controlled his life; as, for instance, Dr. Purgon had told him to walk back and forth in his chamber for exercise, and he had forgotten to ascertain if he was to take this walk in the length or in the breadth of the room. On another occasion he asked Dr. Diafoirus the Elder how many grains of salt he should put in his egg. The answer came back promptly, two, four, or six, the even numbers; the odd numbers being reserved for medicine.

One day when Dr. Diafoirus called on him he

excused himself for not taking off his night cap, saying that Dr. Purgon did not permit him to do so. Even I can remember when "cold" was considered the chief etiological factor in medicine, and nearly all the long list of nervous diseases was referred to it. The paradigm was herpes zoster from a cold draft impinging on the side of the head.

The doctors in this entertaining play are Dr. Purgon, who evidently is a consultant and a most important person, to whom everyone refers all knotty questions, and Dr. Diafoirus, who is a family practitioner, and his son, Thomas. Toinette, the previously mentioned chambermaid, also comes in disguised as a doctor, and in this capacity gets off a number of good things.

The names of the doctors denote their chief occupation. Purgon is from *purgare*, to purge, and the suffix "on" would, as in Spanish, mean something large; therefore, "a mighty purger." Diafoirus would be from the Latin *foria*, a liquid stool, and therefore diafoirus would mean a liquid stool shot through. Both of these gentlemen lived up to their name, and, as we have seen, their patient lent his body, as Toinette would say, gaily to the exercise of their enthusiasm.

Thomas Diafoirus, the son, is the character who is so contemptuous of the "circulateurs," and he also mentions another feature of the times—the public dissections. Vesalius, 1514-1564, and Fabricius had lived and were ancient enough for their works to become sanctified, and public dissections were held, so that it was not unbelievable that this young prig, Thomas Diafoirus, should ask the young lady whom he was courting to attend, as a diversion, a public dissection at which he was to act as demonstrator. To be sure, Toinette made a tart remark on it.

In mentioning the circulation we must not omit one of the most delicate bits of satire in the play.

Diafoirus the Elder suggests to his son that he take the other wrist of the patient and describe the pulse as he feels it. They address one another in stilted Latin, and the youngster's first remark is that the pulse is that of a man not in good health, that it is slightly resistant (*duriuscule*), not to say resistant. This appreciation of a clinical fine point reminds one of the frequent employment in our vocabulary of a few years ago of the prefix sub as subcrepitant, subacute, et cetera.

Young Diafoirus goes on to say that the pulse is repellant and even a little jumpy. The term employed is *caprisant*, meaning jumping like a goat. From this characteristic of the pulse they assumed that there was a change in temperature of the parenchyma of the spleen.

The patient here interrupted to say that Dr. Purgon held that it was his liver, not his spleen, that was affected. Diafoirus the Elder was quick to save his face by explaining that the word "parenchyma" covered the entire field, because of the close sympathy that existed between the organs through the intermediary of the vas breve, the pylorus, and the *meats cholédoques*, and he suddenly shifted the patient away from a field where he might be called upon to assert something precise by telling him what to eat, always an interesting subject for a hypochondriac. The ruse was successful.

The employment of the term "meats," the Latin *meatus*, is interesting. It is here used correctly as indicating a duct. With us the term is limited to the auditory meatus, where it still carries with it something of its original meaning of a channel, and to the external orifice of the urethra, where it certainly means a mouth. Holden, as late as 1878, speaks of the three meatus or passages of the nose.

The hypochondriac's brother, seeing his sad condition, comes to distract him and to wean him away from his medical infatuations, and in the course of his conversation says, as under such circumstances he would, many sharp things against the profession. He said that most of them were well read in the classics, which was true at that time in France; that they knew how to speak a pure Latin, that they could give the Greek name of all the diseases, define and classify them, but as for curing them they did not know anything at all. Furthermore, he said that the inner workings of our corporeal machine were mysteries which had never been penetrated, and that nature had placed before our eyes a veil too thick to be pierced. Many a rent has been made in that veil since Molière's day, and especially in our knowledge of that disease, aortic aneurysm, of which he so tragically perished.

The oath on receiving the Degree of M.D., the famous "juro," is also a precious addition to medical literature. It is a wonderful mixture of Latin, dog-Latin, Italian, French, and fanciful terms belonging to no language. The Hippocratic oath from long service has become somewhat tiresome. If the "juro" of Molière could be occasionally substituted we might go back to the precepts of our more ancient friend, with some hope of practising them.

After the applicant for a degree had sworn to give his prospective patients a clyster, then to bleed, and on top of that to purge, and if the malady turned out to be obstinate to rebleed, repurge, and reclysterize, and throughout to employ only remedies such as were authorized by the faculty, he was endued with the degree, together with full license to medicate, to purge, to bleed, to pierce, to trim, to cut, and to kill, and to practise this without fear of punishment throughout the whole world (*impune per totam terram*).

Teutonic Versus Latin Culture.—Dr. Cruchet, editor of the *Journal de Médecine de Bordeaux*, contributes in the issue of January 25, 1922, xciv, 2, an editorial on an article which had recently appeared in the *Hamburger Nachrichten* on the above subject. This article bristles with personalities directed against Frenchmen eminent in all walks of life. The editor who has often himself pointed out some of the errors of the Teutonic viewpoint, naturally comes in for his share of abuse. Clemenceau is twitted of having a "Mongolian head" and similar personalities are indulged in. No doubt this article in the German periodical is motivated largely by the storm of hostile criticism directed against Teutonic culture during the years of war.

THE PRESENT DAY TUBERCULOSIS PROBLEM IN EUROPE AND IN THE UNITED STATES.*

BY S. ADOLPHUS KNOPF, M.D. (Univ. N. Y. and Paris)

ATTENDING SPECIALIST, UNITED STATES WAR VETERAN HOSPITAL NO. 61.

(Approved for publication by the Surgeon-General U. S. P. H. S.)

THE tuberculosis problem of today in Europe outside of England, is appalling. The following interesting table,† compiled by Mr. J. G. Drolet, statistician of the New York Tuberculosis Association, giving the civilian deathrate from tuberculosis in large European cities and in the United States and England prior to, during, and after the war, speaks for itself:

For Each 10,000 Inhabitants, Period 1913-1920.

	Pre-War, 1913	Mid-War, 1917	After-War. 1920
New York (pulmonary tuberculosis)	171	164	109
London (pulmonary tuberculosis)	130	171	103
Paris (pulmonary tuberculosis)	328	295	227
Berlin (pulmonary tuberculosis)	156	292	148
Vienna (all tuberculosis)	302	425	405
Warsaw (all tuberculosis)	306	840	338
Lodz (all tuberculosis)	...	1,164	...
Cracow (all tuberculosis)	487	908	...
Lwov (all tuberculosis)	480	605	...
U. S. registration area (pulmonary)	128	129	100
England and Wales (pulmonary)	99	134	89

This table shows what the war *per se* has done to increase the tuberculosis deathrate and how disorganized government as in Vienna, Warsaw, Lodz, Cracow, and Lwov is an additional factor in the increase of the tuberculosis deathrate among the civilian population. How much Russia, which always had the highest tuberculosis deathrate of all European countries, has lost in men, women, and children from tuberculosis under the Soviet regime, will never be known. No statistics are available. Only through a wise reconstruction, political, economical, sanitary, and moral, is there hope for Russia to reduce its deathrate from tuberculosis and other social diseases.

In Serbia virtually nothing is done except some propaganda carried on by means of notices in public places, pamphlets, and moving pictures. Only two small hospitals and a few dispensaries for the care of the tuberculous exist. The situation, always bad, has become very desperate since 1914. The mortality is about 10 for every 1000 inhabitants. Of every hundred persons 20 are tainted, and 10 in 100 are ill with tuberculosis. In Roumania, in spite of its small urban population, the mortality from tuberculosis is 31 to 32 per 10,000 inhabitants; in some regions it reaches 50; where the mortality is the greatest, the housing conditions are the worst. Greece presents a little more hopeful outlook; it has established an educational center, one dispensary and a large hospital-sanatorium at Athens, and early cases are sent to climatic resorts.

Heroic efforts are being made by some of the European governments and by private philanthropy, including the vast sums of money contributed by the American people, to reduce the fearful morbidity and mortality from tuberculosis in the war-stricken countries of Europe. In France particularly a most energetic crusade has been carried on for the past few years; firstly, for the education of the rising generation of medical men in tuberculosis science; secondly, for the popular education of the masses in the prevention of tuberculosis; and lastly, for the hospitalization and cure of those afflicted with the disease. The valuable financial assistance contributed by the Rockefeller Foundation, has been in no small way responsible for the impetus to this magnificent work.

In Belgium an admirable governmental as well as private crusade against tuberculosis has been started, mainly under the leadership of Dr. Réné Sand, who came to the United States a few years ago to study our municipal methods of combating tuberculosis and visit a number of our sanatoria for the treatment of tuberculous patients. The Rockefeller Foundation has also generously aided the Belgian people in their combat of tuberculosis. Marine, alpine, and agricultural colonies are contemplated as means to combat the great tuberculosis morbidity and mortality. Tuberculosis is on the increase in Spain (Catalonia) and the housing problem is particularly acute. Italy is active and has recently sent a commission to the United States for study and cooperation in its work. A most active society has been formed under the name of "Italian National Association for War Consumptives." Dispensaries have been increased from twenty-six to more than 100. Since the war, an anti-tuberculosis cooperative society, with a capital of about ten million francs has been established. In the Netherlands an intense effort has been made to combat the appalling increase in tuberculosis that occurred during the war, when the deaths rose from 14 per 10,000 inhabitants in 1914 to 20.25 in 1918. The Scandinavian countries have a remarkably low death rate from tuberculosis compared with other portions of Europe.

Owing to the serious financial conditions in Germany, a number of semi-philanthropic sanatoria

* Read before the Section on Medicine of the N. Y. Academy of Medicine, Feb. 21, 1922.

†Bulletin of the N. Y. Tuberculosis Association, February, 1920.

(workingmen's insurance sanatoria) depending on the support of the public, had to be closed, and according to the *Zeitschrift für Tuberkulose* of January, 1922, one of the most important government institutions, the "Universitäts Polyklinik für Lungenleidende" in Berlin (University Polyclinic for the tuberculous) is to be closed on March 31st. A rather startling notice appeared in the *Zeitschrift* for December, 1921, wherein it was stated that the sanatorium at Loslau (Silesia) had to be closed because of political disturbances. Nevertheless, in Germany and particularly in Prussia they are now trying in some provinces to make it obligatory to report not only the deaths from tuberculosis but also all open cases of tuberculosis of the lungs and larynx. The tuberculosis deathrate, at least in Berlin, is now only half of what it was during mid-war. The education of the masses through lectures by various university professors is a feature of the anti-tuberculosis work in the new Germany. Similar efforts are being made in Austria where, as a result of malnutrition lasting for a number of years, the tuberculosis deathrate particularly among children, has surpassed all existing records. An interesting movement to combat tuberculosis is on foot in Austria. Dr. Tandler has suggested to the Landessanitätsrat that in order to combat syphilis, tuberculosis, and certain other degenerative diseases (cancer), marriage should be forbidden in families where the former two diseases exist and the latter has been observed for a number of generations.

The *Zeitschrift für Tuberkulose* reaches this country regularly again, but all the articles are in German while prior to the war contributions appeared in English, French, German, Swedish, and Dutch. On the other hand, the organ of the International Antituberculosis Association which appears monthly under the name of *Tuberculosis*, prints articles in English, French, and German. This periodical now makes its appearance regularly and Prof. Gotthold Pannwitz is the editor.

The January number contains an article on the subject of the new antituberculosis law, contemplated in the Reichstag, and suggests a union of all the tuberculous patients of the land so that they themselves may have something to say concerning the forthcoming legislation. The nucleus for such an organization is already established under the name of "Verband der Lungen-und Tuberkulose-Erkrankten Deutschlands" (Union of patients afflicted with tuberculosis of the lungs and other organs). The object of the association is set forth as follows:

1. The assurance of ample nourishment for the tuberculous.
2. The establishment of legal rights for sanatorium treatment.
3. The assurance of proper and ample housing conditions.
4. The establishment of special industries for the tuberculous.

Dr. Moses, a member of the Reichstag, who will bring the appeal for the tuberculous before the governmental authorities, is sending out the following inquiry in English, French, and German to the readers of "Tuberculosis:"

1. Do similar unions of tuberculous invalids exist in other countries?
2. How are they organized?
3. Does this movement of tuberculous invalids receive official support?
4. What is the attitude of the medical profession toward such an organization of the tuberculous?
5. What if any was the experience in soliciting voluntary public support, as for instance in the sale of tuberculosis seals?

Dr. Moses will be grateful for an early reply to these questions.

The very large and important International Tuberculosis Conference which was held in Paris a year and a half ago (October 17-21, 1920), to which nearly all the countries of Europe, except Russia and Germany, had sent delegates and at which the United States was also represented, proved a revival of the international interests in the struggle against tuberculosis.

Fortunately, in the United States the deathrate from tuberculosis has decreased in spite of war and a serious grippe epidemic. The tuberculosis problem of to-day in this country is a hopeful one and it is different from the problem which confronted us twenty-five years ago, or even fifteen years ago, when the active work of the National Tuberculosis Association was begun. The legislative, sanitary, medical, and social conditions have been vastly improved since then, and when one reads the favorable reports on the decrease in the tuberculosis deathrate, one is apt to think that we need no longer worry about the disease. In an admirable paper by Dr. Lee K. Frankel, Third Vice-President of the Metropolitan Life Insurance Co., read before the National Tuberculosis Association at its last year's meeting, the author states that 60,000 fewer deaths occurred in the United States Registration Area from pulmonary tuberculosis in 1919 than if the 1900 deathrate had prevailed.

If the encouraging decrease of 40 per cent. in the local deathrate should keep on, one might presume that in a decade or two we would have mastered this plague. Alas, our goal still seems to be far from us. There are still 500 victims every month, and to quote from "Better Times," New York's Welfare Magazine, of December: "Even more disturbing is the fact that the present Department of Health registration of known cases of pulmonary tuberculosis shows that 14,491 patients, or 53 per cent. of the total of 27,252 cases in the entire city on October 1, 1921, were not under medical care."

Efforts are of course constantly being made to get hold of these uncared-for cases, and it is to be hoped that the great number of patients without medical attendance will be materially decreased in the near future so that all tuberculous patients may be placed in a sanatorium or in a hospital, or else be under the care of a physician who will show them as nearly as possible how to obtain at home the same condition as in a sanatorium.

Besides the tuberculous among our civilian population, we have of course also a large number of tuberculous ex-soldiers and sailors. In comparison with other countries, both our allies and the central powers, particularly France and Italy, Austria and Germany, the number of our soldiers who contracted tuberculosis during, or later as a result of the war is indeed small. This fortunate circumstance is due to the care exercised by the draft boards and camp surgeons in eliminating the tuber-

culous or the strongly predisposed men who had been drafted. Nevertheless, an aggregate of 59,903 tuberculous ex-service men and women were given hospital care up to February 1, 1922. So far, the following government hospitals are functioning to take care of tuberculous ex-service men and women:

(District No. 1)

U. S. P. H. S. Hospital, No. 36, Boston, Mass.; No. 41, New Haven, Conn. (also for surgical tuberculosis for this district and districts No. 2 and No. 3); No. 60, Oteen, N. C. (males and females).

N. H. D. V. S. Hospital, Togus, Me.; Rutland, Mass. (When opened.)

(District No. 2)

U. S. P. H. S. Hospital, No. 60, Oteen, N. C. (males and females); No. 61, Fox Hills, N. Y. (observation only).

N. H. D. V. S. Hospital, Johnson City, Tenn.

(District No. 3)

U. S. P. H. S. Hospital, No. 66, Ft. McHenry, Md. (observation only); No. 60, Oteen, N. C. (males and females).

N. H. D. V. S. Hospital, Johnson City, Tenn.

(District No. 4)

U. S. P. H. S. Hospital, No. 32, Washington, D. C. (observation only); No. 56, Ft. McHenry, Md. (observation only); No. 29, Norfolk, Va. (observation only); No. 26, Greenville, S. C.; No. 60, Oteen, N. C. (males and females).

N. H. D. V. S. Hospital, Johnson City, Tenn.

(District No. 5)

U. S. P. H. S. Hospital, No. 26, Greenville, S. C.; No. 60, Oteen, N. C. (male and female); No. 45, Biltmore, N. C. (surgical tuberculosis only for this district and districts No. 4 and No. 6); No. 48, Atlanta, Ga. (observation only); No. 63, Lake City, Fla.

N. H. D. V. S. Hospital, Johnson City, Tenn.

(District No. 6)

U. S. P. H. S. Hospital, No. 27, Alexandria, La.; No. 60, Oteen, N. C. (females only); Algiers, La. (observation only); No. 26, Greenville, S. C.; Dawson Springs, Ky. (when opened).

U. S. Marine Hospital, No. 14, New Orleans, La. (observation only).

N. H. D. V. S. Hospital, Johnson City, Tenn.

(District No. 7)

U. S. P. H. S. Hospital, No. 60, Oteen, N. C. (male and female); No. 69, Newport, Ky. (observation only).

U. S. Marine Hospital, No. 8, Evansville, Ind. (nontransferrable cases and for observation only).

U. S. P. H. S. Hospital, Dawson Springs, Ky. (when opened); No. 26, Greenville, S. C.

N. H. D. V. S. Hospital, Dayton, Ohio; Johnson City, Tenn.

(District No. 8)

U. S. P. H. S. Hospital No. 30, Chicago, Ill. (observation only); No. 75, Maywood, Ill. (observation only); No. 60, Oteen, N. C. (females only); No. 65, St. Paul, Minn. (for observation only for patients residing in Northwestern Wisconsin); Dawson Springs, Ky. (when opened).

U. S. Marine Hospital, No. 8, Evansville, Ind. (for observation only for patients residing south of Springfield, Ill.); No. 18, St. Louis, Mo. (for observation only for patients residing south of Springfield, Ill.).

U. S. Army (Fitzsimmons) General Hospital, Denver, Col.

U. S. Naval Hospital, Ft. Lyons, Col.

(District No. 9)

U. S. Marine Hospital, No. 18, St. Louis, Mo. (nontransferrable cases and observation only).

U. S. P. H. S. Hospital, No. 50, Prescott, Ariz.; No. 60, Oteen, N. C. (females only); No. 55, Ft. Bayard, N. M. (male and female); Dawson Springs, Ky. (when opened); Excelsior Springs, Mo. (when opened).

U. S. Naval Hospital, Ft. Lyons, Col.

U. S. Army (Fitzsimmons) General Hospital, Denver, Col.

(District No. 10)

U. S. P. H. S. Hospital, No. 50, Prescott, Ariz.; No. 55, Ft. Bayard, N. M. (male and female); No. 64, Camp Kearney, Cal. (patients from Montana only, but only until Walla Walla opens); Walla Walla, Wash. (when opened) (patients from Montana only); No. 55, St. Paul, Minn. (observation only); No. 68, Minneapolis, Minn. (observation only); No. 72, Helena, Mont. (observation only).

N. H. D. V. S. Hospital, Hot Springs, S. Dak.

(District No. 11)

U. S. P. H. S. Hospital, No. 55, Ft. Bayard, N. M. (male and female); No. 50, Prescott, Ariz.

U. S. Naval Hospital, Ft. Lyons, Col.

U. S. Army (Fitzsimmons) General Hospital, Denver, Col.

(District No. 12)

U. S. P. H. S. Hospital, No. 51, Tucson, Ariz.; No. 50, Prescott, Ariz.; No. 24, Palo Alto, Cal.

U. S. Naval Hospital, Ft. Lyons, Col.

U. S. Army (Fitzsimmons) General Hospital, Denver, Col.

N. H. D. V. S. Hospital, Sawtelle, Cal.

(District No. 13)

U. S. P. H. S. Hospital, No. 59, Tacoma, Wash.; No. 52, Boise, Idaho (observation only); Walla Walla, Wash. (when opened); No. 44, Camp Kearney, Cal. (only until Walla Walla opens); No. 50, Prescott, Ariz.; (only until Walla Walla opens). No. 55, Fort Bayard, N. M. (females only).

U. S. Naval Hospital, Ft. Lyons, Col.

U. S. Army (Fitzsimmons) General Hospital, Denver, Col.

(District No. 14)

U. S. P. H. S. Hospital, No. 50 Prescott, Ariz.; Excelsior Springs, Mo. (when opened) (patients from Arkansas and eastern Oklahoma only); No. 55, Fort Bayard, N. M.

U. S. Army Station Hospital, Ft. Sam Houston, San Antonio, Tex.

Additional provision for a probable increase in the number of tuberculous ex-soldiers is contemplated.

In answer to occasional public criticism of some of the tuberculosis hospitals, it must be remembered that several of these hospitals had been hastily constructed by the medical department of the U. S. Army because of urgent need and with no thought that they should be permanently occupied by the chronically ill with tuberculosis. As to the medical and general care bestowed upon our tuberculous ex-service men and women, I feel that any criticism has little or no foundation. The officers and nurses entrusted with the care of these men have nearly all seen overseas service, are experienced in the special care of the tuberculous, and devoted to their tasks.

I have visited some of the U. S. Government hospitals in the West and can speak from a lengthy experience in one of the largest of our Eastern institutions. The patients are treated kindly and considerately and many have more freedom regarding their movements than in civilian tuberculosis hospitals. This might be deplored, but we must not forget that the psychology of the tuberculous ex-soldier is somewhat different from that of the civilian patient. Nevertheless, as a whole the discipline is excellent. The morale is good and everything possible is done to obtain an arrest of the disease or a cure in favorable cases, and whenever possible an economic cure is striven for in the moderately advanced case. By an economic cure must be

understood a condition which will enable the tuberculous patient to work a few hours daily in sanitary environments at his trade or calling, or at a job for which he has been prepared by vocational training, without fear of a relapse. The seemingly hopeless are made as comfortable as lies in human power to make them. The American people may rest assured that the United States Government is doing its utmost for all the war wounded and sick and that the tuberculous among them are receiving as good, and in many instances better, care than municipal or even private institutions can offer.

To return again to our civilian problems. In a recent appeal to the American people on behalf of the National, the New York City, and other local Tuberculosis Associations, for financial assistance to the antituberculosis cause by means of the sale of the Christmas seals, I emphasized the following facts: As is well known by all students of tuberculosis, the disease, as a rule, does not begin in adult life. It is most frequently contracted in childhood. While it may always remain a latent infection and never develop into a disease, where there is privation and want, underfeeding, insufficient clothing, and overcrowding, the infected child is bound to develop tuberculosis. Malnutrition among children whose parents are in poor or even moderate circumstances, owing to hard times and winter weather, is more to be feared this year than ever before. Many an adult, predisposed to tuberculosis, retains his good health in prosperous times because he can get good, nutritious food and have a comfortable home. It is different now with the vast army of unemployed, many of whom not only live less comfortably and less hygienically, but must content themselves with insufficient food. Add to this their natural anxiety about the future, and I am sure that unless the situation changes soon we shall have a great many tuberculous adults.

It was gratifying, after my attempt to arouse public interest in the antituberculosis campaign, to see the daily papers express a realization of the seriousness of the situation. In an editorial in the New York *World*, which appeared a few weeks ago, some very good advice for employer and employee was given in the following words: "With an army of workers idle and reduced to less hygienic living conditions, the development of tuberculosis will be encouraged." That is something for employers and restless employees to bear in mind. This admirable editorial, referring to my above mentioned plea, says: "It is an unfavorable time to go on strike without sufficient cause and an equally unpropitious time to enforce wage or working conditions likely to precipitate a strike. The fact that many employees are out of work ought to induce caution both in the counting room and at union headquarters on economic grounds alone. If these are not adequate the question of impaired health in the worker should turn the scale toward conservatism. It is not a time for letting go but for holding on."

Let us all do our share in solving this particular problem. Let us come to the rescue of those thousands of children and the thousands of men and women who are in danger of becoming tuberculous. It will be a glorious preventive work, and if we can add to this the hygienic care, supervision, and frequent cures or at least arrest of the disease in the uncared-for cases, we will accomplish great things. When one reflects that the above-given figures (27,252), uncared-for cases only apply to the city of Greater New York, what must be the number throughout the United States! From the foregoing we see the necessity of keeping up the slogan, "The fight against tuberculosis must still be on."

Besides the antituberculosis campaign so admirably conducted by the National, State, and City Tuberculosis Associations for the education of the public in the prevention of tuberculosis, we must pay more attention to this antituberculosis education in elementary schools, high schools, and colleges. In elementary and high schools, particularly in the latter for girls, there is too much attention paid to the development of the intellectual faculties and too little to the physical, to the detriment of the physique of the future mothers of the country. Not only for the growing child and the adolescent, but for all individuals, "the inordinate stress, physical and mental," should be avoided if we wish to conquer tuberculosis as a disease of the masses. There should be periodical physical examinations of all pupils, no matter whether in public, private, or parochial schools or in colleges. I hope the time will come when the American people as a whole will realize that periodical examinations by their family physicians or some authorized medical examining board, perhaps twice yearly, for the purpose of determining their physical status and the possible checking of an insidious disease, are to their physical, mental, and financial advantage.

In an article, published last August by the Chief of the Tuberculosis Section of the U. S. Public Health Service, entitled "Outline of a Campaign for the Control of Tuberculosis"* this universal examination of adults is strongly endorsed in the following list of proposed activities: "Popularize the practice and form the habit of physical examination among the school children and men and women of every class and age. The routine periodical physical examinations by the Government of all Federal employees; officers and enlisted men of the Army, Navy and Coast Guard; inmates of Federal prisons; policy holders of the Bureau of War Risk Insurance; merchant seamen and other potential beneficiaries of the Public Health Service; and lastly, more efficient examination of immigrants."

There are perhaps now a sufficient number of sanatoria, special hospitals, and dispensaries in most parts of the United States; but in order to solve the problem thoroughly the preventive side must not be neglected, but go hand in hand with all the curative measures. Thus, in my humble opinion, we need maternity sanatoria for tuberculous mothers and more preventoria for predisposed infants and small children. Preventoria are urgently needed and should be established not only by private initiative but also by public authorities. And last but not least, we need more workshops for the partially recovered tuberculous patients or those entirely cured but untrained in any work and not fit to take up a vocation demanding great physical strain. Two such model institutions exist now in the city of New York; one is the Altro Manufacturing Co., 1157 Southern Boulevard. Patients above referred to as economically cured and

*F. C. Smith, *Journal of the Outdoor Life*, August, 1921.

with previous experience in garment making can find remunerative employment there for as many hours as their constitution will permit. At the Reco Manufacturing Co., located at 460 Pierce Avenue, Long Island City, patients are taught watch making, jewelry manufacturing, and cabinet making to enable them to earn a good living after leaving the Reco work shops.

Concerning the care of our recovered tuberculous ex-service men, I quote again from the article just referred to, as follows: "The Federal Board of Vocational Training has already an arrangement with the National Tuberculosis Association whereby a study will be made for a term of years through funds equally contributed by both organizations, to determine vocations suitable for the tuberculous. When we have at least reconciled ourselves to the knowledge that we must live with tuberculosis, that we cannot get away from it, nor isolate the tuberculous, we shall be prepared to entertain many measures not heretofore contemplated, whereby treatment will be carried out in the homes with the aid of visiting nurses, public dispensaries and social vocational workers."

May I conclude this brief survey of the present status of the tuberculosis problem in our own and some of the European countries by repeating a motto with which I headed a little essay on the subject, "Tuberculosis as a Disease of the Masses and How to Combat it." The essay was published nearly 25 years ago and the motto referred to reads as follows: "To combat tuberculosis as a disease of the masses successfully, requires the combined action of a wise government, well trained physicians, large hearted philanthropists, and an intelligent people." This motto is still applicable to present day conditions.

ARSENICAL PIGMENTATION OF THE SKIN.

By DOUGLASS W. MONTGOMERY, M.D.,

AND

GEORGE D. CULVER, M.D.,

SAN FRANCISCO, CAL.

Occasionally arsenic, when taken internally, gives rise to pigmentation of the skin. This is not a deposition of the metal, as in the discoloration produced by taking the salts of silver, but is due to stimulation of the pigment-producing function of the cutaneous cells. It is therefore not permanent, as the silver discoloration is, but slowly fades out on discontinuing the drug.

Arsenical pigmentation is interesting, not alone because of the disfigurement it occasions, but also for what it may simulate, as it may be mistaken for a cachectic pigmentation such as arises in tuberculosis or it may mimic Addison's disease.

It has yet another interest, and this is the principal one to a physician, as it shows conclusively the stimulating effect of this drug on the life processes of the epithelial cell. We shall speak further of this later.

Arsenical pigmentation is rarely seen by us, because it usually requires large doses to produce it, and although we frequently administer arsenic, our dosage, excepting as arsphenamine, is almost invariably low. And arsphenamine is peculiar among arsenical preparations in that it does not give rise to pigmentations; at least we have never seen or heard of its doing so.

Arsenic is one of the oldest drugs, and it undoubtedly is more used now than ever before, if we include, as we should, its organic compounds such as arsphenamine and the cacodylates. There is no question of the influence arsenic exerts on the body. Its very name, arsenic, or "the powerful," indicates what our forefathers thought of it, for although the Greek word "arsen" may be translated as the Latin "mas" or "masculus," it likewise also means "fortis" (strong), and "strenuus" (energetic), and it is this latter signification that probably prevailed. That the ancients were aware of its "strenuous" nature when administered with a free hand is shown by the cheerful use they made of it in ridding themselves of personal rulers. Mahaffy relates that a member of the Royal Egyptian household one day overheard Ptolemy V Epiphanes, inverting Alexander the Great's jest about his friend's money being practically his own. He made haste to remove the jester by a good dose of arsenic, which goes to show that there is nothing quite so trying on friendship as a difference in taste in the matter of jokes.

Tre Relative Frequency of this Bye-Effect.—The pigmentation of chronic arsenical poisoning is almost as frequent as conjunctivitis or congestion of the hands and feet, and much more so than keratodermia of the palms and soles.[1] It must be remembered, however, that all of these bye-effects are rare except when the drug is given in large dosage. As one might expect, the appearance of the discoloration varies in different cases in its topographical distribution, in the size of the patches and also in its intensity. Brocq, for instance, in giving arsenic for acne in young girls, warns the parents that brown patches may appear on the face, and as brunettes are more susceptible to this manifestation than blondes, and as he in France probably sees more brunettes than we do, this may be a wise precaution. Furthermore, he may give large doses in order to get the effect of the arsenic as a laxative, which we never do in acne.

There may be only a few disseminated yellowish-brown patches or they may be of all grades between this and a generalized continuous melanodermia simulating Addison's disease, and only distinguishable from it by the absence of general constitutional symptoms and the lack of pigmentation of the mucous membranes.

In one of our cases a patient who had been under our care for lues came in one day telling us that his abdomen was growing unaccountably dirty looking, and that he was sure it was not due to lack of bathing. As we knew that there was a suspicion in his case that he was suffering from an abdominal tumor, we at first suspected that the discoloration might be owing to involvement of the sympathetic nerves in some pathological process, but the reticulated appearance started an inquiry in regard to arsenic, and we learned that he was taking heavy doses of the cacodylate of iron. He also had some pigmentation of the forehead and temples.

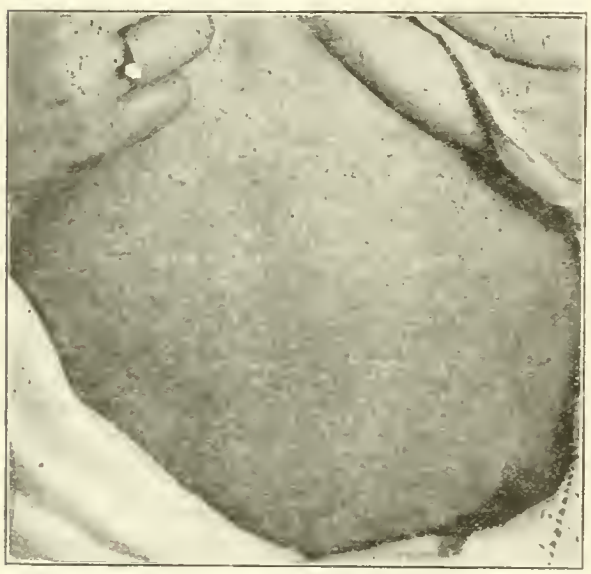
In one of Borsellini's cases the resemblance to the melanotic syphilitic collar was exact.

It is well also to remember that both the syphi-

litic melanotic collar and arsenical pigmentation of the neck are apt to appear more frequently in women than in men. Why the luetic collar should show this preference is not known. The more frequent occurrence of arsenical melanodermia in women is probably due to their more frequent uncontrolled use of the drug taken for its cosmetic effect.

In a woman recently seen by us the dirty brown pigmentation of the neck and upper part of the chest at first gave rise to the idea that it might be cachectic and might furnish a clue to the cause of the rosacea for which she consulted us. On examining the abdomen, however, a typical reticulated arsenical melanodermia was seen, and it then transpired that the discoloration had appeared while taking arsenic "to clear the complexion."

As before referred to, it usually requires high doses and long continued use to produce this pigmentation. Pusey, however, has spoken of a patient, seventy years of age, who developed an intense



Reticulated arsenical melanodermia produced by taking ten drops of Fowler's solution for three weeks. In describing this kind of pigmentation Siqueira very aptly calls it "dappled."

pigmentation after taking five hundred minims of Fowler's solution during a month.[2] This was just about sixteen minims a day or six minims a dose —not an excessive quantity. A patient of ours, the young woman already referred to, said that she took ten drops three times a day for three weeks. The pigmentation was, as shown in the photograph, intense. As before remarked, arsenical pigmentation is not a deposit of metal as in argyria, but a stimulation of the pigment-producing cells, and this is the reason why brunettes are more afflicted than blondes; their pigment-producing cells are more easily stimulated in this direction.

Arsenic As a Cell Stimulant.—That arsenic should so stimulate the life processes of the cell is most interesting, and this cell stimulation by arsenic indicates why this remedy has held its place so long as an independent tonic, and also as an adjunct to other tonics and medicaments.

For instance, we all are aware how a patient will brighten up under the influence of moderate doses of arsphenamine, and how it aids in the therapeutic effect of mercury. It may be recalled that before the discovery of arsphenamine it was often found that when mercury failed in its effect, a dose of atoxyl would so change conditions as to secure success. Also the association of small doses of arsenic with iron in the treatment of anæmia is a well known and appreciated therapeutic measure. This stimulation of metabolism is the probable reason for the excellent effect of arsenic in the status seborrhœicus, in which the fat metabolism of the epithelial cells is undoubtedly faulty. The administration of arsenic acelerates the sluggish chemical processes, and secures the oxidation of the superfluous fat.

The mechanism of this stimulation is not known, but it may be due to the accelerating action of the metal on the oxidizing catalysers contained in the cell, similar to the acceleration of the oxidizing catalysers in the nitroso-monas in the presence of iron and manganese, as explained by Osborn.[3]

This view of the action of arsenic particularly commends itself as offering an explanation of the marked effects produced by small doses.

DISLOCATION OF THE SEMILUNAR BONE OF THE WRIST.

WITH REPORT OF A CASE.

By IRA COHEN, M.D., F.A.C.S.,
NEW YORK.
ADJUNCT SURGEON, MOUNT SINAI HOSPITAL; CHIEF OF SURGICAL CLINIC, MOUNT SINAI HOSPITAL DISPENSARY.

On March 5, 1921, a painter, aged thirty-two, came to the Mount Sinai Hospital Dispensary stating that several hours previously he had fallen a distance of several feet from a ladder and struck his left hand. He did not know what part of his hand he had hit or its position when he landed. There was immediate pain and loss of function; the latter due in part to pain and in part to mechanical inability to extend the fingers. The wrist was very much swollen, the enlargement being most marked in the anteroposterior diameter. The swelling precluded accurate palpation of the bones. A diagnosis of probable fracture of the radius and the ulna at the wrist was made, a temporary anterior padded splint was applied and the patient sent for an *x*-ray examination.

As seen in Fig. 1, the bones of the forearm are intact, but there is a dislocation of the semilunar, which is rotated through an arc of 90 degrees so that its inferior articular surface looks forward. The rest of the carpus is normal. On March 8 an attempt at reduction was made; this was unsuccessful, and roentgenograms showed the position of the semilunar practically unchanged. On March 12, one week after the injury, a second attempt at reduction was made. Traction was made on the hand while the wrist was strongly hyperextended, and at the same time the thumbs made pressure on the semilunar. The bone was felt to slip back and after it was in position could distinctly be felt to wobble. The hand was fixed in a position of moderate flexion by an anterior molded plaster splint. The pain, which had been constant, severe and associated with formication in the distribution of the median nerve, completely disappeared when the

reduction was made. Reontgenograms, Fig. 2, taken at this time, show the semilunar in its normal situation.

Examination a week later with special attention to neurological changes failed to show any alterations in the distribution of either the median or ulnar nerves. The patient was then referred to the department of physicotherapy for treatment.

Fig. 1.—Lateral view showing rotation of the semilunar bone to 90 deg.; the concave articular surface looks forward instead of downward. The anteroposterior view shows the dislocation and rotation of the semilunar bone.

Examination one month after reduction showed no nerve involvement, voluntary motion at the wrist was limited to flexion and ulnar flexion of 5 degrees. There was limited flexion and extension of the fingers. In July, four months after the injury, the range of motion was complete in all directions, but there was some weakness at the wrist. In December the only objective finding was a slight thickening of the wrist, and subjectively the hand tired more readily than normally.

While dislocation of the semilunar bone ranks second in point of frequency among injuries to the carpus, fracture of the scaphoid holding first place, it is not a common lesion. In reporting three cases in 1907 Poulsen,[39] adding the cases collected by him to those previously collected by Eigenbrodt in 1901 was able to list 75 instances of dislocation of the semilunar bone. Of these 53 were simple dislocations, the remainder being associated with injuries to the neighboring bones. From 1905 up to the present time, exclusive of the cases reported by Poulsen, I have collected 84 instances of dislocation of the semilunar bone, 29 of which were uncomplicated. There were three posterior dislocations, [14, 20, 42] in one case the bone was fractured as well as dislocated,[14] one patient had previously dislocated the opposite semilunar, and in two instances there was a bilateral dislocation.[2, 19] Forty-eight cases were complicated by injuries to one or more of the neighboring bones; of these the scaphoid was involved 37 times; in 7 instances it was not stated whether or not there were concomitant injuries.

Etiology and Mechanism.—Because it is unusual for a patient to remember the exact position of his hand and arm at the time of receiving his injury, we are not aided by the history in our search for the mechanism inducing this type of dislocation. The usual result from a fall on the outstretched hand is a Colles fracture or, more rarely, a fracture of the scaphoid. Destot[5] and Lilienfeld,[30] from the experimental side, have succeeded in reproducing typical dislocations of the semilunar in the cadaver by adding ulnar flexion to hyperextension. It is very probable that this position obtains clinically; and this alone or in conjunction with the peculiar "make up" of the patient's bones and ligaments, as Murphy[35] claims, is responsible for the dislocation rather than a scaphoid or Colles fracture.

To appreciate the mechanism of dislocations forward of the semilunar bone we must remember that motion at the wrist is made up not only of movements between the carpals and the bones of the forearm, but also between the proximal and distal rows of carpals. The scaphoid, spanning both rows (which is one factor in the etiology of fractures of that bone), moves with each row. Of the ligaments attached to the semilunar, the one on its anterior aspect connecting it to the radius is the strongest and most important in determining the position of the bone when dislocated. Thebault[43] points out that the larger portion of the body of the semilunar lies anteriorly, and that while it covers rather completely the anterior portion of the head of the os magnum, it leaves the posterior aspect poorly covered.

By some authors the mechanism of the dislocation has been compared to the expression of a cherry pit between the fingers, the pit being the semilunar bone which is compressed between the os magnum below and the radius above, and the propelling force the impact from the fall. The probabilities are that the dislocation is brought about as follows: The age and sex of the individual and shape of the bone are contributing factors. It is very much more frequent in the second and third decades. It is more common in males. And as Delbet[9] claims it seems to occur more often in supple hands, and where the concavity of the semilunar facing the os magnum is shallow and the posterior angle poorly developed. In hyperextension at the wrist, as obtains in falls on the outstretched hand, the head of the os magnum moves behind the semilunar. If the force continue the poorly developed anterior ligament from the semilunar to the os magnum ruptures, and the head of the os magnum, passing further behind the semilunar, acts as a lever to force it forward. The ligament passing from the posterior aspect of the semilunar to the scaphoid facet of the radius gives way and the semilunar dislocates forward. Still

Fig. 2.—Lateral and anteroposterior views after reduction

held by the anterior ligament attaching it to the radius, which acts as a hinge, it rotates. Rotation cannot go beyond 180° unless this last ligament is torn, when complete rotation up to 360° is possible. The bone has been reported driven through

the flexor tendons and lying on the forearm beneath the skin.

Nomenclature. — Whether this type of injury should be known as forward dislocation of the semilunar, backward dislocation of the os magnum, or mediocarpal dislocations, depends on whether the lesion is viewed from the standpoint of the mechanism or the end stage. With a complete dislocation of the semilunar the attention does and should focus on that bone. Its absence from its usual situation and presence in an unusual one causes the symptoms. The alignment of the third metacarpal os magnum and radius is intact, there is no protuberance on the dorsum of the hand either clinically or by *x*-ray. It seems, therefore, that the term forward dislocation of the semilunar bone should be retained, certainly for the cases of isolated and complete lesions of that bone. Where the dislocation is incomplete, and there are concomitant dislocations of surrounding bones, the broader term, mediocarpal dislocation, is applicable.

Symptoms.—The diagnosis of dislocated semilunar should suggest istelf when, with a history of a fall on the outstretched hand, or a corresponding injury whereby the hand is forcibly hyperflexed, examination fails to reveal an injury to the radius or ulna. If in addition there is a globular swelling anteriorly distal to the radius, *x*-ray will but serve to confirm the diagnosis. The wrist is thickened in an anteroposterior plane, but has not the "Silver fork" deformity. There is apparent and actual shortening of the hand as measured from the base of the third metacarpal to the radius. The fingers are held in semiflexion from the shortening of the flexor tendons due to the projection forward of the semilunar. The pain accompanying this lesion is usually more severe than that of other injuries about the wrist. This pain, due to pressure on the median, or more rarely the ulnar nerve, is constant and persists until reduction is made, or pressure relieved by some other means, when it ceases as a rule immediately. At times the pain will have the characteristic distribution of the nerve pressed upon and be associated with objective sensory changes. All motion is limited by pain, extension of the wrist and of the fingers is hindered mechanically as well. The *x*-ray, aside from confirming the diagnosis, will show complicating bone lesions and the exact position and degree of rotation of the semilunar.

Early recognition of this injury is important because it is only at this stage that closed reduction is possible. Delay in instituting proper treatment may not only lead to operation but may initiate an arthritis which will continue after the excision of the semilunar, resulting in the loss of all motion between the carpals. Very many of the reported cases, as was mine, were regarded as Colles fractures, and only after days or months was the true condition recognized.

Complications.—The most frequent complication is fracture of the scaphoid; this occurred either alone or with other bone injuries 37 times in the 84 cases. The bone next most frequently injured is the radius. Fractures of the styloid process of the ulna and fractures or dislocations of the os magnum, cuneiform and unciform have been reported.

The nerve symptoms as a rule are relieved by reduction or excision of the semilunar. Occasionally formication associated with diminished sensation in the distribution of the median nerve remains for some time. I found no instance reported of motor changes attributed to a nerve lesion.

Treatment.—Factors which enter into a decision as to the proper treatment of dislocation of the semilunar bone are (1) the time elapsed since the injury, (2) the complicating bony injuries, and (3) perhaps, the degree of rotation. In recent years, due probably to the earlier diagnosis, there are more reductions than excisions. Destot[8], one of the early advocates of closed reduction, reports one instance where 25 days after the injury he reduced the dislocation with excellent result. This is the longest lapse of time after the injury where reduction has been successful. Excision after 11 months has given a perfect result (Chaput). Injuries to the neighboring bones may make it inadvisable to attempt or impossible to perform a reduction. Where there is a pronounced nerve involvement the added trauma inflicted by reduction may be a contraindication to the attempt. At one time rotation of the bone of more than 45° was considered an obstacle, but there have been many reductions where 90° rotation existed; Golden[21] reports reduction where there was rotation of 225°. Open reduction was performed four times with good results in three instances. The additional manipulations necessary to replace the bone over that needed for excision, and the lack of symptoms incident solely on its removal, would seem to contraindicate this treatment. There is practically no loss of strength in the hand after the bone has been excised.

There were 30 closed reductions (10 uncomplicated dislocations) with 20 good results, 6 poor, and in 4 the result was not stated. In 34 cases the bone was excised (8 uncomplicated) with 18 good results, 7 poor, and 8 not stated. Four bones were reduced by the open method. Physicotherapy was used as the sole treatment in 5 cases and in 11 instances the treatment was not given. Earlier recognition of the lesion with attempts at reduction, where not contraindicated, would improve the figures for this type of treatment, which even now gives slightly better results than excision. Of course, the poor results obtained by excision are in part due to the late stage at which the lesion is recognized.

Reduction is best performed under general anesthesia. Traction is made on the hand while counter traction is provided by an assistant pulling on the forearm. The wrist is first hyperextended and then sharply flexed while pressure is made with the thumbs over the prominent semilunar on the palmar aspect. The hand is put on a short palmar splint in slight flexion. Passive motion may be begun on the fifth day.

For excision the approach is from the anterior surface, the incision being made over the projecting semilunar. The flexor tendons and the median nerve are retracted inward and outward, the bone is readily exposed. In most instances it cannot be removed until its palmar ligamentous attachment to the radius has been divided. Where the scaphoid

is fractured and one fragment dislocated with the semilunar, the attached fragment should also be excised.

Conclusions. — 1. Anterior dislocation of the semilunar bone is the best term for isolated, complete, forward displacements of that bone.

2. In over 50 per cent of cases it is associated with lesions of the neighboring bones.

3. Closed reduction is the treatment of choice in early cases, and may succeed even three weeks after the injury.

A CASE OF MULTIPLE OSTEOMYELITIS.

FROM THE SURGICAL DEPARTMENT OF THE NEW HAVEN DISPENSARY.

By JOSEPH T. NEWMAN, M.D.,

NEW HAVEN, CONN.

CLINICAL ASSISTANT IN SURGERY.

Multiple Osteomyelitis is a disease often obscure in etiology and presenting many difficult problems in its course and treatment. This case is reported with a view of stimulating discussion as to the remedial measures to be carried out in such a chronic condition and because of its comparative infrequency.

Case Report.—The patient is a boy, aged fifteen, born in Boston, the second of three boys whose parents were strong and healthy with no history of tuberculosis, syphilis, or cancer. The past history includes pneumonia at three months, suppurative cervical adenitis at two years with sinus persisting one year, scarlatina at three years. The tonsils were removed at the age of three years. Pneumonia at the age of nine years, followed by a "running ear," completes the past history.

The onset of the present illness dates back to December 23, 1917, when the patient was suddenly attacked with pain and swelling in the left ankle followed in a few days by a similar condition in the hips and knees until in about a week's time almost every joint in the body was involved, including the veretebral column, particularly the cervical region. The pain and swelling would leave one joint only to appear in another as in acute rheumatism. These symptoms were accompanied by high fever and sweating and later on delirium. The pain was so severe that the weight of the bed clothes could not be tolerated. The swelling in the left hip joint persisted and gradually became worse; that in the left knee and ankle remained also, but there was no pain or tenderness. During this period of six weeks the patient lost considerable weight. He received anti-rheumatic treatment, but because of the continued swelling, pain, and tenseness over the head of the left femur a consultation was held and he was sent to the Boston Homeopathic Hospital, where he was admitted February 7, 1918.

The hospital records show that on admission the left knee was markedly swollen, but was not tender to touch or painful on motion. The left hip was very tender to touch, painful on motion, quite swollen, and the skin over it was tense and glossy. Except for some tenderness in the right ankle the other joints were about normal. On March 16, 1918, incision, drainage, and curettement of the left femur at the greater trochanter were performed after a consultation in which amputation of the limb was considered, but not adopted because of the location of the lesion.

March 27, 1918.—The left femur and right tibia were curetted and small sequestra removed from each. The femur was found to be honeycombed. Both wounds continued discharging, and on January 18, 1919, the sinus of the left femur was enlarged to provide more adequate drainage. The drainage from the tibia and femur was quite free until January 31, 1919, when it was necessary to enlarge both wounds, which were then irrigated with Dakin's solution. The patient had suddenly developed pain in the left chest anteriorly, and on January 31, 1919, the fifth rib on the left side was found to be necrotic for three inches and that portion was removed. The wound gradually healed up without much drainage. On August 23, 1919, an incision was made over the right biceps, sequestra were removed, and the bone chiseled out.

October 28, 1919.—The patient was discharged with

the sinuses of the left femur and right tibia draining freely. From October 28, 1919, to January 4, 1920, he remained at home attended by a visiting nurse, who performed the dressings every other day.

On June 4, 1920, the patient was admitted to the New Haven Hospital for observation and treatment, the family having moved to New Haven. At the time of admission to the hospital he was quite deaf, a condition which had been present since March, 1920. The sinuses of the left femur and right tibia were still draining freely.

On August 6, 1920, the sinus of the left femur was again curetted and drained.

July 15, 1920.—An *x*-ray picture of the mastoid regions showed the left mastoid cells almost obliterated. On the right side a somewhat similar condition was observed. A diagnosis of chronic mastoiditis was made at this time, but no indication was found for operation.

On September 13, 1920, signs of pus in the region of the right hip developed and a superficial abscess was opened. A similar condition existing on the left side was likewise treated with incision and drainage.

January 7, 1921.—The old incision over the right tibia near the ankle was enlarged, the bone chiseled out, and packed with iodoform gauze.

January 13, 1921.—Two impacted molar teeth were removed because of swelling and pain in the jaw.

The patient was discharged from the New Haven

From photographs showing the location of the various incisions.

Hospital February 22, 1921, and since then has been coming to the Dispensary for biweekly dressings.

About September 1, 1921, a large superficial abscess was opened in the right upper forearm on the posterior aspect. No involvement of bone was present in this situation.

On November 11, 1921, a superficial abscess over the left sixth and seventh ribs, posteriorly, was opened, and from this a culture and vaccine were made. There was no involvement of the ribs.

At the present time the right tibia, left femur, and abscess on the back are draining freely; the other lesions are entirely healed except the one on the right forearm.

The roentgenograms taken at the New Haven Hospital present the following picture:

1. Head of left femur is smaller than normal and shows considerable decreased density. The acetabular cavity is poorly outlined and decreased in density. Surrounding the head of the femur, rather loosely, is a definite line of density, probably calcium deposit in the synovial membrane. Cortex gives impression of being thickened somewhat. There is definite mottling.

2. Lower end of tibia enlarged. It shows definite periosteal and osteomyelitic changes.

The blood examination showed a white count of 9,500; polys, 70 per cent.; L. M., 5 per cent.; S. M., 25 per cent.; H. B. G., 75 per cent.; R. B. C., 4,500,000.

The Wassermann reaction was negative.

Culture of pus from the sinuses at the time of operation showed *Staphylococcus aureus* in every instance with one exception, when it was accompanied by a nonhemolytic streptococcus. Autopsy of guinea pig inoculated with pus showed no signs of tuberculosis.

Decalcified bone taken from the lesions presented no signs of tuberculosis or syphilis on pathological examination.

Further treatment of this case has included a course of vaccine therapy instituted August 15, 1921. The results of this treatment were not very satisfactory, although much was hoped for because of good results reported by several French surgeons. A fresh vaccine has been made from a recent abscess, November 21, 1921, and the patient is now receiving injections every fourth or fifth day. This will continue over a long period in the hopes of increasing his resistance and preventing further extension of the infection.

Bacteriologically and pathologically this is a clear case of infectious osteomyelitis with the *Staphylococcus pyogenes aureus* as the offending organism. Clinically, the case is not so clear cut because of the history of acute rheumatic fever at the onset and the absence of any trauma. The multiplicity of the lesions makes it unusual clinically. Whether the condition can be explained by considering acute articular rheumatism as the predisposing factor in producing a lowered resistance in the body and hence the resultant osteomyelitis remains an open question. The possibility of infection secondary to an otitis deserves some consideration although no record of a case of this nature has been found in the literature of the past 15 years.

The photographs presented show very clearly the patient's present condition and the location of the numerous incisions.

50 Shelton Avenue.

CRITIQUE OF THE MODERN ROENTGEN THERAPY IN CANCER.

By M. J. Sittenfield, M.D.,

New York.

Roentgen radiation is pretty well recognized at present as an indispensable therapeutic agent. Especially is this true since the modern technique has brought about a better understanding of its physical and biological properties. On account of this the application of radium and *x*-ray has experienced marked advances and given rise to a decided progress in the treatment of malignant diseases. The invention of scientific devices for the accurate measurement of the quality and quantity of the ray at a definite depth, as well as on the surface of the skin, has created our present modern technique. By means of the Iontoquantimeter of Szillard and the electroscope of Wulff, it is possible at present to state definitely what amount of radiation is administered at the surface and what percentage reaches the deeper tissues. Furthermore, with this technique either a physiologically stimulating or a knock-out dose to a tumor 8 or 10 cm. deep can be determined. These scientific attainments have necessarily called for the construction of more powerful apparatus to deliver higher intensities, and with it high voltage tubes to accept a high tension current of 200,000 volts and at present even 300,000.

My own personal experience with the newer methods of Roentgen therapy dates back now 18

months, and it is a great satisfaction to state that there is an earnest desire on the part of every cancer therapist to work with intensive radiation. To illustrate the newer technique let me point out that it requires approximately 5 to 6 hours of intensive radiation to obtain one-half of a cancer dose to a tumor 10 cm. under the surface of the skin, and this with an intensity of 200,000 volts, a filter 0.5 mm. of copper, a large portal of entry, and a distance of 60 cm. from the target of the tube to the skin.

The size of the portal of entry is of utmost importance; for instance, with a surface area of 1.5 by 2 cm. a tissue situated 10 cm. under the skin receives 9 per cent. of a surface dose, whilst with a portal of entry 10 by 15 cm., the depth dose is 35 per cent. Therefore our aim is to utilize a large skin area to obtain the optimum amount of radiation in the deeper tissues.

So, too, the increased distance from the target of the tube to the skin surface plays an important part by bettering quantitatively the amount of penetrating rays. Here secondary scattered radiation increases the amount of radiation. For instance, a tumor situated 10 cm. under the skin receives by means of secondary radiation from a high focal distance three and a half times the amount of the primary beam of ray emitted from the tube to the tissue underneath. In other words, the focal distance and the size of the portal of entry together, have a most important bearing upon the quantitative factors of the Roentgen or radium rays, while the quality of the ray depends entirely upon the substance and thickness of the filter.

Scientific and experimental studies by Dessauer, Friedrich, Seitz, and Wintz, and others have established that zinc and copper filters are best suited to effect an even and homogeneous radiation and also to improve penetration.

From these preliminary remarks I hope that no one will gain the impression that a panacea for cancer is already at hand, but at any rate better results will be looked for if an intelligent use is made of the newer methods of radium and Roentgen therapy in cancer. More gratifying results will be obtained, wherever possible, if first preoperative radiation is instituted, followed in about two weeks by radical surgical excision of the malignant growth, and finally intensive postoperative radiation. The intensive raying before operation will prevent transplantation of live cancer cells in the field of operation. This is borne out by experimental studies which I reported six years ago and which have been confirmed by others since, describing the interesting phenomenon, that a tumor excised from a rat and rayed insufficiently will grow again upon inoculation; on the other hand, if subjected to a large dose of *x*-ray, it will fail to grow upon reinoculation—in other words, preoperative raying seems to minimize the danger of transplanting malignant cells during operation to an adjacent healthy area. The rough handling during operation may cause cancer cells to become grafted on denuded surfaces. This is well illustrated in an address by Charles Mayo, describing the traumatizing of the tissues by the vulsellum forceps during vaginal hysterectomy for carcinoma of the cervix, resulting in local recurrences.

Preoperative radiation, he says, sickens carcinoma cells beyond the area of the local disease, and during the period of cell sickness their resistance is so reduced that operation at this time is most efficient. Aside from this, adequate preoperative radiation destroys cancer cells for a certain distance, so that their reproductivity is checked, and fibrous tissue formation ensues which acts as a barrier to the further extension of the malignant process. In carcinoma of the cervix, for instance, preoperative raying—either by radium in the cervix, of 50 or 100 mgs. for 24 hours, or *x*-ray administered about a week before radical operation, has rendered inoperable cases operable, and has proved most gratifying in the hands of the ablest gynecologists in England.

In carcinoma of the breast it is perhaps of greatest value. Here especially are we most frequently confronted with local postoperative recurrences in the scar and field of operation. My recent experience causes me to emphasize this point. In one case of preoperative radiation for carcinoma of the breast, operated upon two weeks later, it was most gratifying to receive the report from one of our foremost pathologists stating that the tumor in the breast had so diminished that upon sectioning the breast he had difficulty in finding it. Upon microscopical examination, he states, the cancer cells were simply a shadow of a cell without protoplasm, and only the faint remains of a nucleus could be detected.

Since the advent of modern therapy sufficient time has not elapsed to permit us to draw clear cut and definite conclusions, but *a priori*, it would seem that with intelligent radiation before operation, and followed as soon as possible after the operation with a complete knockout dose of intensive radiation, more satisfactory results in cancer of the breast will be obtained.

On the other hand, it is indeed most discouraging to read the recent report of Sistrunk of the Mayo Clinic. Of 218 cases of cancer of the breast operated upon in 1911, 1912, 1913, 78 per cent. had succumbed during the five-year period, and of the 22 per cent. of the patients alive the greatest number originally showed localized breast tumors with no axillary lymphatic involvement.

My own technique for preoperative radiation in cancer of the breast consists of a two-hour dose, with an intensity of 200,000 volts, 2½ MA, at a focal distance of 40 cm., through 0.5 mm. of copper, for the purpose of sickening the cancer cells and preventing grafting of living cells onto denuded surfaces. I follow this as soon as the patient is able to report after the operation with an intensive radiation of 8 to 10 hours, administered over 4 areas, one dose over the anterior field of operation, one over the supraclavicular, one into the axilla, and one postscapular. The anterior dose is administered through a large focal distance and a portal of entry 15 by 20 cm. in order to radiate evenly the tissues 3 cm. underneath with homogeneous rays. To accomplish homogeneous radiation it is desirable to obtain an even surface of the chest. This is done by placing over the chest a thin rubber bag filled with

water, or better yet an ox-bladder. This renders the anterior surface of the chest an even plane and causes uniform penetration to the tissues underneath. Secondly, it excites secondary radiations which are so beneficial in increasing the amount of radiation absorbed into the depths. For the axilla and supraclavicular doses, a smaller focal distance is made use of, and for the postscapular dose a 50 cm. distance is used. Since the introduction of the modern technique, I have treated 65 cases of carcinoma of the breast. This group comprises cases which were inoperable to start with, some had extensive involvement of the supraclavicular glands not touched at the time of operation because of their inaccessibility, others which presented themselves with postoperative recurrences in the scar or field of operation anywhere from two months to eight years after the operation. From this complex group only eight have died. I am reporting this group in detail in an article which I am preparing and will not bother you with the particulars now. The one thing that stands out very prominently in my mind is the fact that with the older technique no such results were ever obtainable.

Postoperative radiation, be it radium or *x*-ray, requires highly specialized technique. The marked improvement and great changes in the technique are due directly to scientific experimentation. There are at hand now accurate measurements as to the dosage required to knock out a cancer and the amount of radiation which reaches the tumor mass under the skin. This together with the absorption coefficient and also the determination of the secondary radiation from the tissues themselves, constitutes the dosage quotient and is perhaps one of the most important factors in the therapy of malignant disease.

Biological studies, according to Seitz and Wintz, put the cancer dose at 95 to 110 per cent. that of a skin erythema dose, that of sarcoma at 60 to 70 per cent., and that of the ovary at 25 to 30 per cent. This sounds perfectly simple and it would be if the cancer were situated on the surface of the skin. But if the tumor is 6 or 8 or 10 cm. under the surface, the full amount of a knock-out dose is attended with greater difficulties, as every centimeter of tissue absorbs a certain definite amount of the beam of *x*-ray, so that the amount reaching a rumor 10 cm. under the skin from one portal of entry is inadequate and insufficient to knock out a cancer mass. Herein lies the explanation of our former failures and can be ascribed to the inefficient radiation obtainable from the older type apparatus and tubes. In the technique of newer therapy, a more powerful apparatus is used, which furnishes intensities in sufficient amounts to penetrate 10 centimeters or more with 40 to 50 per cent. of the skin dose. In other words, it is easily possible to-day to attack a tumor 10 cm. in the depths of the body with one-half of a cancer dose from one portal of entry, the same quantity can be administered through a portal of entry on the opposite side, and if still more is required it can be given laterally from either side. The main and important thing to bear in mind is that it is absolutely necessary that every part of the tumor is rayed evenly and homogeneously so that the entire tumor mass receives the complete knock-out dose throughout. This comprises many physical and technical details and is a specialty in itself, requiring a thorough understanding of the physics of radiation, a familiarity with the biology of tumors, and their clinical behavior, and a knowledge of the exact localization of the malignant disease. An intelligent summation of the above-mentioned factors, together with the aim to administer the necessary radiation dose will doubtless yield more gratifying results.

Furthermore, it is most essential that the entire dose be given in one session. If for some reason it is expedient to protract the administration of the entire dose beyond one day; for instance, if the condition of the patient does not permit it because of Roentgen sickness, then it should be given on subsequent days and over a period not longer than a week. With small doses repeated over more than a week, the tissue has a chance to recuperate from the previous radiation and a dose 20 to 25 per cent. larger is required to obtain the necessary effect, and with this occurs an unwarranted strain upon the overlying skin.

My own technique, for instance, in carcinoma of the uterus is a modification of the one used by Opitz in Freiburg. In a woman whose anteroposterior diameter measures 18 to 22 cm., one dose of intensive radiation is administered from the anterior surface of the abdomen from the umbilicus to the outlet of the pelvis, the target of the tube is about 60 cm. from the skin and filters of copper or zinc are used. The intensity is generally from 190,000 to 200,000 volts, corresponding to a spark gap of 40 to 42 cm., and 2½ to 3½ milliamperes. This dose requires about 4 to 4½ hours, and is 50 to 55 per cent. of a cancer dose to the tumor mass. Another application is made from the posterior surface over an area 15 to 18 cm. square, this totals in all parts of the tumor about 110 per cent. of a skin erythema dose. In other cases before the radiation 50 to 100 mgs. of radium are inserted into the cervix and uterus, and left in about 24 hours, this gives us about 25 to 30 per cent. of a dose from the interior of the uterus, and consequently not more than 85 or 90 per cent. need be administered from the anterior and posterior surfaces. If for any reason it is desirable to shorten the time of treatment, the anterior and posterior radiation can be administered simultaneously by placing one tube over the patient as she lies on the table and one tube below.

This one session constitutes the entire treatment, and is not to be repeated for 3 to 6 months and, better yet, not for a longer interval. Most of the gynecologists in Germany have abolished surgical intervention in cases of cancer of the uterus, since the results with radiotherapy in their hands are superior to operative procedure, so much so that the ablest gynecologists have turned to radium and *x*-ray for the treatment of cancer of the uterus. In cancer of the body of the uterus their clinical cures are 80 to 85 per cent., and in cervical cancers 45 per cent. over a period of 4 years. Professor Opitz of Freiburg, the successor of Kroenig, informed me in a personal communication that since Jan. 1, 1919, no case of

cancer of the uterus had been operated upon in his clinic. His statistics then were 36 cases of cancer of the body of the uterus with 78 per cent. arrest of the disease, and in 63 cases of cancer of the cervix, 49 per cent. recession of the malignancy of the cervix occurred.

Leucemia, lymphosarcoma, and Hodgkin's disease have been transferred to the domain of the radiotherapists. Glandular tissue is the most radiosensitive of any tissue in the body, with the exception, perhaps, of the highly specialized reproductive organs, as the Graafian follicles and spermatogenic tissue. A very small amount of ray will destroy lymphoid tissue; glands almost melt within 48 hours after the application of radium or *x*-ray.

Localized metastases in the scar after radical excision of a carcinoma of the breast or, for that matter, localized metastases in any accessible area will respond favorably either to radium or Roentgen ray, or both combined.

Sarcomata as a rule require a dose of 60 to 70 per cent. that of a skin erythema dose, hence lend themselves readily to Roentgen therapy, providing no generalized sarcomatosis is present. Osteosarcoma or sarcoma of soft parts or glands should clear up if the proper dose is administered. Always bear in mind that 40 per cent. or less of the proper dose will stimulate the malignant tissue, and, on the other hand, anything in excess of a proper dose will destroy healthy tissue and cause irreparable damage by injuring the connective tissue barrier of the malignant growth, and so cause it to invade adjacent tissues, and favor metastases.

Another factor that requires careful analysis is the determination of whether radium or *x*-ray should be used in a given case. The amount of radium at present available is inadequate to penetrate into the deeper tissue, say 8 or 10 centimeters deep, in sufficient quantities to knock out a cancer cell unless a large amount of radium, much larger than any in use now, could be used at a distance with suitable heavy screening. Only with much larger quantities could an even and homogeneous radiation be obtained to penetrate in sufficient amounts to influence a cancer in the deeper structures. Furthermore, the dosage of radium and its accurate measurement have not been worked out carefully as yet, and until a standardized dosage, dispersion, and absorption coefficient, etc., has been established, we are hampered in the use of this most potent agent. Radium is to be preferred when a small, localized area is to be rayed, or when it can be placed in the center of a tumor mass. Here, too, a great danger arises, as it is perfectly clear that the malignant cells near the radium tube are readily destroyed, but more distant ones, however, not receiving sufficient radiation, may assume increased activity, and hence the growth may be stimulated instead of destroyed.

Right here it would not be amiss to point out that radiation by indifferent methods, or in the hands of an unskilled operator, is a very dangerous procedure. Both of these powerful agents are most valuable in the fight against cancer if intelligently handled as to dosage, filtration, focal distance, etc. On the other hand, the harm and injury that will necessarily follow irresponsible methods will more than offset the benefit derived from it.

The technique is not simple and requires extensive training. Looking back upon my own experience, I am aware of my own shortcomings in the early days of radiotherapy, and it is only fair to say that everyone must profit by his own mistakes. Errors of the unskillful, however, are likely to give rise to very unfortunate and serious consequences.

The salient points which I wish to emphasize in my conclusion, therefore, are:

1. The early diagnosis of carcinoma to insure better prognosis. Preoperative radiation should be instituted to prevent transplantation of malignant cells during surgical excision, which should be performed about 2 weeks later and followed by postoperative raying to the extent of a complete knockout dose for cancer.

2. The modern technique of Roentgen and radium therapy depends upon proper filtration, to obtain homogeneous and evenly dispersed radiation, proper focal distance, proper portal of entry. Moreover, the entire diseased area should receive the needed quantity of radiation of the same quality throughout. Care should be taken to avoid over or under dosing.

3. Inoperability does not necessarily mean incurability, since modern Roentgen therapy has caused inoperable cases to become operable, and in the otherwise hopeless cases has brought relief of pain and discomfort.

4. Irradiation is more effective if the entire dose be administered at one time, and with the maximum intensity, than if it is split up over a longer period of time.

5. The necessity for the surgeon and radiotherapists to meet on common grounds for a correct analysis and standardization in the treatment of malignant disease, as surgery and radiation combined would better, perhaps, the now none too satisfactory results in malignant diseases.

6. Modern therapy is only a beginning in the right direction, and my personal observation leads me to believe that scientific and experimental studies along this line will yield still greater progress in our fight against cancer.

73 East Ninetieth Street.

RÉSUMÉ OF VACCINE THERAPEUTICS.

By E. C. LAVERTY, M.D.,

LOUISVILLE, KY.

Experience is our best teacher. In therapeutics careful clinical observation under the use of certain therapeutic measures is our safest and surest guide toward therapeutic progress and the lessons taught by experience are often just the reverse of what was expected. In the treatment of extensive acute infections with high temperature, according to our early theoretic conception vaccines would be contraindicated, but I have found the reverse to be true; that instead of bein contraindicated our very best results are obtained in just this class of cases.

These concepts were based on the theory that high temperature indicated extensive toxemia and that this was a positive indication of an excessive amount of toxic bacterial products in the patient's body, and that under such conditions nothing except harm could be expected from injecting more toxins in the form of killed bacteria or vaccines. If this problem of infection and immunity were simply a question of toxins and immunizing responses the foregoing concept would hold good, but a closer study of immunity shows that there is more than this involved in the immunizing process in the presence of infecting organisms. In active infections the fact that we are dealing with a living entity that has gained entrance to the tissues and fluids of the body must also be taken into account, that this living entity performs certain functions for its own growth and development; that during this growth and development certain toxic ferments are produced by this living entity which have a very destructive influence, but little if any of the properties which go toward stimulating cells in their defensive capacity for antibody production. To depend on the infecting organism as the means of stimulating cells for antibody formation, of necessity involves taking chances that enough toxic materials, which do not favorably influence cell activities in their defensive capacity, might destroy the life of the patient.

A toxic condition as the result of an infection does not necessarily imply that the substances which are responsible for the toxemia are of the kind which will favorably influence the resistance of the patient. When a high temperature is encountered it does not follow that the germ-produced toxins which are responsible for the toxemia are of the kind which will favorably influence the resistance of the patient. When a high temperature is encountered it does not follow that the germ-produced toxins which are responsible for the high temperature will of necessity favorably influence the defensive mechanism, but on the contrary may overtax, fatigue, and be destructive in character. So when a high temperature is encountered it is more than likely that the germ-produced toxins which are responsible for the fever are not of the kind which stimulate cells in their defensive capacity to bring about an immunity; that no adequate influence is operating toward immunization with a resulting elimination of the infection; and that the infecting organism does not of necessity possess antigenic properties which stimulate the defenses of the body, but rather retards or inhibits their action.

The essential requirements under these conditions are the immediate application of a stimulus to cell structures which will arouse their defensive forces for the development of suitable antibodies. That killed bacterial suspensions or bacterial vaccines when injected into healthy tissues stimulate cells for antibody formation is no longer questioned, it is believed only by the inexperienced that this can not hold good under toxic conditions as shown by high temperature. The fear is that the injection of the killed germs would add enough toxic material to cause an increase of toxic symptoms. In this connection it is important to realize that bacterial vaccines are never given in what might be regarded as toxic doses. In proportion to the amount of toxic materials that are produced by an active extensive acute infection every hour of the day, the dose of a bacterial vaccine is infinitesimal. The bacterial content of an average dose of vaccine would weigh less than .0004 of a grain, a quantity so small that it amounts to nothing as compared to the amount of toxic material that the patient is already contending with. It is for this reason that no appreciable difference in temperature or other toxic symptoms will follow a vaccine injection when given during the presence of a high temperature, even when so-called large doses are given. The essential difference between the action of the killed organisms contained in the injected vaccine and the action of the live organism responsible for the infection is that the live organism, on account of its extremely toxic properties, does not favorably influence tissue cells with which it comes in contact for antibody production, while the injected killed organisms do so influence them and thus hasten the development of an immunity.

That bacterial vaccine injections do not increase the toxicity of the patient, when given in extensive acute infections, is readily determined by a careful observation of the temperature curve and the pulse rate. When given under high temperature conditions no appreciable rise of temperature will follow a vaccine injection nor will there be any increase in the pulse rate, nor do any other unfavorable symptoms develop which can be ascribed to the vaccine injection. But, on the contrary, as a rule it will be found that the temperature will come down, the pulse will improve, and other toxic symptoms will start to abate within twenty-four hours providing the proper vaccine in a sufficiently large dose—usually one mil of a stock suspension—has been given before the infection has advanced sufficiently to cripple the responses of the patient. Usually this will hold good during the first few days of the infection; but the best results are obtained if the vaccines are given soon, within a day, after clinical symptoms show the presence of an active acute infection.

In severe acute infections where germ development is extensive antibodies are used up rapidly. A small area of tissues where the vaccine was injected may become actively engaged in the production of antibodies; but, as a result of toxic materials distributed throughout the system from the infecting organisms, these activated cells may in time become fatigued in this capacity; then after a short spell of clinical improvement the infection gains the upper hand again. It is not an uncommon clinical experience to find marked improvement within one day after the first vaccine injection; an improvement often so dramatic that one is inclined to think the trouble is over with, and the case is allowed to drift along until within three or four days the condition becomes just as bad as before the vaccine was given, and not uncommonly when this condition develops the vaccine will not produce the striking results that the first dose did; meantime, as a result of accumulated toxemia from the progressing infection, the cells of the body have become less responsive to the antigenic influence of the vaccine. For these various reasons it is very important that inoculations should be made at comparatively short intervals in extensive acute infections, so that another immunizing response will

have time to develop from newly involved tissue at the site of injection before the immunizing influence from the previous injection has had time to wear off. Clinical experience indicates that this is best accomplished by giving the vaccine at daily intervals until the temperature shows a distinct tendency to remain down, but it is never wise to give less than two or three injections at daily intervals even if the temperature does come down to normal meantime. After a normal temperature is obtained inoculations should be made at 2 to 4 day intervals until convalescence is complete. In extremely bad cases it is advisable to give the vaccine twice daily until the very severe symptoms are brought under control.

When giving vaccine in febrile conditions we must divorce our thought from the idea that vaccines reduce temperature in a way similar to that of drugs. Infections are toxic, especially those produced by the streptococcus and pneumococcus, because the ferments which the germs secrete for the purpose of digesting the food on which they live are toxic. Some of these ferments are liberated from the infecting organisms and are conveyed throughout the system by means of the circulating medium. Immunity is primarily brought about by antibodies combining with the ferments which the infecting organisms utilize for digesting their food, thus neutralizing, inactivating, destroying the only weapon which they possess for growth and multiplication, and at the same time rendering them subject to phagocytic action by the white blood cells. By injecting vaccines into healthy tissues we arouse rapid antibody production by the tissues into which the vaccines were injected. These antibodies are conveyed to all parts of the body by the circulating medium and will combine with the ferments that have escaped from the infecting organism, scattered throughout the patient's system, just the same as with those surrounding the infecting organism, and it is the neutralizing of these toxic ferments which accounts for the rapid drop in temperature which is so often seen when vaccines are given in the early stages of high fever. These toxic ferments do not necessarily produce fever. Extremely toxic cases are often found with a subnormal temperature even during the early stages of the infection, and these cases are generally regarded more dangerous than when high temperature develops. Vaccine injections stimulate the production of antibodies, and that antibodies neutralize these toxic ferments is illustrated by the use of vaccines in cases where subnormal temperatures are produced by extensive infections. During the recent influenza epidemic many of the worst cases started with a subnormal temperature. Vaccines in these cases brought the temperature up, as well as down in the cases where it was high.

The objections to the use of bacterial vaccines in the treatment of extensive acute infections are purely theoretical. The contentions are, that the toxic symptoms which prevail in these acute infections show that the patient is suffering from an overload of bacteria and their products; that to give vaccines under such conditions is irrational because we thereby simply add more bacterial toxins where it is clearly evident that the patient is suffering from an excessive amount of toxins; and that by giving vaccines under such conditions we are liable to thrust the patient into the so-called "negative phase" and make matters worse.

Many of these objectors have heard of the good results that are being obtained with vaccines in extensive acute infections, but as a rule their theoretical prejudices are so strong that they are unwilling to give them a trial, and if perchance they do try them, nine times out of ten they allow their preconceived notions to prevail; allow the thought, that by giving vaccines we make the patient more toxic, to dominate, with the result that the patient receives entirely too small doses at much too long intervals. Such trials would naturally result in failure, and yet the contention from these sources will carry more weight with many otherwise well informed physicians than statements from general practitioners who have used vaccines with success, because they use them in such a way that experience teaches them to be most efficient. Most of the available literature on vaccine therapy has been written by laboratory research workers who hold that vaccines are contraindicated in extensive acute infections and that, if vaccines are employed in such cases, very small doses should be recommended.

I find, however, that absolutely contrary conditions prevail. I find that in subacute and chronic infections, to obtain the best results, treatment must be started with a small dose, usually 0.2 mil of a standardized suspension, and the dose should then be gradually increased to 1 mil or more, and inoculations made at 4 to 7 day intervals. If in chronic infections treatment is started with a large dose, unpleasant reactions are almost sure to follow and if the injections are repeated at short intervals the infection will not subside as rapidly as if small doses are employed at long intervals. In extensive acute infections, large doses—1 mil of a standard suspension given at the earliest possible moment, repeated at daily intervals—give decidedly the best results, and in extremely bad cases the vaccine may be given twice a day to advantage. No appreciable reactions follow the use of 1 mil doses of vaccine when given during a high temperature and other indications of a toxic infection, nor does any material infiltration develop at the site of infection. The rule should be that in the most severe infections, the largest dose should be given at the shortest intervals and the less severe cases should receive the smaller dose at longer intervals. Unless this general rule is followed, no satisfactory results will be obtained from the use of bacterial vaccines.

So long as objectors to vaccine therapy remain obstinate, so long as they are unwilling to give vaccines an efficient trial, we must expect the unfortunate victims of pneumonia and similar infections to pay the penalty; but surely this apathy cannot continue much longer. If any dangerous or unpleasant symptoms followed the use of vaccines, there would be some excuse for hesitation, but all available information shows that the treatment is absolutely harmless. The reason for the necessity of large doses of vaccines at short intervals may be explained on the ground that in extensive acute infections we have a large number of organisms multiplying rapidly to contend with and to destroy these organisms there is required a large amount of

antibody. If the antibody that was produced as the result of the first injection is all consumed before all the infecting organisms are destroyed, the infection may "light up" again, but by repeating the inoculations at short intervals, the antibody producing process will be continued until the infection is eliminated.

THE MODERN HEALING OF MASTOID WOUNDS:

ITS RELATION TO MASTOIDECTOMY AND POSTOPERATIVE DRESSINGS.*

By HUGH B. BLACKWELL, M.D.,

NEW YORK.

Those who recall the long and painful convalescence with the resultant unsightly depressed cicatrix which usually attended a simple mastoid operation performed ten years ago or more and from a modern standpoint compares the postoperative recovery of the patient who has more recently undergone this procedure are usually impressed by the marked modification generally speaking of the distressing factors of convalescence which were at one time regarded as the necessary incidents of the mastoid operation.

So great has our progress been along these lines that to-day one may fairly say that the time required for the healing of a mastoid wound is usually three of four weeks which is half or less than half of the period formerly considered necessary. At present the dressings are comparatively painless and now instead of healing taking place with an unsightly hole behind the auricle the mastoid scar more frequently resembles an ordinary incision with little or no depression.

The influences which have brought about this happy change of convalescence in the mastoid patient are many, but from a technical standpoint we believe can be grouped under the following heads:

1. The general dissemination of knowledge concerning the technique of the simple mastoid operation, with a resulting improvement in operative skill shown by specialists generally.

2. A complete change of attitude as regards the use of gauze in postoperative dressings. Formerly this agent was employed in a mastoid wound not so much for drainage as for the production of pressure, which for some inscrutable reason was considered necessary in the wound. In the old days, immediately upon the conclusion of the operation the mastoid cavity was packed tightly with gauze, the final strip was frequently forced into the wound by the operator leaning with his weight against the dressing. It was not uncommon to employ five or six strips of gauze one inch wide. A dry external dressing was then usually applied and the first complete dressing performed on the fourth or fifth day. This tight packing and mass of external dry gauze acted as an excellent cork, frequently damming retained wound secretions. So great was the pain attendant upon the first dressing that it was commonly considered necessary to give a general anesthetic. During this era of tight packing the rubber-tissue dressing advocated by Dr. Whiting was often used to relieve the pain of dressing. I have not seen it employed for a number of years, that is since tight packing has been discarded. Our modern practice is not to use gauze packing so as to produce pressure in the wound, but only in such amount as to secure drainage and by light contact with the wall of the cavity stimulate rather than discourage the formation of granulations. We believe that operators generally use to-day less than one-half the quantity of gauze in the mastoid wound than was formerly the case. We have learned that when a thorough mastoidectomy has been performed it is no longer necessary to pack the wound tightly, as the disease processes have been removed now, generally speaking, by the operation.

3. The use of more sutures at the conclusion of the operation; now it is customary to suture the upper half of the wound only, the lower half or one-third being left open.

4. A much more tolerant and sympathetic attitude is held to-day toward the development and growth of granulations in the mastoid wound. The former practice of scraping, excising, and cauterizing these loops of blood vessels is no longer practised with the same religious fervor, they are even frequently permitted to become redundant, and some of us hold that the wound when clean may be permitted to heal from above downward, below upward, behind forward, or without inward with perfect safety. Since our operative skill has improved and we have become more thorough in removing these diseased mastoid cells our postoperative dressings have become simpler and infected wounds have become infrequent. During the era of tight packing, owing to the great pressure exerted by the gauze, the inside of the mastoid cavity often presented a hard white appearance resembling a tea cup with no evidence of granulation tissue for a period of sometimes two weeks or more after the operation; and if in some cases where a more thorough operation was performed, should this tight packing especially in the antrum region be continued the mucous membrane of the middle ear would grow out into the mastoid wound resulting in a deep postaural depression with a permanent fistula at the bottom, or form an air sack at the bottom of the wound underneath a thin cicatrix which would balloon out upon forcibly blowing the nose or tend to break down at future intervals.

5. Wet and frequent dressings. This subject really comes under the head of improved drainage as the latter is best promoted by the application of these principles. Mastoids are to-day dressed more frequently than heretofore. We believe in dressing all mastoids every day, and for the first ten days or two weeks employ an external wet dressing as the moist gauze seems to absorb discharge more readily.

In reviewing the history of this movement for the better and comparatively more rapid healing of the mastoid wound one is impressed by the gradual almost insensible recognition and general adoption of most of the principles here stated. It is interesting to recall some of the attempts made to secure the results which are now commonly obtained by the employment of other methods and if possible to

*Read before the American Otological Society, June 1, 1921.

relate their influence on our present attitude toward this subject. We believe the members of this society will support us in the contention that the best results from both the surgical and functional standpoints follows the mastoid operation when a thorough exenteration of all the diseased bone has been performed, and that the improvement in healing, as shown by the present-day procedure, is dependent first of all upon a thorough and complete operation. Given a clean cavity as a beginning, then we may safely apply subsequently in the process of healing our own individual ideas as to the exact manner of dressing, and provided we do not violate cardinal surgical principles all of us arrive at practically the same result. It is not our intention to attempt to instruct those present as to how to dress a mastoid wound, but merely to indicate in a general way the lines along which the best results are now secured and to show the remarkable change in our attitude toward this subject in recent years and the probable reasons therefor. We remember some eight or nine years ago hearing a paper read before this society in which the operator urged the importance of preserving what he called the capsule of the antrum, or antral capsule, he attempted to attribute the cases of delayed healing, etc., which were so common at that time to the practice of curetting the mastoid antrum. How many of us to-day would allow this mass of infected bone and tissue to remain undisturbed in the bottom of the wound at the conclusion of a mastoid operation?

We are all familiar with the work done by various authors along the lines of straight blood-clot healing; that is, in cases where the cavity is allowed to fill with blood the posterior wound is sutured throughout, no gauze packing being used in the mastoid, healing being expected to take place by primary organization of the blood clot. The brilliant promises which the early results held forth in this field have not been fulfilled, and we believe that the members here present will generally support us in disapproving of this method of recovery as being not entirely unattended by danger. There was another variety of cases differing widely from the above which unfortunately, owing to the justifiable prejudice held by most of the physicians against straight blood-clot healing, were called cases of modified or partial blood-clot healing. In these patients the posterior wound was allowed to remain open in its lower one-half or one-third, and posterior gauze packing was employed in the mastoid from the beginning, perhaps not so much as we use today; however, the postoperative treatment of these cases differed only in degree from what is now our usual custom. We believe that in effect a marked analogy exists between what was formerly known as the healing of a modified or partial blood clot case and our own present modern form of healing. Our reason for this belief is based on the fact that immediately upon the conclusion of a simple mastoid operation, unless the wound is packed tightly, in a short time the cavity will contain more or less blood, where the packing is loose this blood will naturally accumulate and clot in the space between the gauze and the walls of the cavity: the thickness of the clot will depend entirely upon the amount of gauze placed in the wound at the conclusion of the operation; and while it may be digested and thrown out subsequently in the process of healing, yet we believe before doing so this blood promotes the development of granulations and shortens the time of healing. It is a matter of no small gratification for the author to observe that the principles which he laid down as necessary for the more rapid healing of mastoid wounds in a paper read before this society nine years ago, which were in effect: (1) thorough mastoidectomy, (2) light packing, (3) frequent dressings, are today regarded as essential factors in the modern healing of mastoid wounds.

REPORTS OF SEVEN CESAREAN SECTIONS:

FIVE FOR ECLAMPSIA AND TWO FOR CONTRACTED PELVIS.*

By W. L. Dunning, M.D.,

Newburgh, N. Y.

Case I.—Mrs. B., aged nineteen, was referred to St. Luke's Hospital by Dr. Moshier. She was six and a half months advanced in her first pregnancy. Her symptoms began with headache on January 14, 1919, but a week later became intensified and referred to the vertex and parietal regions, with dizziness and spots before her eyes. At 5 A. M. she began vomiting and at 10 o'clock was stricken with blindness. Convulsions started at 11 A. M. January 21, 1919, and between that hour and 4 P. M., when she arrived at the hospital, she had twelve convusions, remaining in deep coma. There was edema of face and lower extremities. The laboratory report showed the specific gravity of urine to be 1,016, with a large amount of albumin and granular and hyaline casts. The cervix uteri was narrow and undilated; uterus showed a six and a half months' gestation. The patient was hastily prepared and taken to the operating room, where a cesarean section was performed. She was then removed to her bed, her stomach washed out, and two ounces of magnesium sulphate introduced. A copious enema of soapsuds was given, followed by hot colonic irrigations. Tincture veratrum viride and nitroglycerine were given by hypodermic and repeated every two hours. Four convulsions occurred after the operation. Coma continued for eight hours, followed by gradual improvement. She left the hospital by request at the end of two weeks, with a trace of albumin in her urine.

The infant did not survive.

Case II.—Mrs. S. was referred to the hospital by Dr. Waterbury. She arrived at 5 A. M. on January 9, 1919, in deep coma; she was six and a half months advanced in her first pregnancy. She had six convulsions before admission. Uranalysis by Dr. Mars: Specific gravity 1,036, solid albumin, hyaline and granular casts. At six o'clock, one hour after admission, she was removed to the operating room, and a cesarean section was performed. The placenta occupied the median line; it was separated and pushed aside and a male child delivered. After completion of the operation the patient was removed to her bed, her stomach washed out, and magnesium sulphate left in the stomach. Hot colonic irrigations given. Veratrum viride and nitroglycerine given hypodermically. She had four convulsions after the operation. Coma continued three days, followed by gradual improvement, and she left the hospital four weeks after admission in good condition. The infant lived seventeen days.

Case III.—Mrs. E., aged twenty-two, primipara, thirty-eight weeks pregnant. Referred to the hospital by Dr. Cotter. Pelvic measurements normal; blood pressure 120-80. Uranalysis by Dr. Westcott: Specific gravity 1,020, acid, heavy cloud of albumin, many granular and hyaline casts. She was admitted to the hospital Dec. 12, 1920, and went into convulsions at 4

*Read before the Newburgh Bay Medical Society. The first three cases on May 11, 1920, the latter four cases on November 2, 1921.

P. M.; within the next hour she had four convulsions, remaining in coma. Cesarean section was performed at 5 P. M., one hour after the outset of the convulsions. A seven and a half pound boy was delivered. Patient was removed to her bad; stomach washed out. Hot irrigations by bowel, and nitroglycerine and veratrum viride by hypodermic; a large dose of magnesium sulphate left in stomach. She had sixteen convulsions after the operation, after which she showed improvement. She nursed her infant and left the hospital January 18, 1920.

Mother and infant in good condition.

CASE IV.—Mrs. M., aged twenty-five, primipara. Pelvic measurements: Interspinal, 22 cm. (8.8 in.); intercristal, 26 cm. (10.4 in.); ext. conjugate, 17 cm. (6.8 in.); rt. ext. oblique, 20 cm. (8 in.); lft. ext. oblique, 20 cm. (8 in.); diagonal conjugate, 11 cm. (4.4 in.); true conjugate, 8.5 cm. (3.4 in.). She went into labor in September 17, 1920, at 9 A. M, breech presenting L. S. A. After a trial of labor lasting fifty-five hours, the presenting part was not engaged, and the patient, showing signs of exhaustion, was removed to the operating room September 19, 1920, at 4 P. M. Cesarean section was performed and a girl baby, weighing six pounds and twelve ounces, delivered.

She made a good recovery and left the hospital nursing her baby on October 14, 1920.

CASE V.—Mrs. S., a young primipara, six and a fourth months' gestation, was seen in consultation with Dr. D. I. O'Leary. She went into convulsions on October 9, 1920, at 12 o'clock noon, had four convulsions between noon and 4 P. M., remaining in coma. Uranalysis by Dr. Westcott: Specific gravity, 1,050, acid, albumin almost solid, very numerous granular and hyaline casts. Cesarean section was performed at 4 P. M., removing a male child that survived two hours. No further convulsions occurred after operation. The usual anti-eclamptic measures followed. She made a rapid recovery, leaving the hospital about the twenty-first day.

CASE VI.—Mrs. E., aged twenty-three, primipara, full term. Pelvic measurements: Interspinal, 22 cm. (8.8 in.); intercristal, 26 cm. (10.4 in.); right ext. oblique, 20 cm. (8 in.); left ext. oblique, 20 cm. (8 in.); external conjugate, 20 cm. (8 in.); diagonal conjugate, 11 cm. (4.4 in.); true conjugate, 8.5 cm. (3.4 in.). The amniotic sac broke on July 7, 1921. On July 15, as labor had not started, it was proposed that labor be induced, with the prospect of an operation. The patient chose cesarean section, which was performed on the same day at 11.20 A. M. Operation completed in forty minutes; placenta was in the median line and caused more than the usual amount of hemorrhage. A female child, weighing six pounds and fifteen ounces, was delivered. Both mother and child made a good recovery, and left the hospital in excellent condition on August 27, 1921.

CASE VII.—Mrs. S., aged twenty-two, primipara, seven months' gestation. Referred to the hospital by Dr. Sprague. While on her way to the hospital for treatment she went into convulsions. She arrived at the hospital on August 24, 1921, at 11 A. M. Between the hour of her arrival at the hospital and 1 P. M. she had four convulsions, remaining in coma. Uranalysis by Dr. Westcott: Specific gravity 1,030, acid, albumin 55 per cent., microscopical field filled with granular and hyaline casts. Cesarean section was performed at 1 P. M Duration fifty minutes. A female child, weighing three and a half pounds, was delivered, and survived two days. After operation the mother's stomach was washed out and two ounces of magnesium sulphate left in the stomach. Tincture of veratrum viride and nitroglycerine given by hyperdermic every two hours. High colonic flushings given every six hours. Six hours after the operation convulsions returned and recurred every forty minutes for about seven hours, making fourteen convulsions in all, after which they ceased. The patient became conscious on the third day. Recovery was rapid. She left the hospital in good condition on the eighteenth day.

The prevention of eclampsia should begin with pregnancy. The family physician may do much to teach the patient the necessity of engaging her physician early and making frequent visits to him for advice in diet, exercise, proper dress, attention to bowels, the frequent examination of urine, arterial tension, etc., and that constipation, scanty urine, dropsy, spots before the eyes, headache are danger signals and call for immediate attention. As important as this is in the first half of pregnancy, it becomes more so in the second half. The nearer full term, the greater is the danger. When toxæmia is present due to the involvement of the kidneys active treatment is required, and if it should become necessary to interrupt pregnancy, this procedure should not be too long delayed. If convulsions occur the interruption of pregnancy becomes imperative. In such cases cesarean section to the writer is the operation of choice.

286 LIBERTY STREET.

THE DIAGNOSIS OF HERNIA OF THE OVARY AND TUBE.

BY LEIGH F. WATSON, M.D.,
CHICAGO, ILL.

HERNIAS of the ovary, tube and uterus are exposed to certain complications, the most frequent being torsion and strangulation of the adnexa and infection of the sac.

Torsion of the adnexa is a frequent complication of hernia of the ovary and tube in children under two years of age. The symptoms are indefinite crying, restlessness and irritability. Vomiting and tympanites are rare. There is an irreducible tumor in the hernial region, which is swollen, tender, and painful. If the torsion is long continued or severe, strangulation is liable to occur. Muller reported the case of an infant five months old whose left ovary and tube had been removed on account of strangulation; five weeks after this was done a hernia of the tube and ovary appeared on the right side. On account of the strangulation, an operation was performed and the tube and ovary returned to the abdominal cavity and the hernial opening closed. Eustace and McNealy record a case of strangulated inguinal hernia of the ovary and tube in an infant six months old. The right labium majus was red, swollen, tender, and pitted on pressure. There was no fluctuation or pulsation in the mass. At operation a torsion of the tube and ovary of 180 degrees was found. The adnexa were resected and the child made an uneventful recovery.

Strangulation is usually manifested by a tender, painful, irreducible mass, unless intestine is present, when there will be symptoms of nausea, vomiting and constipation. The mass tends to increase in size and may resemble a strangulated omentocele. In some instances there is no pain, and strangulation is not discovered until during the course of an operation for a supposedly simple irreducible hernia. Peritonitis is rare. Muller saw a case in which a loop of intestine was strangulated in the hernial sac by the round ligament and ovary. Torsion of the tube is common (Lockwood, Morgan, Schnitzler and Gangele).

Brunner, Vogeland and Lejars saw cases in which the tube was strangulated at the internal inguinal ring. Retrograde strangulation of the Fallopian tube is very rare. Maydl reported a case, and a second one has been reported by Vas. The latter

case occurred in a sixteen year old girl with a right inguinal hernia. The loop in the sac was 11 cm. long. The free end in the abdominal cavity was gangrenous. Prompt recovery followed excision.

In Wyeth's case of strangulation of the Fallopian tube alone, the infection spread through the disintegrating sac and reached the abdominal cavity, causing a fatal peritonitis.

Suppuration sometimes occurs as a result of infection from the Fallopian tube, which may also involve the ovary.

Hernia of the ovary, tube and uterus may be mistaken for a variety of conditions because of the frequency of congenital malformation in the internal genitalia, as well as other developmental anomalies. The presence of hermaphrodism or pseudohermaphrodism is not rare, and for this reason a testicle may be mistaken for the ovary and tube. Intestinal hernia is resonant, and is usually reducible, with a gurgling sound. If it is irreducible, the symptoms are those of intestinal obstruction or strangulation. Omentum adherent in the hernial sac may confuse diagnosis. If the hernia contains intestine, omentum, ovary and tube, a diagnosis is almost impossible unless the intestine and omentum can be returned to the abdominal cavity, and movement of the ovary obtained by vaginal examination. Cysts in the canal of Nuck may be differentiated easily, as they are fluctuating, transluscent, and irreducible; and vaginal examination shows the uterus and adnexæ in their normal position. Strangulated hernia of the ovary and tube simulating abscess in the labium majus is difficult to diagnose when seen in infancy. Two cases in patients under six months of age have been reported by Erdmann and Harper and Skinner.

Other conditions that may simulate hernia of the ovary and tube are: Dermoid cyst in the canal of Nuck (Patterson, Kepler and Waiss); enlarged lymph glands (Pott, Lassus); cyst of the labium majus (Guersant); and a tag of omentum, which is usually found attached to the upper part of the inguinal canal (Eccles).

The non-gravid uterus in a hernial sac is usually difficult to diagnose and is hardly ever looked for unless it causes symptoms. Its presence can sometimes be detected by vaginal examination or by passing a uterine sound which enters the hernial sac. Hernia of the pregnant uterus may be mistaken for extrauterine pregnancy. When examination discloses the non-gravid uterus in the abdominal cavity, displaced toward, and connected with the gradually enlarging tumor in the hernial sac, the condition is probably one of extrauterine pregnancy. In the case observed by Malherbe and Jordan, a tubal pregnancy presented symptoms of irreducible hernia and partial strangulation. At operation a fetus five inches long was found.

30 North Michigan Avenue.

Type of Infantile Convulsions.—Reiche in analyzing the convulsions of childhood isolates a type seen in whooping cough expressed clinically as infantile eclampsia. This he found to be associated with meningitis. In this affection lumbar puncture was found to be of great efficacy. The tension of the fluid was seen to be increased and the chlorides increased—the first named phenomenon was believed to be due to the second and to be responsible for the convulsions.—*La Pediatria.*

AN UNUSUAL CASE OF STONE IN THE POSTERIOR URETHRA.

By Leo Michel, M.D.,

New York.

Stone in any part of the urethra is an uncommon finding. Ordinarily two varieties are described. The first type is known as primary, and these arise within the urethra itself. The second type is secondary. Such stones are delayed in passage from the place of formation to the outside world at some site along the urethra. Recently we had the opportunity of observing a patient who exhibited a most interesting case of the latter type, and who gave an even more interesting history, which is thought worthy of reporting.

L. W., aged thirty-one years, was referred by Dr. I. Arthur Stoloff. The patient was a presser by occupation. He was married. For a period of between five and six years he had been suffering with symptoms referabe to the genitourinary tract, and had been under the care of numerous good urologists and surgeons. He dated the beginning of this trouble to 1916, at which time he was seized with most acute pains in the region of the left flank and lower left abdomen. An *x*-ray examination revealed a stone in the lower third of the left ureter, and an operation for this stone was done. Despite every effort to locate the stone at the time of operation, however, none could be found, and the patient was sewed up. The patient experienced no relief following this procedure, and he sought aid from various men, submitting to repeated cystoscopic examinations, irrigation of the kidney pelvis, irrigation of the bladder, etc., the diagnoses offered varying from tuberculosis of the kidney to cystitis, omitting stone. The symptoms during this time had changed, and he was suffering with frequency of urination both day and night. It was not unusual for the patient to void as often as thirty times daily, only a small quantity at any one urination, and both the initial and closing efforts were attended by severe pains so that he was doubled over. During this period of five years he had had the bladder infected and required treatment for cystitis, but recently the urine had cleared up nicely, and there had been no evidence of cystitis. Some six weeks before he was referred to me the patient complained of pains along the right side such as he had had on the left side, but there was no evidence of stone in the right kidney.

The patient was cystoscoped at the request of Dr. Stoloff, but no stone was seen within the bladder. The left ureter was patulous, and the trigone was congested. On the passage of the instrument a peculiar gritting sensation had been transmitted which gave the impression that a stone was passed over. The cystoscope was removed and through a cystourethroscope, an examination of the floor of the sphincter margin (urethral aspect) revealed a prominence which extended upward about 0.5 cm. and looked not unlike an inverted uvula. Attempts at removal by slitting the mucous membrane and removing the stone through the cystourethroscope failed, as no satisfactory grip could be had on the stone. An open straight endoscope was then passed and a Mathew's forceps readily grasped the stone and it was removed. The entire operation was done under local anesthesia. Very little bleeding attended this procedure, and the patient had no discomfort. All symptoms were immediately relieved. For the first time in a long while urination was free from the severe pain he had come to expect and there has been no recurrence.

The secret of diagnosis of the position of the stone in this case lay with the delicacy of manipulation so that the unusual "feel" of the passage of an instrument could be interpreted as it was. The stone after removal proved to be rather flat, irregularly oval, with sharp edge, and 80 x 40 x 120 mm.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

See fourth page following reading matter for Rates of Subscription and Information for Contributors and Subscribers.

New York, April 22, 1922.

TO OUR READERS.

The first number of the MEDICAL RECORD appeared on March 1, 1866. The last number, as such, is the present issue.

The MEDICAL RECORD is justly proud of its history. Almost all of the epoch-making discoveries in Medicine and Surgery in the past half century were first announced in its pages. Questions of the first importance to the medical profession were discussed as occasion arose, and the influence of the paper became very large.

Two men only have filled the editorial chair in these fifty-six years: Dr. George F. Shrady, and Dr. Thomas L. Stedman. The journalistic acumen and enterprise of the former and the ripe judgment and polished scholarship of the latter have borne fruit in the reputation always enjoyed by the MEDICAL RECORD.

The increasing demands of their medical book business have made it advisable for the publishers to transfer the publication of the paper. It will be combined with the *New York Medical Journal*, a periodical which is even older than the MEDICAL RECORD.

Subscriptions will be completed by service of the combined journal.

We would express to our many friends our appreciation of their loyal support, which we have always tried to merit.

Publishers of the MEDICAL RECORD.

ANAPHYLAXIS AND IDIOSYNCRASY.

SPONTANEOUS anaphylaxis in man is admitted to differ notably from experimental anaphylaxis. In the former the soil plays a prominent role which in the latter is effaced. In the experimental anaphylaxis of animals the phenomena closely follow the animal species. In spontaneous human anaphylaxis it is often a matter of individuality—of specificity not for the species but for the individual. In other words, we are dealing with so-called idiosyncrasy. This is not strictly limited to the individual, but may be shared by members of his family and he may transmit it to his offspring.

The phenomenon of sensibilization differs in man as compared with laboratory animals. We can sensibilize a guinea pig to a serum injection with almost mathematical precision, and this is equally the case with the dog and rabbit. But with man there are numerous individual differences. The second injection may provoke no reaction at all or a delayed reaction. In not over half the subjects will there be anything approximating a constant behavior. In this class of findings in man and animals we are dealing, of course, with parenteral exhibition of the serum. In spontaneous anaphylaxis, on the contrary, all of the finds are based on buccal ingestion. Those subjects who develop hay fever, asthma, and urticaria, including angioneurotic edema, from certain foods often come from families which present the same peculiarities. We are justified in the statement that in such subjects there is a true diathesis. In modern parlance their "plasma colloids are unstable and disposed to colloidoclastic shock." It is common experience that a small dose of serum is apt to induce colloidal shock in any of these subjects. The antigen in these cases need not be of protein nature at all, for the intravenous injection of a small amount of isotonic saline infusion is sufficient to provoke a severe colloidal shock. Here the predisposition is everything.

In these subjects an antecedent sensibilization is not always necessary. Asthma, Quincke's disease, etc., are not of necessity anaphylactic phenomena at all. Given a sufficient degree of colloidal instability, colloidal shock can occur from a variety of causes which do not depend on the mechanisms of sensibilization and anaphylaxis. In the clinic it is often extremely difficult to discriminate between an idiosyncrasy and an anaphylaxis. In theory the two sets of phenomena do not exclude each other, but just the reverse. The subject, with inborn, perhaps inherited colloidal instability, should become easily sensibilized to various antigens, while at the same time other causes in the absence of sensibilization should be able to provoke phenomena of the nature of pure idiosyncrasy. That this is what actually occurs is well shown in an article by Widal, Abrami, and Leromeyez in *La Presse Médicale* for March 4, 1922, xxx, 18, from which we have abstracted the above presentation of the subject. The subject was a woman of thirty-nine who had been free from ailments until the age of twenty-eight. She then developed paroxysms of urticaria, spasmodic coryza, and asthma, suggesting the diathesis of colloidal instability. It was also found that she had idiosyncrasies toward aspirin and antipyrin. The simple act of chilling was enough to induce paroxysms of the affections mentioned, while food of all kinds gave negative results. Pollens were able to produce the coryza and asthma when rubbed into the abraded skin. In all positive results the blood showed the hemoclastic shock. Aspirin could provoke all three of the clinical behaviors as could also antipyrin, both by ingestion and cutireaction. In a patient of this type it is difficult to decide as to the possibility of early sensibilization to cold, pol-

lens, and drugs, but the latter hardly stands to reason. The authors succeeded in desensibilizing the woman to aspirin, but this is no certain demonstration of an anaphylaxis. They were entirely unable to relieve her of the hay fever, asthma, and urticaria, by any of the antianaphylactic resources.

SYPHILIS, ANCIENT AND MODERN, IN PERSIA.

THAT syphilis has existed from the earliest times in Asia is an old belief which some modern controversialists like Bloch have vainly attempted to discredit. Internal evidence, such as vernacular terms for various ailments, seems to show that there have always been in use certain designations. Even if the diseases themselves are new, the names, as applied to diseases, are old. With these names may be associated certain beliefs, folk-lore, etc., showing a common suggestiveness among ancient and modern peoples. There are also archeological evidence of excavation finds. Dr. Christidi of Constantinople, who has studied syphilis and leprosy among the Persians (*La Presse Médical*, March 15, 1922, xxx, 21) believes that the former has prevailed in that country, like leprosy, from very early times, at least as far back as the days of the Phœnician merchants, who, as the only commercial travelers of the period, were able to disseminate the infection. There is an ancient Persian anathema, "kouft," equivalent to our "pox" and similar expletives, which, as the native word for syphilis, speaks volumes. The collections of old terra cotta in Persia—images with certain inscriptions—speak for the existence of a disease with such symptoms as sore mouth, snuffles, severe headache, etc. These exhibits the author has personally studied. Moreover, there was confusion between syphilis and leprosy, as happened also in medieval Europe. Some descriptions of leprosy apply clearly to both diseases. The same confusion exists to-day in the minds of the empiric physicians of Persia. The author cites a very ancient manuscript, the source of which is not stated, save that the original antedates the Christian era by several centuries. The manuscript of the present day is a copy in Arabic which goes by the name of the "Bouquet of Medicine." It speaks of two forms of leprosy, one acute and contagious in evolution, the other much more chronic and but slightly contagious. The acute contagious form answers to syphilis.

Persian syphilis, considering that there is no evidence of any common successful plan of treatment, is on the whole relatively benign. If this was not originally the case—and the use of the expletive "kouft" would seem to indicate that it was once a scourge—it has evidently become so through saturation of generations of Persians. Mercury is in use to-day, and has been for years past, but not treatment as we understand the term. To-day only one in fifty gets prolonged and thorough medication. Innocent transmission is very common, just as in Russia. When a European contracts the disease from a Persian woman the course is usually benign. The author noted some severe cases of the disease in which the woman in the case was not a Persian and in two of these cases paresis developed. The nationality of these foreign women is not stated. The author saw at least 3000 cases of syphilis in Persia, and in general Persian syphilis sufficiently resembles the European, with some notable differences. He saw no metasyphilis in native Persians, but, singular to relate, there seemed to be a well-defined syphilitic epilepsy which was present in hereditary cases and most commonly in women.

PSYCHICAL AND PHYSICAL CONCEPTIONS OF SEXUALITY.

AT first sight the hormonic factor in normal sexuality seems to exclude the possibility of a purely psychogenic motivation of abnormal and excessive sexuality. Stekel in the preface of one of his books implies that Steinach's discoveries have in no wise disturbed his faith in psychically motivated sexuality. The views of Steinach seem at first to exclude those of Freud and his school, and vice versa; for the Freudians insist on infantile sexuality, and according to the hormonic view this is an impossibility. Steinach through his operating surgeons claims to have cured homosexuality by testicular grafting alone, on the basis that the gonads of the homosexual are lacking in the testicular hormone; Stekel claims to have made the same cures through psychotherapy alone. A connecting link between the two schools is seen in the high-class castrate, who appears to retain his sexuality through his original mental constitution. It is assumed that this negative result of castration is most likely to be encountered in late castrates, in whom normal sexuality had long been established, and it is further held that it is only a matter of time before the original sexuality must disappear. Another argument in favor of the cerebral theory is the fact that men of normal sexuality occasionally lead abnormal sexual lives. A third argument for the prominence of the cerebral component is seen in the pseudohermaphrodite. Most of these are sexually male, yet we find that psychically either sex may be represented, depending largely on the manner of raising. Even in animal experiments there may be exceptional behavior, male castrates continuing for a time at least to behave like intact males. Evidently the cerebral or psychical component in sexuality must always be borne in mind in the individual case. This has been apparent since the earliest times, for the mere removal of the testicles evolved into the so-called total castration in which the penis was also removed.

The homosexual or invert possesses a mental makeup in which the attitude toward sex is only a detail. In an article by Schwartz in the *Wiener klinische Wochenschrift* for March 10, 1922, xxxv, 11, attention is called to the inferiority complex in this class of subjects which leads to defense reac-

tions of various kinds. Along with an exaggerated ambition, he exhibits an extraordinary degree of prudence and timidity, extending to all relations of life. If this is the key note of the character of the so-called homosexual, much else in his make-up could be deduced therefrom. He would have the motive for a bachelor existence and with his peculiar inhibitions in sexual directions would preserve his infantile sexuality.

Pesticemia.

As is well known, there are several distinct clinical forms of bubonic plague, the nomenclature of which is susceptible of improvement. In the ordinary bubonic form there is a secondary septicemia and secondary pneumonia, and the primary pneumonic form is associated with hemic infection, while finally there is a pure primary septicemia. The use by Brazilian authors of the term "pesticemia" is not a pure instance of word coinage but a legitimate contraction of pestous or plague septicemia. In the *Brazil-Medico* for February 11, 1922, xxxvi, i, 6, is found an article by Gonzaga on hemoculture in the forms of the bubonic-pneumonic plague based on the study of 163 cases interned in the Isolation Hospital of the Oswaldo Cruz Institute. Numerous photographs give the reader an idea of the appearance of the inguinal buboes. Victims of the disease are photographed, at times in standing position, and apparently in good general condition, while at the same time presenting huge masses of enlarged glands. In such cases hemoculture should in theory be negative. Nevertheless, in a case of this type in which recovery occurred in a short time inoculation of guinea-pigs with the patient's blood caused the entire picture of experimental plague. In this class of case there were recovered from the blood vacuolated gram-negative coccobacilli, but the author does not straightway term that Yersin's bacilli, the latter being recovered in typical form, however, from the inoculated guinea-pigs. The purpose of the paper seems largely to point out the omnipresence of blood infection in all cases, mild and semibenign bubonic types included. This gives us the right to speak of one grand basic condition common to all forms which may be termed pesticemia. This word has also a distinct advantage over septicemia, because the latter connotes a malignant clinical condition. The objection to it is that it is barbarous in composition, being of mixed Latin and Greek derivation.

Large Doses of Potassium Chloride in the Treatment of Acute Renal Dropsy.

Potassium chloride is hardly ever mentioned specifically, either under therapeutics or toxicology. In theory if sodium chloride will cause edema in a nephritic it might be possible for a potassium salt by expelling the sodium salt from the body to antagonize this action. Moreover, in the diabetic at least, large doses of sodium carbonate will cause edema. Professor Blum of Strassbourg recently conceived the idea that retention of the sodium ion is responsible for the edema and that potassium might cause its elimination. He first tested the potassium chloride to determine the limits, if any, of tolerance; and found that as much as 20 grams daily produced no ill effects. However, prolonged use, even of much smaller doses, gives rise to colicky pain and diarrhea, and eventually to potassium poisoning of the heart muscle, indicated by low tension pulse, cyanosis, and dyspnea. This salt is therefore never to be thought of at all in cardiac dropsy. In the renal type some brilliant results seem to have been obtained, although no particulars are available. We know of Blum in this connection only through an article by Mauriac and Damade in the *Gazette hebdomadaire des sciences médicales de Bordeaux*, March 10, 1922, xliii, 12. The authors report a case of acute nephritis with edema in an elderly man, which proved rebellious to all ordinary measures. There was a degree of nitrogen retention which gave a gloomy prognosis. Professor Arnozan determined to test Blum's treatment and administered 3 grams of potassium chloride daily, increasing gradually to 10 grams. The treatment was maintained for two months and at present the patient is in fair condition and improving. His blood urea has dropped from over 5 grams per liter to 0.68 gram. No ill effects of the potassium are mentioned, and at last accounts the patient was eliminating 11 grams of sodium chloride daily.

Nitrogen Retention and Acidosis in Mental Confusion.

Studies of metabolism in the mental patient are not numerous. In the epileptic we find an exception to this statement, and a special line of study has appeared in the mental aberrations of the uremic subject, including the period of preuremia. Circular insanity has in some cases been associated with retention of nitrogen from renal insufficiency. Targowla reports a case (*La Presse Médicale*, March 15, 1922, xxx, 21) of a woman with intermittent insanity of the confusional type with maniacal behavior, passing later, after internment, into anxious melancholia, with recovery at the end of two months. Four years later she was readmitted with the same psychosis, and for the third time after a period of two more years. On this last occasion some studies of metabolism were made and the finds comprised acetonuria and slight nitrogen retention. A fortnight after admission she was in the anxiety phase with delusions of persecution, based in part on auditory hallucinations. The acetonuria and nitrogen retention had by this time disappeared, preceding the period of recovery. Apparently these metabolic anomalies coincided with the phase of disorientation, maniacal excitement, agitation, insomnia, etc. The case would of itself mean little, but examination of other patients with intermittent insanity showed a similar behavior of metabolism. The coexistence of acetonuria, urobiluria and slight nitrogen retention appeared to point to hepatic insufficiency as concerned in the production of the psychotic crises. In some of these cases the kidneys seemed to be insufficient, but there was no approximation to the mental aberrations of Bright's disease. On the other hand, there may have been some affinity with the delirium of acute infectious diseases.

Theft As An Initial Symptom of Paresis.

Criminal acts are often the means of revealing incipient paresis, for people of excellent reputation may commit statutory offenses which lead to a mental examination. While sexual offenses, especially against children, are first to be thought of in this connection, any criminal behavior may be in evidence save perhaps such as requires great strength or deliberate planning or in general the use of such faculties as suffer notably in this disease. In *La Presse Médicale* for March 1, 1922, xxx, 17, Vallon of Toulouse mentions the case of a woman of 39, caught squarely in the act of shoplifting. She was sent to prison for two months and on being released went direct to the same establishment and was caught a second time. The tribunal then had her case examined into. She gave a history of loss of consciousness at the funeral of her husband several years before and afterwards menstrual vertigo. There was no further history. She seemed robust in general but the pupils were sluggish. Speech defects could be partly explained by her loss of teeth. The intelligence and even the moral sense seemed intact to tests. There was a euphoria which seemed quite out of place under the circumstances. She explained her thefts by stating that she was absent minded, in a sort of automatic state. Vallon as expert attributed the thefts to the euphoric mental state, which is favorable to irresponsibility of conduct; such pathological happiness making one more or less indifferent to consequences. He had the patient interned for observation and in a month a picture of beginning paresis was partly evident—slurring speech, and exaggeration of reflexes; while lumbar puncture showed an abundant lymphocytosis and a positive Wassermann. Alteration of the moral sense at the début of this disease appears to be a consequence of circulatory disturbance in the cortex preceding the development of meningoencephalitis.

The Evolution of Rejuvenation Experiments.

This subject belongs essentially to experimental biology and it is, therefore, possible to discuss it without allusion to work on mankind undertaken from a purely therapeutic viewpoint. The starting point is usually the work of Brown-Séquard, but that scientist had no intimation of the existence of the endocrine portion of the male gland. Credit for the discovery of the interstitial endocrine gland of the testicle is unanimously awarded to Ancel and Bouin in 1903-4. In addition, these biologists, whose articles appeared in the *Archives experimentales de zoologie*, practised ligation of the vas deferens and noted that it was followed by hypertrophy of the interstitial gland. Resection of the vas had the same result. Steinach has recently given to Ancel and Bouin full credit for priority, and apparently likewise for supplying him with his original idea of rejuvenation in rats by vas ligation. He has also been able to study the results of the work of Voronoff and Retterer upon aged rams and he-goats, which consists entirely of grafting. Steinach's work in the latter field is now well known, including his grafts upon intact males and females. The same investigator's work in cross-grafting of gonads led him to attempt the cure of homosexual males in the same manner. Americans have from the first worked only on mankind and without any basis of animal experiment; and their work involved simple grafting in castrates. Nathan, who supplies this analysis to *La Presse Médicale* for March 18, 1922, xxx, 22, adds that recently Sand of Copenhagen obtained a remarkable degree of regeneration of an aged hunting dog by vas ligation, the animal having recovered its hearing, smell, and genital sense.

Sequelæ of Epidemic Encephalitis.

That epidemic encephalitis is proving a potent cause of chronic nervous affections is becoming more and more apparent from day to day, a fact which should make the practitioner very cautious in his prognoses. These sequelæ show much polymorphism. At a recent session of the Paris Neurological Society (*Le Bulletin Médical*, February 15-18, 1922, xxxvi, 8) Souques presented one patient and related a second case in which lethargic encephalitis had first been followed by hemimyoclonus, which, however, had been succeeded by a parkinsonian tremor without pyramidal signs of any kind. Apparently these are the first of the kind to be recorded. Whether the cloni and tremor arose from one and the same lesion or two separate ones is not apparent. Marie presented two patients in which a post-encephalitic parkinsonian syndrome was accompanied by palilalia, one patient repeating the same word as often as twenty-one times. This behavior was also the first of the kind noted after this illness. Claude stated that one of these patients had first presented a tachyphemia, or rapid acceleration of speech and Babinski observed that both speech defects stood in some relationship with the mutism shown by some parkinsonians, and with a form of dysarthria seen by Meige and himself. Babinski had seen one patient who showed at different times both mutism and palilalia. All of these speech defects doubtless have a common origin. In ordinary quiet and formal conversation they are not pronounced, but become so when the subject is excited or angry. Bollack showed a boy who had recovered from ocular paralyses and whose features were mobile; but induced tests showed that associated movements to the left were restricted, with complete paralysis of convergence.

Sokosho, not Sodoku.

In 1911 Frugoni of Florence made the profession of Europe acquainted with the existence of malady new to it, but long known in Japan. He recognized the presence of a case of ratbite fever in Italy, and from that moment other Occidental cases were recognized and published. The name of the new disease went on record as "sodoku" with an etymology of *so*, rat, and *doku*, poison. This spelling and derivation have remained unchallenged until very recently. Dr. Kagawa of Tokio has written a letter to the *Progrès Médical* which appears in the issue of February 25, 1922, l, 8, in which he has tried to put the Westerners right. The word *sodoku* really exists, he says, but it is a Chinese medical term. Dr. Kagawa does not tell us anything more of it. But

in Japan, where the disease was first described, the word *sokosho* is the descriptive name, from *so*, rat, *ko*, bite, and *sho*, malady. The symptoms of the affection are sufficiently well known, but it is not yet common knowledge that sokosho has been proved to be a spirochetosis, due to an organism known as *Spirocheta morsus muris*. For a long time there was much uncertainty as to the exact cause, several spirochetes as well as other microorganisms having been accused. Kakawa says, however, that Professor Ishihara has settled the matter definitely by isolating and cultivating the germ, and reproducing the disease in a number of laboratory animals. The disease yields readily to old salvarsan. The bite of the cat is often followed by a disease quite like sokosho, but the question of absolute identity has not yet been settled.

News of the Week.

Bubonic Plague in the Near East.—According to a statement issued by Dr. Rupert Blue, in charge of the United States immigration service in Europe, following a trip of inspection, virtually every port in the Near East is infected with bubonic plague, cholera or smallpox. He added that the United States would be threatened if any of the disease infected immigrants reaching these ports were allowed to embark for the United States. Disinfection and delousing facilities are either inadequate or do not exist at all.

Will Transfer Soldiers' Hospital.—Fifty-seven public health service hospitals treating disabled soldiers, are to be transferred to the Veterans' Bureau by executive order, effective May 1.

Workman's Compensation Law Amended.—Governor Miller has signed the Knight bill, completely revising the New York State Workmen's Compensation law. One of the most important amendments under the new law is the elimination of the sixty-day limitation for medical treatment of injured workmen, and a requirement that the employer furnish to his injured employee medical care and treatment for as long a time as the nature of the injury requires. At the same time under the amendment the employer is protected by the fact that every physician must report to the employer within twenty days the facts as to the nature of the injury and treatment of an employee. Definite provision also is made for the payment of compensation for 150 weeks for the loss of hearing. The old law made no such provision. The list of occupational diseases included in the law has been enlarged by the addition of diseases not heretofore named, and procedure in relation to proving a claim for an occupational disease has been greatly simplified. Failure to insure the compensation of employee is definitely defined to be punishable by a fine of $500, or by imprisonment for a year, and the procedure for compelling employers to insure is greatly simplified. Another important amendment is that which places upon a contractor the liability for the compensation for an injured employee of any sub-contractor unless the main contractor sees to it that the sub-contractor carries compensation insurance. A number of other changes have been made which greatly simplify the operation of the law and which insure against wastefulness and extravagance in its administration.

State Aid for Disabled Veterans.—Governor Miller has signed the bill appropriating $1,000,000 for disabled veterans, and the board will begin distributing the funds immediately. Application blanks can be obtained from deputies in each Assembly district, who will also make payments. There will be an examining physician in each district who will receive $3 for each examination.

Two Child Welfare Bills Become Law.—Governor Miller has signed the two bills carrying out the recommendations in his annual message for the care of children. One provides for an extension of the powers of the county boards of children welfare and the other establishes children's courts in accordance with a constitutional amendment approved by the people at the election last autumn. The first bill transfers to child welfare boards the jurisdiction of poor officers over dependent children. It is permissive. Under the second bill the County Judge is made the Judge of the children's court in each county in which the County Judge and Board of Supervisors certify that he is able to discharge the duties of the office.

The Framingham Tuberculosis Experiment.—The Committee of National Tuberculosis Association which has supervised the experiment carried out in Framingham, Mass., to demonstrate the possibilities of controlling tuberculosis in an industrial community, has published eight monographs explaining the different stages of this work. The work was commenced in 1916 and was financed by the Metropolitan Life Insurance Company. At the end of five years the death rate from tuberculosis alone in this community of 18,000 population has dropped 67 per cent. The inhabitants have established public health clinics and school clinics, and, through various precautionary measures for safeguarding health, infant mortality has been lowered 22 per cent. From 121 per 10,000, an average for ten years preceding the experiment, it has dropped to 40 per 10,000 in 1921. This rate of decrease is lower than any hitherto reported in any known community in the world. Practically two-thirds of total population of Framingham have been given a thorough medical examination. During the first year of the work examination of tuberculous individuals showed that 45 per cent. of the cases were in the early stages and that 55 per cent. were in advanced stages. At the end of five years examinations of suspected cases showed that 83 per cent. were in the early stages. In the opinion of Dr. Livingston Farrand, the work of the committee has proved conclusively that tuberculosis is a controllable disease.

Relations Between Industries and Health.—Harvard University, through the Division of Industrial Hygiene, which is a part of the new School of Public Health, is making a series of studies of the health hazards of industry, to accumulate fundamental facts on the relation between industrial jobs and ill-health which may prove useful in the prevention of disease. The aim of these investigations, which are still in their early stages, is to collect definite scientific information which may ultimately make it possible to

determine just how harmful to the human system any given kind of dust is, and whether the amount of such dust in any given factory or mine is sufficient to endanger the health of the workers. Meanwhile, at the Massachusetts General Hospital, members of the Division of Industrial Hygiene are operating an industrial clinic in which they study cases of industrial toxications, poisoning inhalation of dust, fatigue of special groups of muscles, and other kinds of cases as they come into the hospital. The division has also been studying the health of employees in 25 department stores in Boston, New York and other cities, and on the basis of this study has advised these stores about methods of protecting the health of their employees.

The Bowling Green Neighborhood Association, which cares for children, providing playgrounds and recreation, and aims to better health conditions in general in the Bowling Green section of New York, recently held its first annual dinner. Dr. Hermann M. Biggs, State Health Commissioner, was the guest of honor. In his address he stated that tuberculosis in the Bowling Green section was worse than in war-ravaged Serbia. Deaths were fifty times greater than in the Central Park residential section.

The Homeopathic Medical Society of the State of New York, which held its seventieth annual meeting in New York City during the week of April 10, voted to confer with the Homeopathic Societies of New England and the Eastern Atlantic States with a view to the formation of an Eastern Homeopathic Association. The purpose will be to bring together all Eastern homeopathic physicians for scientific research. The society passed a resolution asking Governor Miller to veto the Knight mental defective bill, described as a measure that would give any citizen the right to commit a minor on demand pending a medical examination.

Drug Addiction Increasing.—According to a statement made by Bird S. Coler, Commissioner of Public Welfare, all the seeming good which was to be derived from the passage of the Volstead act has passed away and that the outlook for increased dependencies of every kind is growing most alarmingly. The Commissioner said that while the alcoholic wards were practically abandoned in the early part of 1919, their activity at present is greater than it was prior to the passage of the Eighteenth Amendment. Drug addicts, he reports, are growing more numerous all the time and more vicious as well. If the Government had been sincere in the effort to enforce prohibition and to release spirituous liquor for medicinal purposes only, it would have inquired from health departments, welfare departments, and medical societies what amount of liquor is necessary for medicinal purposes. In all the hospitals and dispensaries operated by the City of New York less than 700 gallons a year are used.

Mental Defectives Measure Vetoed.—Governor Miller on April 15 vetoed the Knight mental deficiency measure, which would have made it easy to commit a person who apparently was a mental defective. Of the bill Governor Miller wrote in a memorandum: "This measure is the result of the experience and the study of the State Commission for Mental Defectives and of others who have devoted earnest thought to the problem. It is unquestionably a decided improvement in many important respects upon the present law, but contains some important provisions of doubtful import and of uncertain operation. No doubt the present provisions of law for the commitment of mental defectives are inadequate, but the power to deprive an individual of his liberty for an indefinite period on a finding by a magistrate that he is apparently a mental defective should certainly be most carefully guarded, if it is to be conferred at all."

Hospital Notes.—The United States Government has purchased the property of Mrs. A. W. Church, near Port Chester, N. Y., as a site for a hospital for the treatment of tuberculous veterans. The site consists of about 100 acres and it is hoped to have the new buildings ready for occupancy in six or eight months.

The Bronx General Hospital, officially known as United States Veterans' Hospital No. 83, has been officially opened. This is a plant which was purchased ready built at a cost of $2,000,000 and remodeled by the Government at an added expense of several hundred thousand dollars.

A mammoth exposition is to be held in Madison Square Garden, New York, May 8-13, to raise funds toward the maintenance of the Masonic Memorial Hospital at Utica, N. Y., which was recently completed at a cost of $1,000,000. A fund of $125,000 will be required yearly for the next five years for maintenance when the endowment fund will be ample to cover its operation.

The hospital for the tuberculous of Bergen County, N. J., was opened to public inspection on April 1. This new institution has cost over $400,000.

Additions are soon to be built to the Middletown (Ohio) Hospital, for which a sum of $155,000 has been appropriated.

The commissioners of Hennepin County, Minn., have passed a resolution to issue $500,000 in bonds to raise money for doubling the capacity of the Glen Lake Sanatorium. When the contemplated addition is completed the institution will be prepared to care for 500 patients.

Dr. T. E.. Teah formally opened his private hospital in Williamsport, Pa., on April 1.

A contract for an addition to St. Joseph's Hospital, St. Louis, Mo., has been awarded. When the new addition is completed the hospital will have accommodations for 150 beds.

The hospital for tuberculous ex-service men of New York State, to be constructed by the Veterans' Bureau, will be either at Otisville or Liberty, Sullivan County. Each place is offering inducements to get the institution, which will be a permanent hospital used for the ex-service men as long as needed and thereafter as a hospital for tuberculous patients.

Plans for a $3,000,000 Methodist Episcopal sanatorium in Colorado Springs have been about completed. Bids for the first unit, to cost $250,000, will be opened in May.

A new Catholic hospital was recently dedicated at Bend, Ore.

A committee has been organized and a campaign started to raise funds for a hospital to be known as the Mt. Mercy Hospital, near Cazenovia Park, Buffalo, N. Y.

Gifts and Bequests.—By the will of Morris Freudenheimer of Yonkers, N. Y., Lebanon and Beth Israel Hospitals, New York, each receive $1,000. The St. John's Riverside Hospital in Yonkers received $600.

Dr. George A. Ohl, Jr., has donated $100,000 in cash for an orthopedic hospital in Newark, N. J. He has offered as a site for the hospital the Ohl homestead at 171 Washington Avenue, valued at $50,000. The provisions under which the gift is made require that the hospital be self-supporting and that it be under the guidance of Dr. Adolph Lorenz. It is in memory of Mr. Ohl's mother, Catherine Ohl, and will be named for her.

Medical Society Elections. — The Hartford County (Conn.) Medical Association, at its annual meeting held in Hartford, April 5, 1922, elected the following officers for the ensuing year: *President*, Dr. Edward R. Lampson; *Vice-President*, Arthur S. Brackett, Bristol; *Secretary-Treasurer*, Anthony W. Branon, Hartford; *Censor*, Arthur B. Landry, Hartford.

The Limestone County (Tex.) Medical Association, at its meeting held in Mexia, April 5, 1922, elected the following officers for the ensuing year: *President*, Dr. R. B. Jackson; *Secretary*, Dr. W. W. Shirri.

The Gastroenterological Society of Cuba.—On January 20 there was founded in Havana the Sociedad Cubana de Gastro-Enterologia, and at the election held March 13 the following officers were elected: *President*, Dr. F. Grande Rossi; *Vice-President*, Dr. F. Torralbas; *Secretary*, Dr. F. Solano Ramos; *Vice-Secretary*, Dr. Pedro Barillas.

Obituary Notes. — Dr. Milton C. Sprague of Summerford, Ohio, a graduate of the Cincinnati Medical College in 1873, died on March 24, at the age of seventy-three years.

Dr. Agnes Sparks of Brooklyn, New York, died on April 15 at the age of 70 years. She was born in Canandaigua, N. Y., and was graduated from the Stanford Medical College, California, in 1880. She practised medicine for forty years in Brooklyn, and was the first woman member of the Kings County Medical Society.

Dr. Glover Brown Wilcox of San Francisco, Cal., died of pneumonia on March 13, at the age of forty-four years. He was graduated from the University of Southern California Medical Department, Los Angeles, in 1908.

Dr. Onnie L. Deadwyler of Carlton, Ga., was almost instantly killed in an automobile accident near Athens, on March 18. He was graduated from the University of Georgia Medical Department, Augusta, in 1892, and was fifty-two years of age at the time of his death.

Dr. George MacMurphy of Ortonville, Minn., a graduate of Bellevue Hospital Medical College in 1878, died following a stroke of paralysis on March 10, at the age of seventy years.

Dr. Corydon P. Gowman, a graduate of the Detroit College of Medicine and Surgery in 1893, and a former resident of Detroit, died at Mt. Airy, Md., on March 26, at the age of sixty-one years.

Dr. Charles A. Griswold of New London, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1856, and a surgeon in the Civil War, died in a local hospital on March 30, at the age of ninety-one years.

Dr. James Rufus Bird of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1858 and consulting physician to St. John's Hospital, died on March 28, at the age of eighty-seven years.

Dr. Nelson Stiles of Wichita, Kan., formerly of Medford, Okla., died on March 21, at the age of sixty-eight years. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1882.

Dr. J. Endicott Chapin of Red Wood, Cal., died suddenly on March 24, at the age of fifty-one years. He was graduated from the Washington University Medical School, St. Louis, Mo., in 1909.

Dr. Wesley Asbury Rape of Victoria, Tex., a graduate of the Washington University Medical School, St. Louis, in 1887, died in a Cuero hospital on March 27, at the age of fifty-six years.

Dr. Lewes D. Wilson, a graduate of the Washington University School of Medicine, in 1888 and of the Hahnemann Medical Institute of Philadelphia in 1891, died of heart disease at his home in Washington, D. C., on March 30, at the age of fifty-six years.

Dr. I. N. B. Spence of Social Circle, Ga., died on March 23, at the age of seventy-two years. He was graduated from the University of Georgia Medical School, Augusta, in 1877.

Dr. Elmer Eugene Morgan of Fort Wayne, Ind., died on March 23, at the age of sixty years. He was graduated from Rush Medical College, Chicago, in 1892. He was a fellow of the American Medical Association, treasurer of the Allen County Medical Society, and counsellor for the twelfth district Medical Society for many years.

Dr. Henry B. Thomas of Baltimore, Md., died on April 2, at the age of fifty-seven years. He was graduate from the University of Maryland College of Medicine, Baltimore, in 1888. He was a member of the American Medical Association, and was connected with the Union Memorial Hospital, the Women's Hospital, the University Hospital, Mercy Hospital and the Presbyterian Eye, Ear, and Throat Hospital.

Dr. John S. Phillips of Allegheny, Pa., died following an operation on March 30, at the age of seventy years. He was graduated from the Miami Medical College, in 1876. He was a member of the Allegheny County Medical Society and a Fellow of the American Medical Association.

Dr. Preston E. Waddell of Natchitoches, La., a graduate of Tulane University, New Orleans, in 1895, died on April 1, after a lingering illness, at the age of sixty-one years.

Dr. Laban T. Bremerman of Downington, Pa., died from paralysis at West Chester Hospital on March 31, at the age of seventy-two years. He was graduated from George Washington University, School of Medicine, St. Louis, in 1874. He was President of the local School Board and for twenty-five years had been Burgess of Downington.

Dr. Oan J. Thompson died at Reading, Pa., on April 1, at the age of fifty-one years. He was

graduated from Jefferson Medical College in 1895. He was Past Grand Commander of the Knights of Friendship of Pennsylvania.

Dr. M. HENRY GREEN died at Philadelphia on April 6 at the age of seventy-six years. He was graduated from Jefferson Medical College in 1882.

Dr. HENRY ETTINGER of New York, a graduate of Bellevue Hospital Medical College in 1890, and a Fellow of the American Medical Association, died on April 8, at the age of sixty-two years.

Dr. GEORGE LOVE of Waukesha, Wis., died on March 31 at the age of fifty-five years. He was graduated from the Northwestern University Medical School in 1894. He formerly resided in Pewaukee where he was health officer for a number of years.

Dr. CHARLES M. WILSON of Gouverneur, N. Y., a graduate of Bellevue Hospital Medical College in 1871, died at the home of a relative at Fort Atkinson, Wis., on April 4, at the age of seventy-seven years.

Dr. HERMAN G. KLIPPERT of New York, a graduate of the College of Physicians and Surgeons, New York, in 1889, died suddenly on April 1, at the age of fifty-six years. He was a Fellow of the American Medical Association and a member of the County and State Medical Societies, and of the American Medico-Pharmaceutical League.

Dr. JOHN D. SLAYDEN, a graduate of Jefferson Medical College, Philadelphia, in 1869, and a Fellow of the American Medical Association, died at his home in Clarksville, Tenn., on March 26, at the age of eighty-one years.

Dr. FRANK C. JONES of Los Angeles, Cal., died suddenly on March 22, at the age of seventy-five years. He was graduated from the University of Michigan Medical Department, Ann Arbor, in 1880.

Dr. HANNAH C. G. KINDBOM died of paralysis at Philadelphia on March 19, at the age of fifty-one years. She was graduated from the Woman's Medical College of Pennsylvania in 1910. She was a member of the Philadelphia County Medical Society, the Philadelphia Pediatric Society, the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. JEROME LEVIS PYLE of Gradyville, Pa., died on March 22, at the age of sixty-five years. He was graduated from Jefferson Medical College in 1885.

Dr. DAVID G. WILLETTS, a surgeon of the United State Public Health Service, died in the hospital at Smith's Landing, N. J., on March 26, at the age of forty-nine years. He was graduated from the George Washington University Medical School of Washington D. C., in 1907.

Dr. HOMER BRANDEL SMITH of Lancaster, N. H., died of diphtheria on March 27, at the age of forty-four years. He was graduated from Harvard Medical College in 1903. During the war he was placed in charge of Base Hospital No. 51 overseas and retired from the service with the rank of Lieutenant-Colonel.

Dr. IGNATIUS WALTHALL POWELL of St. Louis, Mo., a graduate of Barnes Medical College, St. Louis, in 1907, died on pneumonia on April 6. He was formerly assistant police surgeon, and was a Fellow of the American Medical Association.

Dr. GEORGE W. HEINITSH of Spartanburg, S. C., died after a lingering illness on April 5, at the age of sixty-three years. He was graduated from Jefferson Medical College in 1879.

Dr. HENRY HAMILTON DEANE of Watertown, N. Y., died after a lingering illness on April 10, at the age of seventy-two years. He was graduated from the University of Vermont College of Medicine, Burlington, in 1876, and was a former president and for ten years secretary of the Jefferson County Medical Society. He was for ten years health officer of the city of Watertown.

Dr. JEPTHA W. SCHURMAN of Detroit, a graduate of the Detroit College of Medicine and Surgery in 1907, died on April 7, at the age of forty-three years. He was a member of the American Medical Association, Wayne County Medical Society, Detroit Otolaryngological Society, Trudeau Society, and was a member of the staff of Providence Hospital.

Dr. JOHN S. HOLLINGSWORTH of Indianapolis, Ind., a graduate of the Indiana Medical College, in 1893, died as the result of injuries received in an automobile accident, on April 5, at the age of fifty-seven years.

Obituary.

EDWARD KELLOGG DUNHAM, M.D.,

NEW YORK.

Dr. EDWARD KELLOGG DUNHAM of New York died suddenly of angina pectoris on April 15 at the age of sixty-two years. He was born in Newburgh, was graduated from Columbia University in 1881, and from the Harvard Medical School in 1886. He studied bacteriology under Koch, and early in his career was bacteriologist to the Massachusetts Board of Health. He was professor of pathology at Bellevue Hospital Medical College from 1898 to 1907. Dr. Dunham was a member of the New York Academy of Sciences, of the American Chemical Society, of the American Pathological and Bacteriological Society, of the New York Academy of Medicine, of the Societies of the County and of the State of New York, and of the American Medical Association. During the World War he was a Major in the Medical Corps of the Army, and at the time of his death was nearing the end of an exhaustive study of the causes of empyema based on his experience in army camps.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 29, 1922.

Women Students in the Hospitals.—It seems now that the question as to whether women should be allowed to study at the hospitals side by side with men does not rest altogether with the hospital authorities. At any rate, it appears that in London the matter is by no means settled. For instance, one important point has not been raised in the controversy brought about by the decision of the London Hospital, that immense institution in the East End of London, to exclude women medicals in the future. It may be stated that during the coming year the London Hospital will receive an additional grant from the London University Grants Committee of £3,000, which added to the £7,000 grant already made and a special grant of £6,000 for their clinical units, makes a total of £16,000 for the session from the Government. It may be pointed out that this is public money contributed to the London Hospital Medical College for the purpose of medical education. Moreover, public money is contributed by the women as well as by the men of the country. There is only one hospital medical school in London which has steadily refused to accept a Government grant precisely in order to maintain a complete freedom of policy, and has never opened its doors to women students. But the London Hospital is in quite a different situation, and in this instance, two separate questions are raised, one of policy on its merits, the other of the hospital's public obligation, due to its being up to a point, a trustee for public money. A correspondent in the Observer recently drew attention to these facts and said that it is hard to escape the conviction that the London Hospital is endeavoring to ride two horses. It is accepting public money and at the same time discriminating against one section of the public which contributes this money. The answer may be that the Treasury grant is made unconditionally, and if taxed on this subject the University Grants Committee would no doubt and with reason, put up the defence that the £16,000 were paid to the London Hospital for the encouragement of medical education, and that it was left to the authorities of the hospital to decide how the money could best be used in the public interest. But if on the other hand, the question were raised in the House of Commons it would be found that a good departmental defence is not necessarily a convincing parliamentary defence. Of course, the end of the matter has not been heard. However, after all, the question is not a legal one. The point is, whether it is to the best interests of all concerned, including the public, that women and men should study medicine together. Opinions here differ so widely on the subject that it appears impossible to come to a decision. As usual in this country, the debatable points are being thoroughly threshed out in the lay as well as in the medical press. As a rule, indeed almost without exception women writers, and these are numerous, insist that women should be allowed all the privileges possessed by men medical students. If they desire to work with men they have a right to do so. Men writers to the press incline to the view that it is injudicious that women and men should work in the same medical schools and hospitals. The pros and cons are many but in the existing financial plight of the hospitals it would appear more reasonable perhaps to shelve the question until these institutions have been placed on a firm basis. It would be interesting to know what is thought of medical coeducation in America, although coeducation in medicine differs in some important respects from coeducation when young, in that students of medicine are adults and presumably have reached the age of discretion.

Large Bequest to King Edward's Hospital Fund for London.—The London hospitals will benefit to the amount of £400,000 by the will of Sir Thomas Sutherland, late chairman of the Peninsular and Oriental Steam Navigation Company, who died on January 1 last, leaving property of the gross value of £723,075.

London University College Annual Report.—The London University College Report for 1920-1921 shows that the total number of students enrolled was 3,143, of whom 1,308 were women. It was a crowded year in many senses. The new building for anatomy provided by the Rockefeller gift of a million and a quarter for medical education was begun and is expected to be finished by March, 1923.

Committee on Light.—The Medical Research Council, a department of the Ministry of Health, has appointed recently a committee to guide it upon researches into the biological action of sunlight and other forms of light in relation to human health and disease. The committee is under the chairmanship of Professor W. M. Bayliss of University College, London. Professor Leonard Hill is also a member. The committee includes as well Sir Henry Gauvain and Dr. Sequeira.

Bronze Medallion of the Carnegie Hero Fund Trust Presented to a Medical Man in Civil Practice.—Dr. J. Hall-Edwards, the well known radiologist of Birmingham, was presented the other day with the Bronze Medallion of the Carnegie Hero Trust Fund, together with an annuity. This medallion may be compared with the Victoria Cross as a distinction. Dr. Hall-Edwards was a pioneer in the use of the *x*-rays in this country. As a result of continual exposure to the *x*-rays it became necessary to amputate his left arm and right hand. Dr. Hall-Edwards was radiographer to the Birmingham General Hospital for a period of twenty years; in the South African war he was radiographer to the Imperial Yeomanry Hospitals, and during the late war he acted in the same capacity to four of the largest military hospitals in this country. No man better deserves honor than he who knowingly risks his life in the pursuit of science and for the benefit of his fellow men, and Dr. Hall-Edwards, as well as several other radiologists did this without a thought for himself.

Honor for Dr. George G. Armstrong of Montreal.—Dr. George G. Armstrong, Professor of Surgery at McGill University, Montreal, has been nominated for the Honorary Degree of Master of Surgery by the Senate of the University of Dublin.

Eclipse of the Sun and Eyesight.—It has been pointed out recently by a medical correspondent to a lay journal here that whenever a solar eclipse takes place a large number of people come under medical treatment, suffering from partial or complete loss of their central vision, as a result of having watched the phenomenon without sufficient protection of their eyes. It is stated that after the eclipse of April, 1912, 3,500 cases of this form of blindness were met with in Germany alone, whilst in many other countries very large numbers of people were known to have been affected. It is interesting to note that eclipse blindness was known to Aristotle, Galen, Lucretius, and Xenophon. It must be borne in mind that it is the very center of vision which is affected; consequently reading, writing, and other occupations which demand the acutest possible vision are seriously interfered with. It is said that the highest medical authorities believe that the trouble is due to the focussing of the solar light rays on the center of the retina. It is incorrect to describe this as a burn because the media of the eye do not permit heat rays to pass through them.

OUR LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, March 20, 1922.

Bismuth in the Treatment of Syphilis.—Several salts of bismuth have been essayed, but it has been found that tartro-bismuthate of sodium and potassium is at the same time the least toxic and the most active. It is a white, insoluble powder, to be used only as intramuscular injections suspended in an oily vehicle. It must never be given subcutaneously or intravenously. The ampoule containing the bismuth in oil must be shaken vigorously for some time in order to obtain a complete suspension of the salt. It is then quickly drawn into the syringe, the needle having been previously planted in the muscular mass of the buttock. The needle should be of large caliber and at least two and a half inches long. As the drug is not tolerated intravenously, one should be sure that the needle has not entered a vein before injecting. The injection is given slowly. The immediate reaction is trifling. The injections are at first given every second day in the dose of 20 centigrams, or every third day in the dose of 30 centigrams. Afterward they are given every fourth, fifth, or sixth day, or less frequently should stomatitis or a blue line on the gums develop. The total amount of the salt given in a series of injections should be from 2 to 2.5 grams in the space of three weeks to one month. In these doses the activity of the drug is unquestionable and rapid. Fournier and Guénot, who have had the largest and longest experience, found that the treponema disappeared in the chancre after the first injection, but more frequently after the second. The primary lesion heals in from six to twenty days, according to its size. The treponema also disappears from the lymphnodes.

The action of the bismuth salt on the secondary manifestations is likewise very powerful. The treponema rapidly disappears from the lesions and the headache, osteocopic pain, etc., subside in patients who resist the action of mercury or the arsenical salts. Bismuth acts favorably in the tertiary period, and in one case of lingual leucoplasia the lesion notably decreased, although it did not disappear entirely.

Fournier and Guénot have observed no general reaction and only a very tolerable local pain following the injections; stomatitis is less serious than that caused by mercury. On the other hand, Emery and Morin, who have also had considerable experience with the drug, are rather reserved as to the local and general tolerance, as well as the therapeutic activity, particularly when compared with the arsenic preparations. All observers have noted local pain occurring soon after the injection, and this attains its maximum on the following day. It is never insignificant and may be very severe. Stomatitis is also met with. It is frequent and develops after the blue line on the gums has appeared, which is a warning that saturation of the organism has taken place. But it may develop without any prodromes. It is to be treated by the local application of a 1 per cent. solution of methylene blue and one of the arsenical preparations in powder dusted on. General complications are less common. In one case gastrointestinal disturbances developed with mild jaundice and a stomatitis, with a temperature of 101.2° F.

All things considered, bismuth is distinctly and often rapidly active and specific. However, Emery and Morin believe that, in the secondary and tertiary phases of syphilis, its action on Wassermann is less rapid and decisive than that of arsenic. They also believe that bismuth is *more potent* than mercury, even when the most active salts of the latter drug are used, such as calomel, or the cyanide given intravenously. Its usefulness is evident in patients who resist the action of the arsenical compounds or the salts of mercury. Such is the consensus of opinion today; perhaps tomorrow improvements will be made in the bismuth salt that will change our ideas in respect to the drug.

1. **Tularemia Francis 1921: A New Disease of Man.**—Edward Francis describes a specific infectious disease due to *Bacterium tularense*, which is transmitted from rodents to man by the bite of an infected, blood-sucking insect or by the handling and dissection of infected rodents by market men or laboratory workers. The insect responsible for transmitting the infection, as studied in Utah, is probably the blood-sucking fly, *Chrysops discalis*. Following the fly bite on some exposed surface of the body, the onset occurs within forty-eight hours with fever and pain in the region of the lymph glands which drain the bitten area; the patient is prostrated and goes to bed; the lymph glands which drain the bitten area become tender, inflamed and swollen, and commonly suppurate, requiring incision. The fever is of a septic type, lasting from three to six weeks, and convalescence is slow. Tularemia is a disease of the rural population, particularly attacking persons who work in the fields. Human cases occur in Utah during the seasonal prevalence of the fly (*Chrysops discalis*) in a community where jack rabbits are dying from an epizootic of a plague-like disease of rodents due to the *Bacterium tularense*. The rabbit, louse, and the bedbug are also capable of transmitting the disease. The writer gives a summary of seven cases investigated clinically and culturally in Millard County, Utah, and refers to six cases occurring in laboratory workers, which have been reported recently by Lake and Francis. This experience, he says, should serve as a warning against unwarranted indifference to an infection which has claimed all those who have worked continuously with it in the laboratory. The ready susceptibility of man to this infection, its wide prevalence in nature in a number of rodents, and the growing number of blood-sucking insects found capable of conveying the infection should combine to put the medical profession of the United States on guard for cases of this new disease in man.

4. **The Kottmann Reaction for Thyroid Activity.**—William F. Petersen, F. T. H'Doubler, S. A. Levinson, and J. E. Laibe direct attention to a unique serum test for thyroid activity devised by Kottmann. The theoretical premises are, on the basis of previous work with serum in pregnancy, that certain physicochemical differences must exist in the serum in cases of thyroid dysfunction, and that the chief difference would exist in the state of dispersion of serum colloids. Because of the peculiar relation of iodine to the glandular metabolism, experiments were carried out with colloidal iodine preparations, using silver iodide because of its well-known photosensitivity. The technique of the test is as follows: To 1 c.c. of clear serum are added 0.25 c.c. of a 0.5 per cent. solution of potassium iodide and 0.3 c.c. of a 5 per cent. solution of silver nitrate. The resulting suspension of silver iodide in the serum is next exposed for five minutes at a distance of 25 cm. to a 500-watt Mazda lamp (or other light of equal intensity). Then 0.5 c.c. of a 0.25 per cent. solution of hydroquinon is added and the color changes observed at five-minute intervals. In carrying out the test a dark room is theoretically desirable, though diffuse daylight does not materially interfere with accurate results. The color reaction that develops after the addition of hydroquinon varies with different serums. With serum from hyperthyroid cases, Kottmann found the original yellowish color of the serum mixture persisted for a considerable time; in normal serums a brown color (silver iodide reduced to free silver) makes its appearance quite promptly; in serums from hypothyroid cases, Kottmann found the development of the brown color reaction accelerated. The serum from individuals who have had bromides retards the reaction, and such medication must be excluded if the test is to be carried out. The writers have studied 400 serums obtained from patients with thyroid dysfunction, as well as those ill with other diseases, and a large group of normal persons. The results demonstrate that the photochemical serum reaction devised by Kottmann yields a close index of the thyroid activity. The test is simple and should be of material aid in the clinical as well as the experimental investigation of thyroid problems.

5. **Hydrogen-Ion Concentration Studies on Distilled Water, Physiologic Sodium Chloride, Glucose and Other Solutions for Intravenous Medication.**—John R. Williams and Madeleine Sweet show that the hydrogen-ion method of determining the reactions of fluids used for therapeusis or clinical investigation is of great importance. When fluids having a higher or lower hydrogen-ion concentration than that of the blood are injected into the circulation at a rate or in an amount that the blood cannot neutralize or buffer, reactions characterized by chills and prostration follow. By the hydrogen-ion method they have determined that distilled water, if not carefully prepared or when stored as a stock solution, becomes highly acid so that when used as a solvent it may produce a solution of a much higher hydrogen-ion concentration than that of the body. Glucose solutions become highly acid when boiled, autoclaved, or when permitted to stand for a few hours. Stock glucose solutions as used clinically are highly acid. Physiological sodium chloride solution, when prepared with stock distilled water or impure salt, may be very acid. A normal or physiological salt solution should not only contain that amount of salt which will make it isotonic with the blood, but it should also have the same hydrogen-ion concentration by the addition of buffer salts. The buffering of glucose and physiological sodium chloride solutions, in the experience of the essayists, has served to prevent reactions. They have studied and will report in a succeeding paper the hydrogen-ion concentration of sodium citrate solutions, serums, vaccines, and antitoxins, arsphenamine preparations, neo-arsphenamine, and hypodermic medication in both tablet and ampoule form.

7. **Syphilis and Trauma: The Workmen's Compensation Act, the Industrial Physician and the Syphilitic Employee.**—Joseph V. Klauder discusses the possible results as seen clinically when syphilitic tissue is subjected to trauma, and emphasizes the fact that not only may syphilitic manifestations develop in the skin and muscles when these are subjected to trauma, but other organs—the osseous system, viscera, and nervous system—may similarly react after the infliction of trauma. The surgeon has long been cognizant of syphilis as a factor in the non-healing of wounds and the non-union of fractures. Therefore, when an employee sustains an injury, it should be the routine procedure on the part of the industrial physician to have the Wassermann test made. If positive, antisyphilitic treatment should at once be administered. In this way untoward results of the injury will doubtless be prevented. If a syphilitic workman has sustained severe head trauma and possibly cerebral injury, prolonged rest with intensive antisyphilitic treatment should be carried out. In this circumstance the wisdom of performing a lumbar puncture for diagnostic purposes soon after the injury can be questioned in view of the disturbance of the meningeal-choroidal mechanism caused by lumbar puncture. In this way it is possible experimentally to infect the neuraxis from the blood.

1. **Orthopedic Aspects of Rheumatoid Arthritis.**—Alan H. Todd calls attention to the fact that rheumatoid arthritis and allied conditions are responsible for a very large amount of physical disability, patients of all ages and in all walks of life becoming crippled by the condition. The nomenclature of this deforming disease is still vague and unscientific, the various forms described possibly being only variants of what is fundamentally one disease. Affecting women more than men, in the proportion of three to one, it occurs with distressing frequency in the middle-aged and even in the young. While there is little doubt that the disease is

due to infection of the joints, and is often associated with the presence of foci of infection in other parts of the body, we are far from being able to afford practical help to the sufferers from an application of this knowledge. It is a regrettable fact that an orthopedic surgeon seldom sees a case of rheumatoid arthritis free from deformity, whereas all deformity is essentially preventable, arising as it does either from faulty posture or adaptive changes which can be foreseen and avoided. The nurse who supports the patient's knees with a well-meant pillow is leading up to flexional deformity for the sake of present comfort. The bedrid feet unsupported by footrests or some form of bed-splint will tire and drop to become permanently fixed in the equinus position. The valgus posture at first assumed by the person with rheumatoid disease of the ankle bones in order to lock the joints and render them less painful becomes organically fixed from periarticular adhesions. Joints should be straightened either by gradual extension with weights or springs or else by open operation. When a patient is feeble, manipulative methods should be avoided. A short, simple, open operation involves a far shorter confinement to bed than does correction by weight extension, and far less shock than any manipulative methods. The writer describes appliances for correcting deformity and for preventing interosseous pressure and various operative procedures in order to emphasize the fact that a great deal can be done for a large number of those who suffer from this disease.

3. Encephalitis Lethargica: Some Clinical Observations on Thirty Cases.—Arthur J. Hall reviews his observations in this series of cases, 11 of which died (a mortality just under 24 per cent.). There was nothing among these cases that indicated direct or indirect infection. It seems that epidemic encephalitis does not protect against influenza or vice versa. With reference to the prognosis of the disease, Hall feels that generalizations are not yet possible. He agrees with Branwell that a steadily progressive stupor with a rising temperature and loss of sphincter control is ominous, though not necessarily fatal. During the progress of a case it is often impossible to form an opinion as to the prospect of recovery. If one compares it with other acute specific infections, it is apparent that the signs upon which we can usually rely in them for prognosis are often not forthcoming in cases of encephalitis. Patients with comparatively mild attacks recover, only to be seriously damaged for very long periods, even permanently. Others who have appeared in the early stages to be at death's door recover quickly and completely, while still others whose illness has seemed moderately severe for one or two weeks suddenly become worse and die without any obvious reason why they should.

4. The Hysterical Nature of So-called Pernicious Vomiting of Pregnancy.—A. F. Hurst believes that pernicious vomiting of pregnancy is always hysterical. He described the case of a patient under his care which makes it possible to prove with certainty that the case was one which would generally be regarded as of the toxemia class. Clinically the patient was a typical example of severe pernicious vomiting; she vomited constantly whether she took food or starved, her tongue was dry, her pulse rapid as in any case of toxemic vomiting. Two days before the writer saw her the ammonia index was 28, nearly three times as high as the point which Whitridge Williams regards as the danger signal. The urine also contained a very large quantity of diacetic acid. Yet relief followed after half an hour's psychotherapy; the vomiting ceased, the pulse rate fell, the ammonia index dropped to normal for pregnant women, the diacetic acid disappeared from the urine, and the patient gained sixteen pounds in weight in four weeks. It is obvious from this case that no reliance can in the future be placed either on the clinical or the chemical diagnosis of toxemic vomiting of pregnancy. Personally, the writer does not believe that such a condition exists apart from eclampsia and acute yellow atrophy. The high ammonia index and the great excess of diacetic acid present in this patient's urine were clearly not caused by toxemia, but were the result of starvation and dehydration. It is clear, therefore, that the division into the nervous and toxemic classes is fallacious. All cases are nervous, but the term hysterical should be substituted for nervous, as the condition is typically hysterical, caused by suggestion, and curable by psychotherapy.

1. "Pernicious Anemia" and "Septic Anemia."—William Hunter, from his extended experience in the study of the anemias, states that the most important outcome of his studies may be summed up in the following sentence: The infective and clinical features of severe anemias go deeper into their nature and help far more in their diagnosis and treatment than the various blood criteria so much before our notice in dealing with anemias. The percentages familiar to us in blood reports make a deep impression on the eye and on the mind, but they have the one great drawback that they always fail precisely in the borderland group of cases, in which the clinical observer most needs their help, and they always fail when the anemia is moderate in degree and when it is particularly necessary to be sure of its character if successful measures are to be taken in time to arrest progress. On the other hand, the outcome of the study of the infective and clinical features presented by cases of severe anemia has yielded the following information briefly summarized: (1) Two forms of severe anemia are to be recognized. The one is the great hemolytic disease *sui generis*, termed idiopathic or pernicious anemia. The other is a very common anemic condition—non-hemolytic in its nature—which the writer has differentiated and termed "septic anemia." (2) The patient who presents the picture of desperate anemia, termed pernicious anemia, is really in the grip of both the above forms of anemia, each of them capable of killing him, and the combination absolutely mortal. The chief one which gives his illness its main characters, clinical features, and course is the hemolytic disease; the other complicating one is the non-hemolytic septic anemia. (3) The outcome of this recognition and differentiation is that the two anemias can be torn apart by removing completely the septic anemia and its causes from the pernicious anemia patient. On doing this, the great hemolytic disease shows itself for the first time in its true uncomplicated characters and course; and these prove to be much milder in severity and with a much better prognosis than were ever formerly presented. (4) A further outcome of these studies has been to reveal certain simple and easily recognizable diagnostic features which enable pernicious anemia to be recognized in its very earliest stages, even within a few weeks of its first contraction, and on an average about two years before it generally comes under treatment. (5) The infective and clinical features here referred to, that help so much in the diagnosis and treatment of both classes of anemia, are connected with observations, not on the blood, but of lesions connected with the mouth. These lesions are combined in the case of the pernicious anemia patient, but are perfectly distinct from one another, and have a totally different pathological and etiological significance. The infective lesions connected with the diagnosis of pernicious anemia are the peculiar sore tongue which this disease presents as one of its earliest features. The lesions concerned with "septic anemia" are septic lesions connected with chronic and overlooked dental and nasal sepsis, especially the former, to which the author has given the name "oral sepsis." When sepsis is removed the powers of recovery from this hemolytic disease are thereby increased. The writer has had under his observation 150 cases of pernicious anemia during the last twenty years, and finds that the dreadful, hopeless pictures which the disease formerly presented he no longer sees in patients in whom he has been able to carry out the full measures of antisepsis which he considers necessary, without using any new methods of treatment other than antiseptic treatment against gastrointestinal sepsis, which he recom-

mended in 1890, and the measures of oral sepsis, which he recommended in 1900. The name "glossitic anemia" would best connote this great hemolytic disease, help in its early diagnosis, and in its control.

3. **The Digestibility of Bacteria.**—C. E. Dukes describes experiments undertaken for the purpose of studying the conditions under which bacteria resist digestion, and under what conditions this protective property can be destroyed. He concludes that bacteria do not adsorb proteolytic ferments. The protein of bacteria is protected from the action of proteolytic ferments by the lypoidal envelope with which the bacteria are surrounded. The agencies which destroy this protective mechanism act by disturbing the lipoid distribution. The antibodies present in immune serum do not in any way render bacteria more digestible by trypsin.

5. **Restriction of Influenza Epidemics in Schools by the Use of "Local" Prophylactic Vaccines.**—A. I. Simey and John W. H. Eyre present a study of several influenza epidemics at Rugby School and recount their experience with a "local" prophylactic vaccine composed of the following organisms obtained from swabs of the throats and nostrils of recent cases: Pneumococcus, 100 million; *Micrococcus catarrhalis*, 75 million; streptococcus, 50 million; pneumobacillus, 100 million; *Bacillus septus*, 100 million, and *Bacillus influenzæ*, 30 million. Strains from other sources were also incorporated whenever necessary. The first injection was with stock vaccine and the second, fourteen days later, with the local vaccine. Of those who received both vaccines at school, 7.3 per cent. only contracted influenza; of those inoculated at home, 41.0 per cent. contracted the disease; of those who were not inoculated at all, 81.0 per cent. came down with the disease, while of those who received only the initial stock vaccine at school, 84 per cent. contracted influenza. Grouping together all those who received one or more inoculations (405 boys), the incidence of the disease in this group was 27.9 per cent., as opposed to 81 per cent. among the uninoculated.

Bulletin of the Johns Hopkins Hospital.

2. The Significance of "Hemolytic Influenza Bacilli." Arthur Bloomfield.
3. Experimental Studies on Hydrocephalus. Juan C. Nañagas.
4. Sulphemoglobinemia. V. R. Mason and F. D. Conroy.
5. Morphological and Physiological Studies on the Musculature of the Mature Graafian Follicle of the Sow. M. S. and A. F. Guttmacher.

1. Experimental Inoculation of Human Throats with Virulent Diphtheria Bacilli.—C. G. Guthrie, B. C. Marshall, and W. L. Moss conclude that virulent diphtheria bacilli present in the throats of healthy carriers are capable of producing clinical diphtheria and do not differ from those obtained from patients with the disease. Virulent diphtheria bacilli retain their characteristics despite long residence in the human throat or transfer from one human being to another. The guinea-pig test is a reliable index of the inherent ability of diphtheria bacilli to cause clinical diphtheria in susceptible human beings. The Schick test is a reliable index of the presence or absence of antitoxic immunity against diphtheria. Experimental diphtheria in human beings has a short incubation period, produces marked constitutional effects, and is accompanied by a sharp febrile reaction. It may be cured promptly by the early injection of antitoxin in adequate dosage.

2. The Significance of "Hemolytic Influenza Bacilli."—Arthur L. Bloomfield presents observations on the occurrence of these organisms in a heterogeneous group of physicians, nurses, medical students, laboratory attendants and hospital patients. "Colds" were prevalent during a part of the period covered by the study, and some of the subjects were affected at the time the cultures were obtained. Hemolytic influenza bacilli were found almost uniformly in cultures made during November and December, 1920, whereas since then the incidence has been somewhat below 50 per cent. In every case but one the organisms were present only sporadically and in small numbers. In this one case they were constantly present in large numbers on the pharynx and both tonsils. This subject had no clinical respiratory infection during the last winter and showed no special abnormality in the upper air passages. A consideration of these findings leads the writers to the belief that a carrier state in association with a local focus of diseased tissue cannot be assumed as an explanation of the presence of this organism. It is possible that the presence of these organisms in over 50 per cent. of a large series of throat culture may be explained by the possibility that, under special and as yet undefinable circumstances, abortive or temporary adaptation of organisms to growth in the upper air passages may occur. Such an assumption would account for the wide occurrence of influenza bacilli at the time of the epidemic of 1918 and during the year following it, and for the reported instances of large numbers of temporary carriers of hemolytic streptococci and meningococci in association with epidemics of diseases due to these organisms.

3. Experimental Studies in Hydrocephalus.—Juan C. Nañagas has made a study of experimental hydrocephalus in kittens and from observations as to the results of the intravenous injection of hypertonic solutions in this series of animals, he concludes that the cerebrospinal fluid in the dilated ventricles may be acted upon by alterations in salt concentration of the blood, and that the volume of the intraventricular fluid may be apparently increased or diminished by the administration of solutions of different concentrations. Intraventricular absorption of cerebrospinal fluid took place through the ependyma into the underlying capillary network. This absorption was hastened by the intravenous administration of strongly hypertonic solutions. The choroid plexuses took absolutely no part in the intraventricular absorption of the cerebrospinal fluid.

1. Encircling of a Fusiform Aneurysm of the Aorta. Tuffier. Translated by H. E. Bernadas.
2. Blood Transfusion in Obstetrics. E. L. King.
3. Report of a Case of Raynaud's Disease. R. S. Crichlow.
4. Removal of Foreign Bodies from the Eye. H. Dickson Bruns.
5. The Treatment of Empyema. F. W. Parham.
6. How Apothesin Compares with Other Agents Used in Spinal Anesthesia, with Special Reference to a Near Accident. Paul J. Gelpi.

2. Blood Transfusion in Obstetrics.—E. L. King has employed transfusion in four classes of cases: (1) Hemorrhage; (2) puerperal infections; (3) hemorrhagic disease of the newborn; (4) pernicious vomiting of pregnancy. The advantages of transfusion in hemorrhage are generally admitted in puerperal blood stream infection the indication is not so generally admitted. Following Polak's suggestions, three patients who were desperately ill were transfused. One had a streptococcic bacteriemia, one a colon bacillus blood stream infection, while the third was suffering from pelvic thrombophlebitis with apparent intermittent bacteriemia, though a positive blood culture was not secured. The prompt response to the transfusion and the rapid recovery of the patients attested the value of the procedure in two cases. The patient with the colon bacillus bacteriemia was in desperate condition at the time of transfusion and died; but not from the effects of the transfusion. If it had been done earlier she might have been saved. A case of hemophilia in the newborn was treated successfully by transfusion through the anterior fontanel. While the author lost the only case of pernicious vomiting which he has treated by transfusion, he feels that it should be of value in these cases. His results have been encouraging and he feels justified in continuing the use of transfusion in cases of the types referred to.

Phlegmonous Gastritis.—This affection may be due to the presence of cancer of the stomach, which it masks. A case of this sort is reported by Sandelin. The phlegmonous process was diffuse but an attempt was made to resect the stomach. In the specimen after hardening with formalin it became possible to recognize the presence of a cancer. A streptococcus infection had apparently occurred in the latter.—*Finska Läkarcsällskapets Handlingar.*

Book Reviews.

OPIATE ADDICTION, ITS HANDLING AND TREATMENT. By EDWARD HUNTINGTON WILLIAMS, M.D. Formerly Associate Professor of Pathology, State University of Iowa; Associate Editor of the Encyclopedia Britannica (Tenth Edition); Assistant Physician, New York State Hospital System; Special Lecturer on Criminology and Mental Hygiene, State University of California, etc. Price, $1.75. New York: The Macmillan Company, 1922.

THIS is a useful and very timely book and one that should be in the hands of every practitioner who has or is liable to have a patient suffering from drug addiction. The author is practically familiar with every phase of his subject, having devoted special study to it for many years, and is one of the few who can speak with authority. In the introduction the author relates the history of the Los Angeles and San Diego Narcotic Clinics, which accomplished a great deal of good during the short time they were in existence, and he urges a revival of them there and in other cities. Both the gradual reduction and the rapid withdrawal methods are described in detail, and many pitiful stories are told of the fiendish work of the drug peddler through whose agency the army of addicts is continually recruited. This is an important companion book to "The Narcotic Drug Problem," by E. S. Bishop, and the two together cover well the entire subject, so far as it is known today, of the drug disease and its treatment.

THE CLINICAL STUDY OF THE EARLY SYMPTOMS AND TREATMENT OF CIRCULATORY DISEASE IN GENERAL PRACTICE. By R. M. WILSON, M.B., Ch.B. Late Assistant to Sir James Mackenzie under Medical Research Committee; Late Cardiologist, War Office Trench Fever Committee; Consulting Physician, Ministry of Pensions. With a Foreword by Sir JAMES MACKENZIE, M.D., F.R.S., F.R.C.P. Price, $4.75. New York: The Oxford Press, American Branch, 1922.

THE keynote of this book is sound common sense, something which characterizes all that Sir James Mackenzie and his pupils discuss. The author treats of various symptoms associated with cardiovascular disorders, and of their interpretation, in a simple and direct manner that opens the eyes of the reader to new views of old subjects and brings conviction to his mind. Among the subjects discussed are: Exhaustion, The Pulse rate as a Symptom, The Extrasystole as a Symptom, Tremor, Breathlessness, Cyanosis, Subjective Symptoms, Cardiac Pain, Earliest Symptoms of Heart Failure, etc. Every chapter is illuminated by one or more rays of a new light, even though the matter treated of is familiar and commonplace. We can confidently recommend this book to every practitioner of medicine, and dare to say that not one will rise from its careful perusal without having gained new knowledge.

AUTOEROTIC PHENOMENA IN ADOLESCENCE. An Analytical Study of the Psychology and Psychopathology of Onanism. By K. MENZIES, with a Foreword by Dr. ERNEST JONES. Second Edition. Price, $1.50. New York: Paul B. Hoeber, 1921.

THE author frankly announces that this second edition is practically a reprint of the first, with few corrections and verbal alterations. Nevertheless, his message is a welcome one and should be regarded closely by those who deal with masturbators. The book is one hundred pages in length, and is devoted to the consideration of the psychology, pathology, ethics, and treatment of masturbation.

THE SURGICAL EXPOSURE OF THE DEEP-SEATED BLOOD-VESSELS. By J. FIOLLE, M.D., and J. DELMAS, M.D. Translated and edited by CHARLES GREENE CUMSTON, B.S.M., M.D. (Geneva), Fellow of the Royal Society of Medicine of London, etc., etc. Price, 8/6 net. London: William Heinemann, 1921.

THE translator regards this volume as one of the small number which really merit translation. There are 34 original illustrations by H. Beaufour. In a short preface by D'Arcy Power attention is called to the fact that as a result of war experience much old knowledge has been rediscovered. The authors served in the 21st Motor Ambulance. The body is divided into 11 surgical regions, each of which is dealt with in a special chapter, while a twelfth chapter is general in scope. The regions are naturally those in which large vascular trunks abound, which selection eliminates the trunk, cranial region, and peripheral segments of the extremities and concentrates on the neck, axillae, groins, and more central segments of the limbs. The neck requires three entire chapters, and the lower extremity five or six, counting the gluteal region; and the axillae and upper extremity two.

ESSENTIALS OF VETERINARY PHYSIOLOGY. By D. NOËL PATON, M.D., B.Sc., LL.D., F.R.S., Professor of Physiology, University of Glasgow, Late Lecturer in Physiology, Royal Veterinary College, Edinburgh, and JOHN BOYD ORR, D.S.O., M.C., M.A., M.D., D.Sc. Third edition. Price, $6.50. New York: William Wood & Co., 1921.

THE present edition has been almost entirely rewritten and brought up to date with especial reference to those facts which bear most directly on veterinary practice. Since there can be no essential differences between animal and human physiology the interest of its casual reader will be concerned chiefly with the animal species or genera concerned. The horse is the animal which serves chiefly to illustrate comparative physiology. Other animals are covered under feeding habits, as herbivora, carnivora and omnivora. The book represents a sort of transition, therefore, between comparative physiology on the one hand and physiology of domesticated animals on the other hand. There are 674 pages in the present edition.

CLINICAL ELECTROCARDIOGRAPHY. By FREDRICK A. WILLIUS, B.S., M.D., M.S. in Medicine Section on Clinical Electrocardiography the Mayo Clinic, Rochester, Minn., and The Mayo Foundation, University of Minnesota. Price, $5.00. Philadelphia and London: W. B. Saunders Company, 1922.

OWING largely to the expense of apparatus and the skill required in operating it, few physicians are familiar with the electrocardiograph and the information which it gives as to both diagnosis and prognosis of cardiac affections. As the author of this little treatise says, "Electrocardiography must always remain subsidiary to practical methods of physical diagnosis, but its value as a most important clinical adjunct cannot be too strongly emphasized." The subject is not an easy one to master, but a great help is given in this book, for the author knows his subject thoroughly and has succeeded in putting his description of the technique of operation and the art of reading and interpreting the cardiograms in simple and intelligible language.

THE SURGICAL TREATMENT OF NON-MALIGNANT AFFECTIONS OF THE STOMACH. By CHARLES GREENE CUMSTON, M.D., and GEORGES PATRY, M.D., Lecturers at the University of Geneva and Members of the Surgical Society of Switzerland. With an Introduction by Sir BERKELEY G. A. MOYNIHAN, K.C.M.G., C.B., M.S., Professor of Clinical Surgery, University of Leeds. Price, $5.00. London: William Heinemann; Philadelphia: J. B. Lippincott Company, 1922.

THIS work deals chiefly with gastric ulcers and, as Moynihan says in his introduction, a work of this kind is very necessary. The literature of gastric ulcer is considerable, but much of it was written before the days when the truths of the pathology of the living were revealed by the work of the surgeon. It is further pointed out that the discrepancy between the older teaching with regard to ulceration of the stomach and the newer opinions promulgated by the surgeon is serious. The authors believe in the fallacy of statistics and consequently few are given, but they state that the book represents the combined experience of an American surgeon well versed in European methods and a European surgeon fully conversant with Anglo-Saxon surgery and practice. In fact, with Sir Berkeley Moynihan's introduction, the book is one of international team work, a distinctive feature, and this should prove of great value to those who wish to know the latest views of the subjects discussed and especially on gastric ulcer from the medicosurgical standpoints.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Sixteenth Annual Meeting, Held in Albany, N. Y., April 17-20, 1922.

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

First Session—Monday, April 17.

THE SPEAKER, DR. E. ELIOT HARRIS OF NEW YORK IN THE CHAIR.

Report of the President.—Dr. JAMES F. ROONEY of Albany submitted this report, in which he said in part that there had been a satisfactory and normal increase in membership in the State Society, although it was lamentable that nearly one-half of the profession of the State were as yet outside of the pale of the organized profession. There were several reasons, it appeared, for this state of affairs, namely: (1) General dissatisfaction with what organized medicine has done for the profession; (2) loss of the professional and predominance of the commercial spirit; (3) apathy. It would seem that some definite effort must be made by the Society to remove the sources for the dissatisfaction of a large minority of the profession and to stimulate them to the recognition of the fact that an organization of democracy was effective largely in direct proportion to its numbers, and to eliminate any causes within the Society that gave justification for suspicion on the part of the minority. It was an undeniable fact that the organization of the Medical Society was on the whole a very loose and to a large degree an uncoordinated one. More effective means must be taken within the district branches, and more especially within the County Societies to organize the profession more solidly, more representatively, more energetically, and thus more effectively than at present. This could not be done without money. It could not be done by devoted and capable practitioners of medicine, who had sacrificed and were now sacrificing their own personal interests and those of their families, at a great loss of their time to the interests of the profession. It was suggested that the House of Delegates should properly consider some means for bettering the present deficiencies in organization. It was an undeniable fact that there had been a steady loss of influence of the organized medical profession upon the public. This had been especially notable within the past ten years, and had occurred *pari passu* with the growth of the various welfare organizations and the extension of public health agencies, the former dominated by lay groups and the latter by members of the profession, who were to a greater or less degree out of touch with the general practitioners. Because of this, the medical profession had been assailed from both within and without, and had been placed upon the defensive. The organized medical profession, because of its lack of influence with the press and its inability to secure therein the continuous and straightforward honest expression of its views, had been placed before the public in the apparent position of opposing the wonderful schemes proposed for the prevention of disease, the lessening of sickness and the amelioration of the condition of the poor. These conditions were responsible for the propaganda on the subjects of Compulsory Health Insurance, the centralization of powers in Federal and State bureaus; the oppressive regulations placed upon the medical profession by the departments of the Federal Government in the prescribing of alcohol and narcotic drugs, which would lead not to the administrative control of the medical profession, but to what would be eventually worse, perhaps, legislative dictation as to therapeutics. The situation was pitiful and ridiculous, not to say tragic. It was the height of silliness to pillory the medical profession before the public as had been done, practically damning it as the chief source of provision of narcotic drugs and alcohol, when as a matter of fact it had been proven that so far as narcotics are concerned the medical profession was responsible for the supply of less than ¼ of 1 per cent. of drugs of addiction, and so far as alcohol was concerned probably for less than 1/100 of 1 per cent. The regulations as relating to both remedies undoubtedly caused unnecessary suffering and perhaps death. The recent requirement of the Federal Narcotic Bureau imposing upon the physician the necessity, where opiates were prescribed over a period longer than ten days, of writing the diagnosis upon the prescribing blank, in all probability was a violation of the law of this State as related to privileged communications; so that the physician of this State was placed in the anomalous position of complying with the Federal law by violation of the State law. The usurpation by Congress of the therapeutic rights of the medical profession, as evidenced in the recent amendment of the Volstead Act, was indicative of what was coming to the profession. The reason for this appeared to be largely due to dereliction of duty on the part of the officers of the organized profession of the nation, or of their inability to properly represent the profession. In either instance, or in both, it demanded a complete national reorganization, in order that the medical profession of the country be properly and adequately represented at Washington. An instance in point was the weak shilly-shally resolution relating to State Medicine passed by the House of Delegates of the A. M. A. at Boston, which was construed by the congressional committee having consideration of the Sheppard-Towner bill as placing the A. M. A. in the attitude of favoring this legislation. This should not be permitted to occur again, and it was recommended that the House of Delegates of this Society consider what action might be deemed proper, that this condition might be prevented from occurring again. The danger of all organized democratic bodies was their control by a small, alert, and effective group, similar to the domination of the Japanese Government by the Genro, the "elder statesmen." It was against human nature to wield power for long periods of time and not develop a complaisant belief in one's own infallibility. It was especially essential, therefore, that great care be exercised in the choice of officers and delegates to be sure that they would be truly representative not of the opinions of the Genro, but of the best interests of the public and the profession. For five years the medical profession had attempted to secure the passage of legislation raising the standards of admission to the practice of medicine and procuring the vigorous enforcement of the Medical Practice Act, and for five years had failed. This year the two bills providing for this purpose were passed by the Senate, one was passed by the Assembly, and that one was vetoed by the Governor. The memorandum attached giving his reasons for this veto would give great comfort and satisfaction to all the violators of the present Medical Practice Act and, unfortunately, would apparently give them reason for the continuance of their efforts to be licensed. It was a remarkable phenomenon that a group of not more than 1500 chiropractors, who practically acknowledged that they were practising in violation of the law, were able to defeat legislation proposed by the Medical Society of the State of New York in conjunction with the Departments of Education and Health of this State. It might then be well for the Society not to oppose the repeal of the entire Medical Practice Act as it to-day existed and to permit a reversion to the status that existed before 1885; that there should be no State license, no examination, no registration, and that only holders of the degree of M.D., conferred by a medical school recognized by the Regents of the State, should be eligible to sign birth or death certificates or to make returns for infectious or communicable diseases.

Report of the Speaker.—Dr. E. ELIOT HARRIS of New York presented this report. He stated that it seemed fitting and timely that the House of Delegates should respond to the urge of the stirring words of the constitution and consider the abuse of medical charity, especially in the form of the pay clinic, which was an abuse of medical charity as defined by the dispensary law of the State and the rules and regulations promulgated by the State Board of Charities in harmony with the spirit and intent of that law. After reviewing these

rules and regulations, Dr. Harris said that as there was a movement pressing toward a radical change in the dispensary law, he recommended that the House of Delegates refer the questions of the abuse of medical charity, dispensaries and pay clinics to the council for consideration and action in behalf of the society. The revised constitution and by-laws would be presented to the House of Delegates for adoption. In this revision there was no mention of the principles of ethics and he recommended that the principles of ethics of the American Medical Association as revised May 7, 1903, be incorporated in either the constitution or the by-laws.

Report of the Secretary.—Dr. EDWARD LIVINGSTON HUNT of New York submitted this report, which showed that the membership on December 31, 1921, was 7,853, and on January 1, 1922, it was 8,664. The report contained an appreciation of Dr. Dwight H. Murray of Syracuse, Vice-Speaker of the House of Delegates and Speaker of the House of Delegates of the American Medical Association. It called upon the members of the House of Delegates to make a careful study of the revised constitution and by-laws, to the Group Liability plan of insurance, which had now been in effect for over a year. He stated that about 3,000 members, or one-third of the membership of the Society, had availed themselves of its privileges. He also called attention to the success of the Legislative Bureau of the Society at Albany and recommended that the House of Delegates authorize a continuation of this bureau and vote an appropriation for its maintenance.

Report of the Treasurer.—Dr. SETH M. MILLIKEN of New York submitted this report, which had been duly audited, and showed that the income of the Society for the year was $46,298.89 and expenditures $40,331.62, leaving an excess of income of $5,697.27.

Report of the Committee on Legislation.—Dr. JAMES N. VANDER VEER of Albany submitted this report, which, owing to the establishment of the Legislative Bureau at Albany, represented a much greater amount of work than had been covered in previous years. So soon as the bureau was established it proceeded to inform the various officials of the constituent county societies that they might know where to look for information and to foster in their home counties through them the sending of information relative to the wishes of the doctors in the counties, the lay people interested in public health and its conservation, and the attitudes of the various State legislative officials and others interested in politics relative to these State wide questions. Information was asked first of the county society presidents as to who constituted their various committees and their chairmen, that liaison might be established at once with the proper officials. About twenty per cent. of these officials fell down on their work and did not answer this communication. Then followed communications to the county legislative chairmen asking that they interview the prospective legislative candidates of all parties in the primaries, relative to their attitudes on the four great questions which heretofore had greatly concerned the medical profession: (1) Health Insurance; (2) Health Center; (3) Chiropractic legislation since that had appeared for so many years in the legislative halls and was the leading extra medical cult seeking admission for its practice in this State; (4) Reregistration, which had been discussed at great length at several previous sessions and might crop up once more. It was realized that many legislators might not care to discuss these questions until they really came to the legislative halls, yet it was hoped that the county chairmen would establish such a type of entente cordiale with their several Senators and Assemblymen that matters could be discussed on a broad, free, and frank basis later, for the medical profession had nothing to hide in its legislative desires, despite the slurs which were continually aimed at it as being selfish in type. The report contained a detailed record of the bills with which it had concerned itself and made a number of recommendations in regard to the administration and financing of its work. Among the recommendations was one urging that there should be a studied and concentrated effort made by this State in association with other States of the Union against further enactments by Congress of burdensome, unnecessary, and restrictive laws relating to the administration of needful and indispensable drugs as had been evidenced by the regulations so far put in force relating to alcohol and narcotics. The October, 1921, Federal regulations relating to narcotic drugs had made it necessary to inscribe on every prescription which was a semi-public record the name, etc., *and diagnosis*, where narcotic drugs were given for a period of longer than thirty days. This violated the law of the State of New York, if a physician did so, relative to privileged communications. This condition of affairs presented an anomaly and should be coordinated satisfactorily in some way. It was also recommended, in view of the fact that the drafted chiropractic bills as introduced tended to a lower and lower standard in each successive instance, and that the chiropractors tacitly admitted before his excellency the Governor, in their hearing, that they were practising a type of healing that rejected 95 per cent. of recognized medical knowledge, strongly urged that a uniform bill be drawn with the basic ideas as in the osteopathic bill of 1907, relative to the waiver clause, and that no deviation of line of action be recommended other than allowed by the basic principles of such bill.

Report of Committee on Medical Research.—Dr. FREDERICK E. SONDERN of New York presented this report, which called attention to the fact that during the current session of the Legislature the Betts Assembly Bill, No. 353, and the Boylan Senate Bill Int. No. 371 were introduced to amend the penal law to prevent experiments of all kinds upon living dogs. Public spirited citizens, representatives of colleges, medical and public health organizations, and the members of this committee protested to the members of both Houses and proper objections were also detailed at the hearing before the Assembly committee on February 7. The bills had not been reported out of committee to date.

Report of Committee on Public Health and Medical Education.—Dr. JOSHUA M. VAN COTT of Brooklyn reported that many questions involving health in the broader sense had been discussed and constructive work had been accomplished. They had watched the workings of the new Medical Legislative Bureau and thoroughly indorsed the work they were doing. There had been no era in the history of the Medical Society of the State of New York when so many difficult problems involving not only the public health and happiness but the very existence of decent medicine in the State were before us for adjustment; and if we were to cope with them successfully, we must be ready for sacrifice of time, energy and money to whatever extent may be necessary. Those who could not afford the time and energy must be willing to give liberally of their money. This was not only a public duty but also a necessity, if we proposed to hold the respect and confidence of the public and keep medicine on a plane which would induce men of high ideals and mental ability to join our ranks. The problems of public health, of medical legislation and medical practice should be regarded as individual to every person holding a license to practise medicine in our State; and it should be the duty of each and all to forget personality and give all of the best of self to any form of work or sacrifice which might offer for the solution of these problems. If the individual could not see this point, then the whole state of medicine in New York State was menaced.

Report of the Committee on Medical Economics.—Dr. HENRY LYLE WINTER of Cornwall submitted this report, which first considered conditions in the nursing profession, and recommended that the preliminary requirement of one year in high school which was now obligatory for entrance into training schools be suspended; (2) they advised that the age of admission to training schools, which was ordinarily fixed at twenty years, be reduced; (3) they presented to the Board of Regents the advisability of suspending its regulations relative (a) to the hours of training for pupil nurses, the hours required for school work, time off duty, and, for the smaller cities, attendance upon metropolitan hospitals for training in special subjects; (b) that they should also suspend their regulations requiring specified numbers of nurse-teachers and supervisors. In other words they should endeavor to simplify a situation which these added regulations were complicating. (4) They recommended to the hospital authorities a general reduction in the course of training to two years.

This met the requirements of the State Board of Regents and had already been done in some hospitals. The committee recommended that a State-wide publicity campaign be undertaken by this Society. Such a campaign should be conducted like the one already under way in one of our constituent county societies. It should be done under the auspices of the State Society by each County Society and by means of syndicated articles of real merit produced by a capable writer, and appearing in every desirable newspaper in the State. This committee appreciated that much harm might be done and much injustice worked by such a plan as this unless it was made absolutely to preclude publicity for any one physician or group of physicians, or any one hospital or group of hospitals. There was no such risk, however, if the plan were properly carried out. Public opinion could be formed and public action could be led by such a plan. The committee had viewed with some alarm the tendency to encroachment on community health problems by the Federal Government. This had been centered during the past year in the propaganda developed in favor of the Shepard-Towner bill. The question of Federal support and control, either direct or indirect, of community health problems was a serious one for the practice of medicine.

Report of Committee on Narcotic Drugs.—Dr. EDWARD D. FISHER submitted this report as chairman of a committee composed of Dr. Edward B. Angell, Dr. Edward A. Sharpe and Dr. Walter Timme, which stated that we must endeavor to approach drug addiction with the hope of ameliorating conditions rather than expecting to end them. The education of the public to an understanding of its influence in destroying character and citizenship, and especially its influence on the more or less mentally weak or defective, should be emphasized. We should, however, not exaggerate the present conditions. Sentimentalism must be avoided. Drug addiction has always been with us. The influence of the drug addict on the community, as a whole, was small. The private addict concealed his infirmity; did not try to spread the habit, except perhaps in a very limited circle. The social addict was in a class by himself, was avoided by the public, and found friends only in his own class. There should be, therefore, a classification of the habitual users of narcotic drugs: (1) Those who required narcotic drugs for the treatment of disease. (2) Addicts who were weak, unstable, or defective and used narcotic drugs as the result of an acquired habit. Under this head would fall a large proportion of the criminal class. The committee did not consider drug addiction as a disease entity, but rather as a habit similar to the excessive use of any other stimulant or sedative, as coffee, tobacco, etc. The question was the character of the stimulant or sedative used by the habitué. Functional disturbances of the internal organs followed acute excesses or prolonged use of these drugs. These conditions could be cured, but the fundamental psychopathic state was not cured by cutting off the drug, hence a relapse to the former habit when opportunity offered. The Committee had not taken up the question of any special method of treatment, as that depended on the individual cases and also on the skill and experience of the physician in attendance. A thorough examination of every case should be made which should include the mental condition as shown by his heredity, previous history, etc. The Committee approved the Harrison Law and agreed with the recommendations of the American Medical Association Narcotic Committee of 1921 that a larger amount of the monies derived from its administration be employed in carrying it out. The report of the special Committee on Narcotic Drugs issued by the Council on Health and Public Instruction of the American Medical Association seemed to cover the general aspect of drug addiction. This committee considered that defective and criminal addicts to drugs should be under proper State or county custodial care, as long as the authorities might deem advisable. Private sanatoria were also necessary, subject to the same rules and regulations as were at present observed. They were of the opinion that so-called ambulatory treatment had proved ineffectual in the cure of addicts. The question of the importation, manufacture, and exportation of narcotic drugs the Committee had not considered within its province. The Federal Government should be responsible for this division of the subject. The Committe recommended the restriction of the manufacture of heroine as unnecessary in the practice of medicine.

Report of Counsel for Period from April 1, 1921, to March 15, 1922.—GEORGE W. WHITESIDE, ESQ., submitted this report, in which he said that the work of the Counsel during this period had consisted not only in the protection of members in malpractice actions in accordance with the long established policy of the Society, but the initiation of the additional feature of indemnity protection against such suits. A misconception of what has happened in the past in malpractice cases or a misunderstanding of the financial liability of a physician arising from his professional relation with his patient had given many doctors a false sense of security against the law hazard of medical practice. Some of the responsible insurance companies that had been engaged in writing this type of protection for physicians announced an increase in their rates of about 300 per cent. These companies claimed the hazard of this line justified the increase in rates. The members of the Society through the adoption of the group plan were spared the expense of this exceptional raise in rates.

On motion these reports were referred to appropriate reference committees appointed by the Speaker.

Revised Constitution and By-Laws.—Dr. DANIEL S. DOUGHERTY of New York presented the tentative draft of the revised Constitution and By-Laws of the Society as published in the *New York State Journal of Medicine* of February, 1922. It was voted on section by section and many minor changes were made for purposes of greater clarity. One change provided that hereafter there should be but one vice-president instead of three. Provision was made for a referendum on any question in accordance with such general regulations respecting the manner of submission as the House of Delegates might prescribe.

Lucien Howe Prize.—Dr. EDWARC D. FISHER of New York, chairman of the Committee on Prize essays, announced that the committee recommended that the Lucien Howe prize be awarded to Dr. Arthur J. Bedell of Albany for his essay on "Cataract."

This recommendation was adopted by the House of Delegates.

Reports of Reference Committees.—The Reference Committee on the President's Address, of which Dr. GROVER WENDE of Buffalo was chairman, reported that they approved of the recommendation that the work of the county societies be reorganized and coordinated, and recommended that this matter be referred to the Council which should devise ways and means for stimulating county societies to greater action. In reference to that portion of the address dealing with legislation like the Sheppard-Towner bill, the committee pointed out that the American Medical Association had opposed the Sheppard-Towner bill. In regard to the recommendation that the medical profession cease to carry the onus of protecting the public health, the committee was of the opinion that the medical profession was opposed to abandoning all that it had achieved in this direction during past years and which had been crystallized in the Medical Practice Act. They recommended that resolutions be adopted advising a concerted program for public health education and the publication of a popular national health journal. It was further recommended that steps be taken to make provisions for the disciplining of unworthy members and that such provisions be made a part of the by-laws of the Society. They also recommended approval of a national legislative bureau which should coordinate the legislative activities of all the State societies, and that the American Medical Association be advised of this recommendation.

Dr. ROONEY pointed out certain dangers connected with a centralized bureau for coordinating legislative activities, and made a plea for home rule and State autonomy. He said that this bureau, if established, should be nothing more than a bureau of information for State societies. It should not rule over the houses of delegates of the various State societies and it should not be utilized for the dissemination of propaganda.

The delegates to the American Medical Association should be instructed that this House of Delegates desired that if such a bureau was established more power than was necessary should not be granted to it.

The Reference Committee on the Speaker's address recommended that the recommendations of the speaker be adopted and that the principles of medical ethics as promulgated by the American Medical Association in May, 1907, be incorporated in the by-laws. They also recommended that the Society adopt the recommendation indorsing the Group Liability insurance plan.

The Reference Committee on Medical Research recommended the adoption of the report of the Committee on Medical Research, but wished to add that the short report presented did not express the great value of the work the chairman of that committee had carried on for years. The Committee therefore recommended a vote of thanks to Dr. Sondern and his committee.

The Reference Committee on the report of the Committee on Medical Economics approved in a general way of the recommendations of that committee, though they were somewhat opposed to the training of attendants as nurses. After considerable discussion, the House adopted the report with the exception of that part dealing with the training of attendants.

The Reference Committee on Constitution and By-Laws recommended that the by-laws with the changes that had been adopted be adopted as a whole. After considerable discussion as to the advisability of incorporating into the by-laws the Code of Ethics adopted by the American Medical Association in 1907, it was decided not to take this action, but to appoint a committee to revise the Code. The new constitution and by-laws were finally adopted as amended.

The Reference Committee on the report of the Narcotic Drug Committee recommended the adoption of the report, but after much discussion and several standing votes the House took no further action.

Home for Aged Physicians.—Dr. Robert T. Morris of New York announced that a home for aged physicians had become an accomplished fact. He said that they all felt at times that if they worked long enough in the good work they were doing they might be without a home and friends and in need of care. Physicians now had a home, the first in this country, at Amityville, N. Y., where they had a two-hundred and eighty-six-acre farm with buildings, all complete, and money in the bank. Physicians in need of a home might be sent there provided those who sent them paid the bills. This invitation did not apply to New York State only but to the entire country.

Election of Officers.—*President*, Dr. Arthur W. Booth, Elmira; *Vice-President*, Dr. Nathan B. Van Etten, New York; *Speaker of the House of Delegates*, Dr. Eliott Harris, New York; *Vice-Speaker*, Dr. George M. Fisher, Utica; *Secretary*, Dr. Edward Livingston Hunt, New York; *Assistant Secretary*, Dr. Wilbur Ward, New York; *Treasurer*, Dr. Seth M. Milliken, New York; *Assistant Treasurer*, Dr. Charles Gordon Heyd, New York; *Chairman of Committee on Public Health and Medical Education*, Joshua M. Van Cott, Brooklyn; *Chairman of Committee on Scientific Work*, Dr. James N. Vander Veer, Albany; *Chairman of Committee on Medical Economies*, Henry Lyle Winter, Cornwall; *Chairman of Committee on Scientific Research*, Dr. Frederic E. Sondern, New York; *Chairman of Committee on Prize Essays*, Dr. Lucien Howe, Buffalo; *Delegates to the American Medical Association:* Dr. E. Eliot Harris, New York; Dr. Edward Livingston Hunt, New York; Dr. Arthur J. Bedell, Albany; Dr. Richard Kevin, Brooklyn; Dr. Grant Madill, Ogdensburg; Dr. Thomas Chalmers, Queens; *Alternates:* Dr. Allan A. Jones, Buffalo; Dr. Alfred C. Prentice, New York; Dr. Albert A. Ferris, Saratoga; Dr. Albert T. Lytle, Buffalo; Dr. Paul B. Brooks, Albany; Dr. O. E. Jones, Rochester.

OPENING MEETING.

Tuesday, April 18.

The President, Dr. James F. Rooney of Albany, in the Chair.

Address on Surgery.—Dr. John B. Deaver of Philadelphia delivered this address. The work of Lister and Esmarch, he said, had combined to develop an art which had been confined to emergency surgical procedures, into one robbed of its terrors, and which had been the means of diminishing or even abolishing much of the suffering of mankind. As time went on it was recognized that the dominant note in Lister's work was cleanliness; and although the spirit of antisepsis still remained the keynote of modern surgery, by being shorn of three of its letters it became asepsis and was translated from a chemical to a physical disinfection by means of heat. An indispensable factor in the development of the surgery of our day was, of course, animal experimentation. It had probably done more than anything else to widen the boundaries of our knowledge by substituting for vague theories more exact knowledge and refined methods of procedure. The achievements of clinical and experimental research had been innumerable since the time of Lister. This consummation surely was worth the sacrifice of all the animals that had ever been used for experimental work. Our entire method of study and investigation had its base in experimental work. It was incomprehensible to him how any right minded individual could spend time, effort, and money in furthering propaganda against this indispensable adjunct to the progress of medicine. This spirit of investigation should be encouraged instead of being hindered. It should be subsidized instead of being taxed. Dr. Deaver pointed out the value of clinical research, stating that in surgery it had revolutionized our knowledge of gallbladder and bile duct surgery, of gastric, intestinal and renal surgery. Thus it was the instrument that had given us the problems for experimental surgery. Progress in surgery was not dependent on clinical or animal experimentation alone; equally essential for surgical diagnosis and treatment were the researches in the fields of bacteriology, chemistry, physics and physiochemistry. With these aids at our disposal we were in danger of losing the advantage of the highly trained senses which our ancestors developed and which to a surprising degree enabled them to detect obscure signs. There was too great a tendency on the part of the youthful diagnostician to neglect the development of the God-given gifts of the five senses and to rely too exclusively on more or less mechanical methods of diagnosis. Another one of the principles of surgery which modern methods had developed to a remarkable degree was that of the least amount of tissue injury with the conservation of maximal function. A proper undertsanding of the chemical changes that took place during the process of metabolism was most essential to an understanding of bodily functions in health and disease. Not so little of the satisfactory reduction of operative mortality was due to improvement in methods of administering general anesthetics. Local anesthetics had also come to occupy an important place in operative surgery, particularly in certain types of cases in which a general anesthetic would be attended with too great risk. The method of anociassociation as developed by Crile was proving particularly useful in the "bad risk" patients such as the cases of exophthalmic goiter. Another factor in the improvement of operative mortality was rapidity of operation, not the record-breaking surgical gymnastics that appealed to the gallery, but the quickest maneuvers and minimum of manipulation consistent with exact and careful work. An erroneous impression that was rapidly being corrected was that functional rest was an essential factor in postoperative treatment. Today the wound was allowed to heal with the minimum of interference and the maximum of rest. But with regard to function their efforts took the opposite course. Observation seemed to show that wounds of those parts of the body subject to the most constant and unavoidable activity healed more smoothly and rapidly than elsewhere. In the treatment of sprains, dislocations and fractures, instead of prolonged bandaging and rest, they now encouraged wherever possible early activity of the muscles, and passive and active movement of operated joints, so that by the time union of the bone had taken place the muscles and joints were in a more or less normal condition.

Medical History.

PARACELSUS VERSUS CELSUS.

By W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

WE do not exclusively adopt any opinion, just as we do not reject any in an absolute manner; but we hold a middle point between these contrary sentiments. And this, in general, is the part in discussions those should take who without ambition seek the truth.—*Celsus.*

We know that, in putting forth, upon whatsoever subject, sounder and better ideas, any one has the right to attack at the same time contrary opinions as false and dangerous, and to refute them.—*Paracelsus.*

PHILIPPE-AUREOLE-THEOPHRASTUS Bombastus von Hohenheim, that *was* his name—his real, correct name, asserts Cumston, basing his statement on documents claimed to be incontrovertibly authentic. But his name *is* Paracelsus—by his own choice and assumption, and by common consent and continuous use. And whether a loose, vague classical translation of his patronymic, or whether coined to signify at once affinity with and preeminence to the ancient scholar whose name it connotes, the appellation immediately brings the Swiss in striking contrast with the Roman. Paracelsus *versus* Celsus—the designation implies that relation. The associated terms are in antithesis. The combinations of personality and character thereby indicated stand respectively the one at the positive pole, the other at the negative. Of the two individualities concerned, the one looks forward, the other backward—the one fronts toward the future, the other toward the past.

Truth is a goddess thickly shrouded, deeply veiled. Not suddenly and wholly does she deign to reveal her shape and features. Her shroud she loosens clasp by clasp, reluctantly fold by fold she lets it fall. Slowly, slowly she lifts her veil, only thus trait by trait to the gaze of enraptured worshipers uncovering lineaments of supernal beauty. The full glory of her form and face no man has ever seen.

Nor do discoveries of truth proceed regularly and without interruption—do not take place in an even, steady, orderly way. The human mind, the mind of humanity, achieves its winnings spasmodically. After a period of energetic, resolute, enthusiastic advancement it halts and rests. Thought, as to its moods and movements, is like Alexander sweeping in conquest across kingdoms and empires, and then sitting down in Babylon, sheathing his sword, and bedecking himself with the robes and garlands of luxurious sloth. Yet these pauses, these lulls, themselves are not altogether devoid of use and benefit. They invite and serve effort to appraise and harmonize and unify and solidify the spoils of victory. Medicine, constituting a distinct and essential factor of civilization, has conformed to the general conditions and methods of progress. It has had its varying epochs of marked activity and advancement, with prolonged intervening eras of stagnation and fixation comparatively unfruitful, yet, withal, promotive of clarification of ideas, reconciliation of doctrines, classification of systems.

At the time of Celsus medicine had well entered upon a term of suspended productivity that was to be unbroken for fifteen centuries. For the healing art, as for other arts and sciences, progress in the main ended with the stalwart Greeks. Virtually, the dark ages began in the twilight of Hellenic culture. In the domain of the higher intellectuality, the Romans were merely the children of the Hellenes—the conquerors were the docile pupils of the vanquished. The offspring of Romulus were original in little else than war, government and law. True, a century before Celsus was Asclepiades, the Bithynian, and a century and a half after him came Galen, the Mysian. But these, in reality, were genuine Greeks, belated and expatriated. And, at any rate, Asclepiades was to the great Alexandrians as is the student to the master. And Galen was to Hippocrates as is a planet to the sun, or as is a taper to the lode-star. All things considered, Celsus actually stood already within the shadows through which so long and so aimlessly mediaeval medicine groped its way.

And Celsus most accurately presents, and most faithfully represents, the medical development that had been accomplished up to the limit of the Greek movement—to the terminal stage of the illustrious march where camp was fixed and all tents pitched. He is the mirror of the conditions and tendencies of the medicine of his day. A Roman of the Romans, as learned as Varro or the elder Pliny, as discerning as Lucretius, as judicial as Tacitus, for the purity and elegance of his Latin called the Cicero of physicians, he is a complete and worthy monument of the lore of the healing art down to his own generation. But he only searches and comments and selects and elects. Even more so than Galen, he is the coryphaeus of eclectics. But that circumstance simply marks the character of his work without detracting from its importance. Conservation need not be correlated with reactionaryism. Still, the significant fact remains that Celsus arranged rather than created—looked around him rather than ahead of him. Of Asclepiades Baas says, "He may be regarded, *mutatis mutandis*, as a kind of antique Paracelsus". Of Celsus that could never be said.

The coming in of the sixteenth century, the century of him of Maria-Einsiedeln, saw medicine occupying the same camp in which its Roman cyclodedist had found and left it—the same except for some minor re-arrangements, a few standards set slightly forward, an occasional tent reared a little farther on. And above and about all might be felt, sensed, the spell-power of quiescence, of stagnancy, of dust and mold and decay. Is Salerno cited as a torch in the darkness? Give her her every due, yet, after all, Salerno's mission mainly was to relight the Greek watch-fires. And Hippocrates, himself, would have been the last man in the world to advise or approve the servile obedience, imitation, adulation which the subsequent ages accorded him. Are the earlier Italian anatomists hailed as emancipators? They strained at their bonds but did not break them—they dissected to verify Galen, not to test him; and where variance became apparent, explanations and apologies healed the breach. Ultimately came the great Belgian. He shook off his chains, and walked forth beneath blue heaven a free man. But before Vesalius' day, volcano-like had burned and thundered Paracelsus. Prior to the inscrutible Swiss, as stated, interpretation and exploitation of the ancients was virtually the exclusive vogue—nobody dreamed he might think for himself. Nobody dared trust independently his own legs—authority was the universal crutch.

Then strode upon the scene Thor with his hammer — Paracelsus, the iconoclast. And idols crumbled and toppled over. In valleys of the dead, dry bones began to stir and live. In medicine's immobile, monotonous camp the blare of trumpets shocked the air, and clamor and bustle told that again was to be taken up the onward march. With respect to men surpassingly great there will be no intermediate, temperate, moderate judgment. Largely depending upon the viewpoint, they will be set down as vastly good or vastly bad. Mediocrity alone elicits mild, reserved, restrained expression as to its worth and quality. So the loud, tense war that has surged and swayed around Paracelsus itself attests his colossal size—proves him the superman. Most medical historians make him the head of an epochal movement—place him as a herald in the dawn of a new era. "He dreams at full noontide, and raves in perfect health," skeptically muses Daremberg. Cruveilhier reflects thus — "Paracelsus, who has been so liberally taxed with extravagance and folly, is the type of those bold innovators, who, braving obstacles, across a thousand chimeras and a thousand reveries hurl themselves to the conquest of a new idea." Bordes-Pagès makes the puzzled remark, "One does not know which should the more astonish, his wisdom or his vagaries." Malgaigne proclaims him "a fore-runner of Bacon and Descartes." In short, he is unique —never before or since has any one been like him. But above all else he had the force and will to start things going. Dissenter, agitator, insurgent, revolutionist, he was the incarnation of vitalizing energy, mightily worked as a leaven in a sterile and inert world. His detractors accentuate the asserted point that to Paracelsus can be accredited very little concrete, practical discovery—that as a producer he is not comparable with Vesalius or Harvey. But let it again be emphasized that he went before these immortals—that he broke through the wall barring the way to progress, leaving a wide, open breach for all aftercomers. And, yet, his work is not without tangible results. He shattered conventionality as to distinctive professional garb—he dressed to suit himself. Although not, as sometimes insinuated, unfamiliar with the Latin of the schools, he threw down the gauntlet to scholasticism by giving his lectures in plain, simple vernacular—the tongue of the people.

And is it a small matter to have led medical investigation and practice back to nature as teacher and healer? This Paracelsus did. Hippocrates first earnestly proclaimed the principle. And theoretically it had never been repudiated. But the pity of it was that, blindly and slavishly, their followers sought and studied nature only as depicted and interpreted on the pages of Galen and Avicenna. "It is nature that furnishes the text, and the doctor who gives the gloss," says Paracelsus. And he urges that the search of nature be direct, immediate, close—insists that she needs no mouthpiece, that her voice is for all and to all.

Then the discovery of zinc and hydrogen, the substitution of tinctures and quintessences of drugs for gross and filthy mixtures of the crude products, the anticipation of the transfusion of blood and of the doctrines of Darwinism, and especially the introduction of the use of mercury in the treatment of syphilis, is all that *peu de chose*?

Still, in truest estimate, it is not as an inventor, an explorer, an innovator that Paracelsus possesses his best, clearest title to transcendant, deathless fame. No; but as the emancipator, the apostle of the morning, the prophet of a new dispensation, standing with his back to the past, and with eye and finger showing the right path down the ages, as such he may be justly ranked as one of earth's few demigods. Therein consists his glory — glory of which nor time nor man can rob him—a glory that will never dim.

Peracelsus, the liberator! How, like mists beneath sunshine, under his daring scrutiny melted away both the sanction and the sanctity of authority!—authority, the ogre in servitude to whom mind had been so helplessly chained! Warningly he exclaims, "Do not believe that through Avicenna you may be sufficiently instructed, that through Galen you may know all, that through Mesuë nothing may escape you." Catching the inspiration of the message, mind rent its shackles, and rose from its grovelling in the dust. And it caught the spirit and power of the truth that no thinker is infallible, that *ex cathedra, ipse dixit* utterances are arrogant and null, that, in very sooth, lower than the throne of God there is no such thing as authority.

Paracelsus, the champion of free and independent thought! He writes on his shield, "*Qui suus esse potest, non sit alterius.*" And intellect shifts from a condition of submission or subjugation to an attitude of defiance and defense. To all would-be dominions and despotisms within its realm it peals out the challenge, you may persuade, but you must not dictate; you may cooperate, but you must not usurp; you may supplement, but you must not supplant.

Paracelsus, the wizard spokesman of unborn time! To his antagonists, the wolves that barked and snarled around him, he announces in disdain, "Truly I shall accomplish more against you after my death, than before." Columbus had discovered on the other side of a spherical world unknown continents the year prior to the birth of Paracelsus. Afterward the latter, too, cast off from the old moorings, and boldly sailed forth upon uncharted seas. But the distance he, himself, traversed has small significance compared with the immense import of the potential pertaining to the new route he opened up and the promising course he marked out. Not so much what he did as what he indicated as possible is it that fills one with wonder, almost with awe. Call him dreamer, mystic, ecstatic, fanatic, aye, maniac, if you please. But his ravings are like the outbursts of a god-possessed oracle, and his visions have strangely the dignity and sublimity of prophecy. A seer, a guide he is. And there he stands, with strained sight looking out across the future's watery wastes. And as he looks and points, from his fervid lips flow these words—"Before the end of the world a great number of effects reputed to be supernatural will be explained by causes wholly physical."

But the freeing of thought from a bondage regarded with half resignation and half veneration, was a task for more than one giant. So God sent three—Luther, Rabelais and Paracelsus—the first a doctor of divinity, the other two doctors of medicine—two of them of the German tongue, the other of the French. Of the first, although of a different

creed, Michelet says, "It is not inexact to say that Luther has been the restorer of liberty for the later centuries." In not adjudging to him his full share of that honor the learned Frenchman has wronged his own illustrious countryman, "the great dissembler." And neither is he without fault in failing to recognize the claims of our titan of Maria-Einsiedeln, who dreamed history, to large credit likewise for the re-establishment of what he, Michelet himself, terms *"le droit d'examen."*

And now remain, and forever will remain, the three giants of reform that the day-break of the *renaissance* revealed standing over the slain monsters of the night — the contemporary immortal three—Luther, Rabelais, Paracelsus—these three, and no whit less than the others is Paracelsus.

NEW BOOKS AND OLD.

XXVII. BROWNE'S ARABIAN MEDICINE.

By JOHN RUHRÄH, M.D.,
BALTIMORE, MD.

If you wish to know something about that part of the history of medicine called the Arabian, because it was written in that language though the work of Persians, Jews, and Spanish born Mohammedans, you can get a brief account in such books as Garrison or Withington, and long accounts in Wüstenfeld's "Geschichte der arabischen Aerzte" (1840) and Lucien Leclerc's "Histoire de la médecine arabe" (1876). If you want to go between the two in length there is the excellent account in Neuburger's "History," the first volume of which has been done into English, or you can go back to Kurt Sprengel and get a readable, reliable story. It always interests me greatly to look up what old Kurt has to say when I encounter some article or book on earlier medicine, he generally has a better account than his successors albeit somewhat long winded. If you want the latest, and indeed one of the best, get the Fitzpatrick lectures for 1919-1920 by Edward G. Browne entitled "Arabian Medicine" and published by the Cambridge University Press. Browne is Sir Thomas Adam's Professor of Arabic in Cambridge University. He is a Bachelor of Medicine and a Fellow of the Royal College of Physicians. This happy combination of medical and linguistic ability led the College to honor him with the Fitzpatrick lectureship for the years mentioned, and, as his work shows, this honor was not misplaced.

There are four lectures in all, containing many quotations in the original tongue but fortunately they are accompanied with translations. One regrets that so competent an authority did not add as an appendix a well chosen bibliography together with some explanatory notes.

The great importance of Arabian medicine is, as Browne points out, not in its originality, not in its being except to a small degree the product of the Arabian mind, but because it kept alive the traditions of the ancients and the translations of the old writers made by the Arabians served as a storehouse for Greek and other medicine. It reminds one of the verse:

As the Moors in their exile their keys treasured still,
To their castles in Spain, so have I and no fear,
But the doors will fly open whenever I will
To the prime of the past and the sweet of the year.

Of recent years the chief sources of Arabian science have been made available both in good editions and through the work of able commentators.

Arabian medicine may be said to start with the great awakening of the Moslem national consciousness, the work of Mohammed in the seventh century, and to continue to the destruction of the power of the Caliphate by the Mongol invasion in the thirteenth century. The Golden Age of Arabian learning reached its climax in the century between A.D. 750 and 850. Browne prefers the term Mohammedan civilization to Arabian but does not object to the latter term as long as it is borne in mind that it refers to the language of the science and not to the peoples who are responsible for it, as it was the work of Persians, Syrians, Jews and even Greeks and to a very small extent the Arabians themselves.

The Arabs did not always hold the physician in great esteem as the following sceptical verses show:

Verily, the physician, with his physic and his drugs,
Cannot avert a summons that hath come.
What ails the physician that he dies of the disease
Which he used to cure in time gone by?
There died alike he who administered the drug, and
he who took the drug,
And he who imported and sold the drug, and he who
bought it.

The physician says to thee, "I can cure thee,"
When he feels thy wrist and thy arm;
But did the physician know a cure for disease
Which would ward off death, he would not himself
suffer the death agony.

The first Arabian physician mentioned by the Mohammedan writers is Al-Ha'rith ibn Kalada, a contemporary of the Prophet from whom doubtless Mohammed derived the hygienic and medical knowledge which came to be incorporated in his collected sayings. He believed that God made a remedy for every disease with which he afflicted mankind but the Prophet rather limited his therapeutic recommendations to the administration of honey, cupping, and the actual cautery. Ibn Khaldún was not over enthusiastic about the Prophet's medicine or perhaps his worldly wisdom either for he tells how "on one occasion he forbade the artificial fecundation of the date palm with such disastrous results that he withdrew his prohibition with the remark, 'You know better than I do what concerns your worldly interest'."

The earlier Arabian medicine is not of as great importance as that which came later. At the time of the birth of the Prophet the great school of Jundí-Shápúr was at the height of its glory. It was located in what is now Sháhábád in southwestern Persia. An idea of the state of knowledge and teaching at this time may be obtained by consulting Bridge's Syriac Book of Medicine. Here oriental and Greek medicine met. The Avesta, the sacred book of the Zoroastrians, mentions healing by prayers and religious observances, by priests; by diet and drugs, by physicians; and by instruments, by surgeons. One ordinance was that the beginner must operate successfully on three unbelievers before he try his hand on the faithful.

When the Caliph at Mansur became ill in A.D. 765 he sent to Jundí-Shápúr for Júrís, the son of Bukt-Yishú, who for four years dwelt in Baghdád.

His family remained pre-eminent for six generations, or some 250 years.

The story of Hunayn is interesting. One anecdote must suffice. The caliph offered him a rich reward to compound a poison for one of his enemies, or imprisonment or death if Hunayn refused. After a year's imprisonment for refusal the offer was repeated and again he told the Caliph that he had studied only to be of benefit. Threatened with sudden death Hunayn added, "I have a Lord who will give me my right tomorrow in the Supreme Uprising, so if the Caliph would injure his own soul let him do so." Satisfied with the answer the Caliph appointed him his physician. In the Arabian Nights is the tragic story of a court physician Dúbán and King Yúnán. Hunayn was famed as a translator, for the quantity of his work as well as the quality.

Hippocrates, Galen, Rufus of Ephesus, Oribasius, Paul of Aegina and Alexander of Tralles were most frequently translated. In some instances texts lost in the original were preserved in the Arabian translations as was the case with the ninth to the sixteenth books of Galen's Anatomy.

Browne gives several examples of the remarkable imagery of the Arabs, and their poets sing of things medical just as did their Greek predecessors. A poem on fever by Al-Mutanabbí (tenth century) is very graphic.

And it is as though she who visits me were filled with modesty,
For she does not pay her visits save under cover of darkness.
I freely offered her my linen and my pillows,
But she refused them, and spent the night in my bones.
My skin is too contracted to contain both my breath and her,
So she relaxes it with all sorts of sickness.
When she leaves me, she washes me (with perspiration)
As though we had retired apart for some forbidden action.
It is as though the morning drives her away,
And her lachrymal ducts are flooded in their four channels.
I watch for her time (of arrival) without desire,
Yet with the watchfulness of the eager lover.
And she is ever faithful to her appointed time, but faithfulness is an evil
When it casts thee into grievous sufferings.

Under such astonishing imagery are clearly depicted the delirium and regular nightly recurrence of the fever, the rigors which mark its onset, and the copious perspiration with which it concluded, the latter being fantastically likened to the weeping of a woman torn from her lover's arm.

Rhazes was perhaps the most famous of the Arabian physicians. He became chief physician to the hospital at Ray, an ancient city not far from the present capital of Persia; later he removed to Baghdád to the great hospital which we helped to build. He was a prolific writer and he has been credited with 113 major, 28 minor works and two poems. Most of these have been lost. His descriptions of small pox and measles are the best known. His most important work is the Háwí or "Continens" of which Browne gives a considerable description.

Avicenna, whose Arabian name is Abú Alí Husayn ibn Abdu'lláh ibn Síná, was a remarkable person, a physician, a philosopher, poet, man of affairs and what we should now term a good sport. Avicenna turned his attention to medicine when he was sixteen and in two years attained such fame that he was called to attend the ruler of the land. He had a checkered career, traveled extensively, and was a typical exponent of the strenuous life. His days were filled with arduous labor, his nights given over to lectures, dictating his books, wine bibbing, minstrelry and the fair sex. Worn out at 58 he died of an illness which he treated himself, which led to the saying that his physic could not save his body nor his metaphysics his soul. He was a prolific writer, not only on medical subjects but on philosophy, theology, philology, and he was a poet of no mean ability, indeed one of his quatrains ascribed to Omar Khayyam is familiar in the Fitzgerald translation:

Up from Earth's Centre through the Seventh Gate
I rose, and on the Throne of Saturn sate,
And many a knot unravelled by the Road,
But not the Master-knot of Human Fate.

The Qánún or treatise on cardiac diseases is his most important work. While Avicenna was still living, Constantine the African was born probably in Tunis. To his labors as a translator and to Gerard of Cremona and Faraj ibn Sálim (Fararius or Faragut) medieval Europe was chiefly indebted for its knowledge of Arabian medicine.

The Arabians delighted in collecting quaint medical stories and Browne gives a number of interesting examples:

In the next anecdote Rhazes is represented as describing the case of a dropsical boy whose father consulted him at Bistám in N. E. Persia as he was returning from his celebrated cure of the Amír of Khurásán, for whom he composed his "Liber Almansoris." Rhazes declared the case to be hopeless, and advised the father to let his son eat and drink whatever he pleased. Twelve months later he returned to the same town, and, to his great astonishment, found the boy completely restored to health. On inquiring how this had come about, he was told that the boy, despairing of health and life, and wishing to put an end to his existence, had one day observed a great snake approach a bowl of *madíra* (a kind of broth prepared with sour milk) which was standing on the ground, drink some of it, and then vomit into the rest, which shortly changed color. Thinking to put an end to his life with this poisonous mixture he consumed the greater part of it, after which he fell into a deep sleep, from which he awoke in a copious perspiration, and, after violent purging, found that he was quit of his dropsy and his appetite had returned.

The Arabians also went in for biography and there is one work composed in 1245 at Damascus which is limited to the lives of medical men. There is also a biographical dictionary of philosophers and physicians composed by one al-Qifti' and accounts of other medical men are to be found in some of the other monumental works.

There were hospitals in great number, many large and important. Browne makes the following significant comment:

It is worth noting that the word *Máristán*, used throughout these books for a hospital, is a corruption of the Persian word *Bímáristán*, which signifies in that language "a place for the sick." It has now been replaced in Egypt by the purely Arabic word *Mustashfá*, meaning "a place where health is sought," while *Máristán* has come to be used in the sense of a mad house.

Before closing one or two oriental thoughts must be included. In the third lecture we find this quotation from Ibn Khaldún, "The Past more closely

resembles the Future than water resembles water," and another wise Arabian likens time to a long poem in which the rhyme, meter and rhythm never vary, though the same rhyming word is never repeated. This has been translated into German as follows:

Die Zeit, die ewig dahin rollt, ist wie ein Gedicht:
Doch denselben Reim wiederholt der Dichter nicht.

The same verse has been rendered into English verse by R. A. Nicholson as follows:

And the Maker infinite,
Whose poem is Time,
He need not weave in it
A forced stale rhyme.

Browne doubts if from a utilitarian point of view that further investigation of the early Arabian medicine is justified but of course that is no reason for not going on with it, though it is rare to meet with a scholar who has the linguistic equipment, the medical knowledge, the leisure, the enthusiasm and the industry necessary to delve deeply into the original sources. In closing Browne says:

More remains to be accomplished in this branch of Arabic studies than in any other of equal importance and much pioneer work is required ere we can hope to reach the ultimate conclusions which are so important for the history of scientific thought throughout the ages. Above all, there has grown in me while communing with the minds of these old Arabian and Persian physicians a realization of the solidarity of the human intelligence beyond all limitations of race, space, or time, and of the essential nobility of the great profession represented by this college.

Statures and Weights of Children Under Six Years of Age.—Under this title the Children's Bureau of the United States Department of Agriculture has brought together the largest mass of data on the heights and weights of children under six years of age ever collected in this country. Of the 172,000 records tabulated, all of which met certain requirements as to accuracy and completeness, 167,024 were records of white and 4,976 records of Negro children. Boys under six years of age were found to average from one-third to one-half an inch taller and to weigh about a pound more than girls of the same ages. California children were found to be slightly taller and heavier than other groups in the study—a difference for which climate or some factor other than the nationality composition of the population, which closely resembles that of other parts of the country, is held responsible. The shorter stature noted in the New York City group is, however, attributed to the presence in that group of a larger proportion than in the country as a whole of short-statured races, such as the Italian and Jewish. A selected group of children of native parentage showed very little deviation in average height and weight from the averages of the larger group, including both children of native and those of foreign-born parents. Children in rural areas slightly exceeded the average for city children in both stature and weight, while the heights and weights of Negro children under four years of age as compared with white children of the same ages showed a deficiency in weight of 11 ounces for boys and 9 ounces for girls, and stature deficiencies of two-fifths and one-fifth inches respectively. These deficiencies, greatest at one year of age and under, may result from the poor nutrition and unfavorable social and economic conditions that cause a high mortality rate among colored infants or, perchance, may be due to a racial difference in rate of growth. At five years of age practically no difference in average height and weight is found between white and Negro children. Besides showing the present average heights and weights of the younger children of America, these records form a basis for measuring possible future progress in physical development.

The Children's Bureau has also published a report entitled "Maternity and Child Care in Selected Rural Areas of Mississippi," which shows that country life does not necessarily insure hygienic living conditions. The mother of every baby born within a selected two-year period was visited, a total of 675. The inadequacy of prenatal care shown in this study is comparable to that in other rural areas studied by the Children's Bureau; not more than 17 per cent. of the 675 mothers had received any type of prenatal care. Failure to recognize the need for such care was in large measure accountable for its lack, though other factors, such as distance from a doctor, entered in. Only two-fifths of the mothers studied were attended at confinement by physicians. The choice of attendant was apparently a matter of custom; 79 per cent. of the white women secured the services of a physician, and 88 per cent. of the colored women employed midwives.

Essential features of the general constructive program recommended by the Children's Bureau for the conservation of the lives and health of older children, as well as of mothers and babies, include: The employment of a county public health nurse; the full-time employment of a well-trained public health official; a conveniently located county hospital; strict enforcement of the birth and death registration laws and of the law to prevent blindness in the new-born; control of midwifery practice.

Death of Monprofit.—The recent demise of this well known French operating surgeon recalls the type of medical man who prefers to settle and remain in his native town despite the urge to locate in the metropolis. The deceased was born, lived and died in Angers, where he built up a surgical clinic of the first rank. His book on surgery of the stomach aided in establishing his reputation. Although not of Paris, he spent much time there in attendance at the sessions of the Academy of Medicine, Society of Surgery, etc. He became mayor of Angers and later represented his fellow citizens in parliament. The Parisian surgeons were glad to visit his surgical clinic and witness his operating skill, and not to have attended this clinic was to be unknown as a metropolitan operator. But the deceased was a home town man in other ways, for he was at the head of the local medical school. Interested in journalism, he was syndic during 1921 of the French Medical Press Association. He entered the war as a plain surgeon-major of the second class and emerged from it with five stripes and the cross of the Chevalier of the Legion of Honor. The war exhausted him and he was seldom seen in Paris of late years, although he attended the recent Strasbourg medical congresses and delivered a fine oration which seems to have been his last public effort.—*Gazette des Hôpitaux.*
